GALL WASP. Insecta, Hymenoptera. A minute **insect** whose attack on plants produces **galls.** They are of many species, making up the subfamily Cynipinae. (A.W.L.)

GALLIFORMES. The order of birds (Aves) containing the more common domestic species and many game birds, such as the **quails, pheasants,** and **grouse.** They are predominantly ground birds although they may fly strongly for short distances and may roost in trees. (A.W.L.)

GALLINULE. Aves, Gruiformes. Wading birds related to the **coots** and **rails.** (A.W.L.)

GALLIUM. Symbol: Ga. Atomic number: 31. Atomic weight: 69.72. Density: 5.89. Melting point: 29.75° C. Boiling point: 1700° C. (**Isotopes:** page 290.)

Gallium is a white, tough metal, soft enough to be cut with a knife, fresh surface soon oxidized superficially to bluish-gray, burns in air upon being heated to 500° C. The temperature range at which gallium is a liquid permits its use as a substitute for mercury in high-temperature thermometers. Gallium metal is only slightly affected by water at room temperature, but reacts vigorously upon boiling; dissolves in **hydrochloric acid** and in **sodium** hydroxide; reacts vigorously with chlorine at room temperature. Discovered by Boisbaudran in 1875.

Gallium occurs in very small amount in **zinc blende, magnetite, pyrite, bauxite,** and **kaolin** of certain localities. A few parts per million is present in Oklahoma zinc ores. The recovery of gallium from zinc flue dust is effected by solution of the dust in excess of **hydrochloric acid,** addition of potassium chlorate, and distillation to remove **germanium.** When the residue is converted into sulfate, fractional electrolysis of the slightly acid solution removes **zinc,** and the gallium is obtained almost free from **indium.**

Hydroxide: Gallium hydroxide ($Ga(OH)_3$), white, gelatinous precipitate by reaction of **ammonium** hydroxide on gallium salt solutions; precipitate is soluble in **sodium** hydroxide to form sodium gallate.

Oxide: Gallium oxide (Ga_2O_3), white solid, infusible at red heat, obtained by ignition of gallium nitrate or hydroxide.

Salts: Gallium sulfate ($Ga_2(SO_4)_3$), nitrate ($Ga(NO_3)_3$), and chloride ($GaCl_3$, melting point 76° C.) are white, soluble in water, and upon boiling the solution a basic salt is precipitated. Gallium dichloride, gallous chloride ($GaCl_2$), melting point 164° C. (R.K.S.)

GALLOTANNINS. **Tannins.**

GALLS. Galls are abnormal outgrowths in plants caused by plant or animal **parasites,** which attack various parts of the plant. While no part of the plant is immune, galls most frequently occur in those regions composed of actively growing **cells,** such as the leaves, or the cortical tissues of the stem, or young roots. The irritation caused by the parasite may result in a tremendous **hypertrophy** of all cells affected or may cause numerous cell divisions which result in tremendous increase in the affected tissues.

The organisms which cause gall formation are many. **Nematode worms** often enter the roots of plants and cause the formation of irregular tumorous growth. These same organisms often infect the larger brown **algae** and cause hypertrophies, or at least gall-like malformations. Many parasitic **fungi** cause galls to form in the tissues which they attack. Galls occur in the leaves and stems of blueberry and cranberry bushes, due to fungus infection by *Exobasidium vaccinii,* a **basidiomycete.** The **hyphae** of the fungus penetrate the cells of the host, which enlarge tremendously in consequence. All **chlorophyll** in these enlarged cells is destroyed, and a red pigment forms, causing the galls to appear very conspicuous. Several species of *Taphrina,* a fungus of the **ascomycete** group, cause galls in the leaves of many plants. Those caused by *Taphrina aurea* in the leaves and fruits of poplar trees are especially common. Many **rusts** also cause gall formation.

However, probably the most striking and best known galls are caused by insects. (See **Gall-Wasps and Gall-Gnats.**) A gall-producing insect lays its eggs in the tissues of the plant. Apparently as a result of the irritations caused by the young **larvae,** the surrounding cells become greatly enlarged, and the gall is formed. The galls caused by each species of insect have a very characteristic shape. The leaves and stems of rose bushes, for example, are frequently infected. One insect causes a smoothly spherical gall to form; the gall produced by another is similarly shaped but studded with stiff spines; while a third causes the formation of a dense growth of matted, branched hairs, forming a structure an inch or more in diameter. Within, there may be a single insect larvae, or many, feeding on the loose **parenchymatous** inner tissues of the gall and protected from enemies by the firm outer layers. Often the young buds of willow twigs are parasitized, causing bud galls to form. As the bud grows older, the internodes enlarge tremendously in diameter but elongate very little, so that a gigantic bud is formed.

The leaves of oak trees are very commonly parasitized by gall-forming organisms, both fungus and insect. Considerable value attaches to these galls, because of the large accumulation of **tannin** occurring in the developing gall. In countries where cheap labor is available these galls are gathered in quantities. They are used in tanning leather, in the manufacture of ink, and in the preparation of an astringent ointment. (R.M.W., A.W.L.)

GALLSTONES. **Cholelithiasis.**

GALVANIZING. The application of a layer of zinc to the surface of iron and steel for protection from

corrosion is known as galvanizing. Galvanizing is one of the most effective means of preventing rusting because of its low cost and ease of application compared with other metallic coatings.

In the hot dip process, the sheets or other articles to be coated must be free from scale, dirt, grease, etc., and are usually prepared by **pickling** and washing before immersion in molten zinc commercially known as spelter. Articles fabricated from iron and steel sheets and wire are hand-dipped. Sheets and wire are handled mechanically.

An increasing proportion of sheet-metal products is being coated as sheet or strip before fabrication. This requires a tightly adhering coating to prevent peeling during **stamping** or **forming** operations. In order to obtain good adherence in hot-dipped coatings special processing is necessary, especially with the heavier weights of coating which give longer protection. For lighter weight coatings a duplex bath consisting of a layer of molten lead under the molten zinc is often used. The steel sheet passes through the lead, which does not adhere, and up through the zinc. The time in which the steel is in contact with the spelter is greatly reduced and consequently less zinc is deposited. Another product which resists peeling is known as Galvannealed, a sheet which is annealed after dipping in order to form a coating consisting entirely of iron-zinc compounds. This coating is quite brittle and tends to powder when deformed but does not peel. A product known as Zincgrip is processed to minimize the formation of iron-zinc compounds and this sheet retains its coating intact even through extremely severe fabricating operations. Another method of applying a very ductile, adherent coating is by **electrodeposition.** This process is usually limited to rather light weights of coating because of the cost. (R.H.H.)

GALVANOLUMINESCENCE. **Luminescence.**

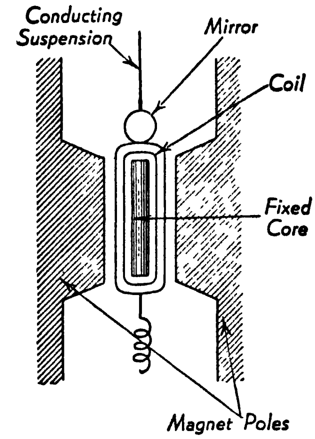
GALVANOMETERS. A galvanometer is an instrument for measuring electric currents, usually by means of their magnetic effect. Observations are made by noting the deflection produced by the reactive **torque** exerted between an **electric circuit** and a magnet. Galvanometers may be divided broadly into two classes, according to whether the coil is stationary and the magnet turns, or vice versa.

Perhaps the most highly developed of the first type is the Kelvin astatic galvanometer. This has two magnets equally magnetized but antiparallel mounted on the same suspension, one above the other, and each magnet is surrounded by a coil. The two coils are joined in series and are oppositely wound, so that a current through them will turn their respective magnets in the same direction. The earth's uniform field has no effect upon such an astatic pair of magnets; but there is a large control magnet, placed above the pair, against whose field the current turns the suspended system. The movement is observed by the usual mirror-and-scale or **optical lever** device. Galvanometers of this type are now nearly obsolete.

Among galvanometers of the second type, that of d'Arsonval is best known. The magnet in this instrument is a fixed, permanent magnet of the horseshoe or double-horseshoe form, with a light, rectangular coil suspended in the strong field between its poles, the suspension carrying the feeble current. The current causes the coil to turn in the field. Often a fixed iron core is supported inside the movable coil to concentrate the field.

If these galvanometers are undamped, they will give a "throw" when a charge of electricity is sent through them, and the charge can be thereby measured. Such an instrument, with a heavy coil, called a ballistic galvanometer, is useful in capacitance measurements. The oscillations may be damped by shunting.

There are also string galvanometers, in which a straight, slender wire carrying the current is thrust to one side by a magnetic field; and vibration galvanometers, in which the string vibrates in synchronism with the alternating current traversing it. (L.D.W.)



Essential parts of d'Arsonval galvanometer.

GAMBOGE. **Garcinia.** Guttiferae.

GAMETANGIA. **Gamete.**

GAMETE. A sexual reproductive cell or **germ cell** which normally unites with another to produce a new individual.

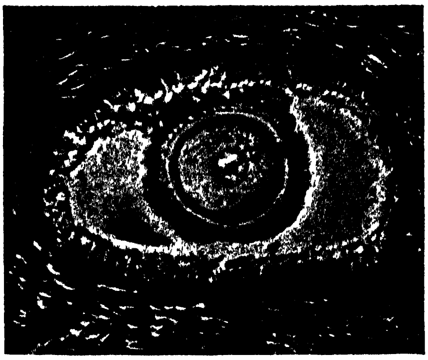
The gametes of some primitive organisms are of one form; these are single cells which swim about in the water. Such organisms are said to be isogamous and the germ cells are called isogametes. In most species, however, only the male gametes retain the power of locomotion. The female gametes are larger inert cells and the organisms are called heterogamous. The male cells of these species are known as sperms or spermatozoa and the female cells as ova or eggs. Because of its smaller size the male gamete is also known as a microgamete, and the female gamete as a megagamete.

The union of two unlike gametes (heterogametes) is called heterogamy. The cell which is formed by the union of two gametes is called the zygote; from it a new plant or animal develops. The cells in which gametes are formed are called gametangia. In heterogamous plants, the gametangia-containing sperms are called antheridia; those containing eggs, either oögonia or archegonia. (In rare cases, a gamete does develop without two gametes having previously united.)

The development of two forms of gametes permits both the freedom of movement necessary to bring the two cells together for **fertilization** and the storage of the **protoplasm** and food necessary for the development of any body of reasonable size and complexity to a stage in which it can secure more materials for itself. By the delegation of one function to each kind of cell neither is subject to harmful restriction.

In most species of animals the sperm is a minute cell with a slender **flagellum** or tail whose undulating movements propel it through the water or the seminal fluid. The main part of the sperm is the head, which contains an apical body and the **nucleus.** Behind the head is a neck, or a middle piece of more complex structure, from which the sperm aster involved in the fertilization process sometimes develops. The sperms of some **worms** and **arthropods** lack the flagellum although many bear processes of other kinds. They are much less motile than flagellate sperms but they are said to move slowly by amoeboid action or by means of their processes.

Ova are more compact cells, often spherical in form. They contain abundant **cytoplasm** and in many species an enormous amount of food material (yolk, deutoplasm), as in the egg of a bird. Here the yolk is the egg cell or **ovum** proper but the living protoplasm is a



Graafian follicle and ovum of the cat, within the ovary. *(Dr. B. F. Kingsbury.)*

tiny mass at some point on its periphery. Ova may also have special envelopes such as the albumen or white of the bird's egg, the shell membrane, and the shell. Insect eggs are enclosed by a shell called the **chorion** which is often beautifully sculptured and strangely shaped. Where such coverings occur, a minute opening, the micropyle, sometimes provides an entrance for the sperm. (A.W.L., R.M.W.)

GAMETOGENESIS. The formation of **gametes.** In animals, usually accompanied by **meiosis.** (A.W.L.)

GAMETOPHYTE. One of the two **generations** which **alternate** with each other in the life-history of many plants is called the gametophyte generation. It is the generation in which the gametes or sexual cells are formed, and so is frequently called the sexual generation. The cells of plants in this generation have the reduced or haploid number of **chromosomes**, which is half the number found in cells of plants of the diploid sporophyte generation. (R.M.W.)

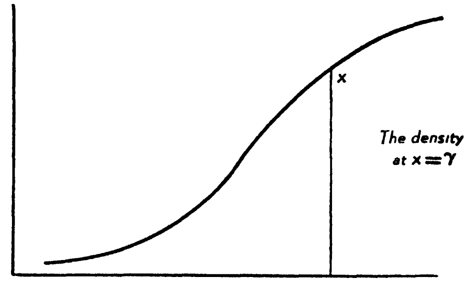
GAMMA. 1. The one-millionth part of a gram. 2. A unit of magnetic field intensity. 3. The tangent of the angle of the straight-line portion of the $D \log E$ curve and the $\log E$ axis is a measure of the degree of development and was termed by Hurter and Driffield the *development factor* and designated by the Greek letter γ (gamma). Gamma may also be defined as

$$\gamma = \frac{D_2 - D_1}{\log E_2 - \log E_1}$$

where D_2 and D_1 are densities on the straight-line portion of the $D \log E$ curve produced by $\log E_2$ and $\log E_1$, respectively.

Gamma is frequently regarded as expressing negative contrast, but the contrast of a negative depends upon several factors of which gamma is but one. Gamma, however, indicates the ratio of the negative contrast to that of the subject if the exposures lie entirely on the straight-line portion of the $D \log E$ curve, a condition not usually observed in the making of the negative.

The gamma of a $D \log E$ curve may be determined (1) by substituting values from the curve in the formula above, (2) by measuring the angle of the straight-line of the $D \log E$ curve and ascertaining the value of its tangent, (3) by constructing a right-angle triangle of which the $\log E$ axis is the base, the range in $\log E$ being equal to 1.0, and the straight-line portion of the curve the hypotenuse. The density at the point of intersection of the perpendicular forming the right side of the triangle and the $D \log E$ curve is equal to gamma. (C.B.N.)



GAMMA FUNCTION. The gamma function is a certain type of mathematical function which is met in advanced parts of **calculus**; it is a **transcendental function.** The **infinite integral**

$$\Gamma(\alpha) = \int_0^\infty x^{\alpha-1} e^{-x} dx$$

converges for all positive values of α, and defines **a function** of α which is called the gamma function.

A few of its important properties are:

$$\Gamma(\alpha + 1) = \alpha\Gamma(\alpha),$$

$$\Gamma(n)\Gamma(1 - n) = \frac{\pi}{\sin n\pi},$$

$$\Gamma(\tfrac{1}{2}) = \sqrt{\pi},$$

$$\Gamma(n + 1) = n! \text{ when } n \text{ is a positive integer.}$$

Tables of values of the gamma function are published. (L.L.S.)

GAMMA GLOBULIN. The proteins of human blood serum consist of fibrinogen, albumin, and several globulins. The latter have been electrophoretically characterized as α_1, α_2, β, and γ globulins. The gamma globulin fraction has been found to contain the greatest concentration of **antibodies**—approximately 25-fold concentration of most of the antibodies present in normal human serum. This material is therefore an effective agent in providing passive **immunity** to certain diseases. When given intra-muscularly within 7 days after exposure, gamma globulin has the same effect as convalescent serum in preventing or modifying **measles**; because of its concentration it has the advantage of small dosage—1/10 to 1/4 that of convalescent serum. If injected soon after exposure, gamma globulin is effective also in preventing **mumps** and infectious **hepatitis.**

GAMMA RAYS. Gamma rays are **x-rays** of short wavelengths emitted by **radioactive** substances. (R.K.S.)

GAMONT. An individual in the life cycle of certain one-celled animals whose subdivision produces **gametes.** (A.W.L.)

GANG PLANING. Planer.

GANGLION. In zoology, a ganglion is a small mass of nervous tissue isolated from the central system but containing cell bodies as well as fibers. Many ganglia bear special names. The brain of many **invertebrates**, for example, is also called the **cerebral ganglion**, and the more numerous centers of the molluscan nervous system bear names, such as the visceral ganglia and the pedal ganglia. The dorsal root of each nerve arising from the vertebrate **spinal cord** bears a spinal ganglion and the sympathetic system contains numerous ganglia.

In medicine, a ganglion is a tense globular cystic swelling, usually on the back of the wrist or the hand, com-

municating with one of the tendon sheathes or nearby joints. It is formed by a synovial membrane (see **Synovia**), and is filled with a thick gelatinous fluid. The nature of a ganglion is obscure. It represents either a degeneration in the involved synovial tissue, or simply a herniation of this tissue. The treatment is by mechanical rupturing, aspiration with a needle, or by surgical excision. (A.W.L., D.M.H.)

GANGRENE. Local death of tissue due primarily to total interference with the blood supply to the area or part involved. It is characterized by **anesthesia** of the part, loss of function, change in color to a dusky, cyanotic hue, lack of warmth, and in some cases, invasion by bacteria, causing decomposition of the tissue with spreading infection.

Many disease processes may terminate in gangrene. Thus in cases of injury, severe crushing of tissues may destroy their viability by interfering with the circulation. Again, inflammation, when intense, may shut off circulation by thrombosis or clotting, or by strangulation of blood vessels. This occurs in gangrenous appendicitis. Gangrene may also result from arrest of circulation, however produced, as is seen in various diseases causing obstruction of arteries or veins. Examples are severe hardening of the arteries (**arteriosclerosis**) common in the older age groups, particularly as a complication of **diabetes**, Raynaud's disease, and Buerger's disease. Chemical and physical agents, including **phenol**, or merely prolonged exposure to heat and cold, cause local death of tissue, just as does the prolonged constriction of a part. (D.M.H.)

GANGUE. The term gangue is used to refer to the non-valuable minerals associated with a metalliferous ore deposit. Commonly the gangue minerals are nonmetallics such as **quartz** or **calcite.** (R.M.F.)

GANISTER ROCK. This term was originally applied to a **siliceous** underclay occurring in certain **coal** beds in the north of England. Now it is often applied to highly siliceous, fine-grained rocks used for refractory purposes or to a mixture of ground **quartz** and **fire-clay** used for furnace linings. (R.M.F.)

GANNET. Aves, Pelecaniformes. *Sula.* Large fishing birds (**Aves**) found on the seacoasts in the higher latitudes of both hemispheres. (A.W.L.)

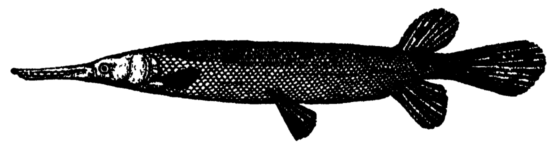
GANOIDEI. A division of the fishes (Class **Pisces**) used in some classifications to include the orders **Chondrostei** and **Holostei.** (See also **Fossil Fishes.**) (A.W.L.)

GAP. In geology, a gap is an opening through a ridge connecting the valleys or lowlands on either side. Gaps may be formed by a river which earlier in the cycle of **erosion** was able to cut its way through the hard rocks now making up the ridge. If the stream is still flowing through this opening it is spoken of as a water gap, if the stream has disappeared because of its diversion or for other reasons it is then spoken of as a wind gap.

An electric gap is the distance separating two **electrodes** between which a **spark** or **arc** is caused to pass. Magnetically, a gap is the distance across an air gap separating two parts of a **magnetic circuit.** The clearance between pole pieces and rotor of **dynamo** machinery is such a gap.

In aviation a gap is a measurement used to describe the position of biplane wings. It is the distance between the upper and lower wings, measured from the mean aerodynamic **chord** of the upper wing to the mean **aerodynamic** chord of the lower wing. If the wings are staggered, the forward tri-section points of the mean aerodynamic chords are connected to determine the gap. The gap is frequently given in terms of the chord length, thus a biplane wing cellule might be said to have a gap of 80%, which would mean that the gap was 80% of the wing chord. A gap of 100% is a relatively large one, though not considered a rarity. Small gaps, as low as 40%, have also been used. Larger gaps yield wing arrangements which are more efficient, aerodynamically, but smaller gaps lead to trimmer airplanes due to the compact arrangement of wings. (R.M.F., F.T.M.)

GAR, GARPIKE. Pisces, Holostei. Slender fishes (**Pisces**) with long, narrow jaws and sharp teeth. Three species in the rivers and lakes of North America and one



Garpike.

in Central America. The common garpike, *Lepisosteus osseus,* reaches a length of 4′, the short-nosed gar, *L. platystomus,* about 3′, and the alligator gar, *L. tristaechus,* as much as 18′. They are of little value as food fishes. (A.W.L.)

GARCINIA. Mangosteen; Gamboge. Guttiferae. A genus of trees and shrubs found wild in the tropics of the Old World. The leathery leaves are simple and opposite, and contain numerous oil glands. The fruit is a berry. Several species bear edible fruits. *Garcinia Mangostana* is the best known of these, the fruit being the famous mangosteen, considered by many to be the most delicious of all fruits. It has been introduced into tropical America.

Several species are tapped by cutting notches in the bark, through which **resin** exudes. This is the drug gamboge, a harsh cathartic, ordinarily mixed before use with other less violent drugs. (R.M.W.)

GARDENIA. Madder Family.

GAREFOWL. Aves, Charadriiformes. The great **auk,** *Pinguinus impennis,* now extinct. (A.W.L.)

GARFISH. Billfish.

GARGANEY. Aves, Anseriformes. A **duck,** the summer teal of Europe. *Anas guerguedula.* (A.W.L.)

GARIAL, GAVIAL. Reptilia, Crocodilia. A large fish-eating crocodile of India with an extremely long

Garial. (*N. Y. Zoological Society.*)

slender snout. The name gavial is said to have been an error for the vernacular name garial but it is much

the commoner term and is perpetuated in the scientific names of the genus and family. (A.W.L.)

GARLIC. Allium.

GARNET. The name garnet is now applied to a group of very important minerals crystallizing in the **isometric** system and showing the same habit of **dodecahedrons** and **trapezohedrons.** They have the same general formulas, **orthosilicates,** and are to a limited degree **isomorphous.** Many different elements are included in the several varieties of garnet as **calcium, magnesium, aluminum,** ferrous or ferric **iron, chromium, manganese** and **titanium.** While garnets show no **cleavage** a dodecahedral **parting** is sometimes noted; fracture conchoidal to uneven; some varieties very tough and valuable for abrasive purposes. The hardness of garnet is 6.5–7.5; specific gravity, 3.1–4.3; luster, vitreous to resinous; colors, red, yellow, brown, black, green, or colorless; transparent to opaque. The word garnet is derived from the Latin *granatus,* a grain.

In general six varieties of garnet are recognized, based on their chemical composition: Grossularite (which is also called hessonite and cinnamon-stone), pyrope, almandine or carbuncle, spessarite, uvarovite, and andradite. Grossularite is a calcium-aluminum garnet which corresponds to the formula $Ca_3Al_2(SiO_4)_3$; the calcium may, however, be in part replaced by ferrous iron and the aluminum by ferric iron. The name grossularite is derived from the botanical name for the gooseberry, *grossularia,* in reference to the green garnet of this composition found in Siberia. Other shades are the well-known cinnamon brown, reds and yellows. Because of its inferior hardness to **zircon,** which mineral the yellow crystals resemble, they have been termed hessonite, from the Greek meaning inferior. Curiously enough, in the gem-bearing gravels of Ceylon both zircon and hessonite are found and indiscriminately called hyacinth, from the Greek, seemingly general term used by Pliny for the transparent varieties of corundum; later it was used for yellow zircons.

Grossularite is found in crystalline limestones with **vesuvianite, diopside, wollastonite** and **wernerite.** Among the many localities may be mentioned Siberia, the Urals, Italy, Switzerland, Mexico, and in the United States in Maine and New Hampshire.

Pyrope, sometimes called Cape ruby, is ruby-red in color and chemically a magnesium aluminum silicate with the formula $Mg_3Al_2(SiO_4)_3$; the magnesium may be replaced in part by calcium and ferrous iron. The color of pyrope varies from deep red to almost black. The transparent pyropes are used as gems, but some have a slight tinge of yellow. The name pyrope is derived from the Greek word meaning *fire-like.* A sub variety of pyrope from Macon County, North Carolina, is of a violet red shade and has been called rhodolite, from the Greek meaning *a rose.* In chemical composition it may be considered as essentially an **isomorphous** mixture of pyrope and almandite, in the proportion of two molecules of pyrope to one molecule of almandite. Pyrope is found at Teplitz and Aussig, Bohemia; in the Kimberley diamond mines in South Africa; in Australia and elsewhere. In the United States important localities are in Arizona, New Mexico, and Utah.

Almandite, sometimes called almandine, is the modern gem the carbuncle, although in Pliny's time this term was used for almost any red stone. The term carbuncle is derived from the Latin *carbunculus,* meaning a little spark. The name almandite or almandine is a corruption of Alabanda, a locality in Asia Minor where, in ancient times, these red stones were cut. Chemically, almandite is an iron-aluminum garnet corresponding to the formula $Fe_3Al_2(SiO_4)_3$. The deep red transparent stones are often called precious garnet and used for gems. Almandite occurs in metamorphic rocks like mica schists usually associated with typically metamorphic minerals such as **staurolite, kyanite, andalusite,** etc. Good gem material comes from India and Brazil. Almandite is also found in Australia, Alaska, Africa, Norway, Sweden, Madagascar, and Japan. In the United States almandite is found in the **gneisses** of the Adirondack region of New York, sometimes of very large size, in New England and elsewhere.

Spessartite is manganese aluminum garnet, $Mn_3Al_2(SiO_4)_3$. The name of this mineral is derived from Spessart in Bavaria, a well-known European locality. Spessartite of a beautiful orange-yellow comes from the Island of Madagascar. Violet-red spessartite has occurred in **rhyolites** in Colorado and Maine. Uvarovite is a calcium chromium silicate the formula being $Ca_3Cr_2(SiO_4)_3$. It is a rather rare garnet, bright green in color, usually in small crystals associated with **chromite** in **serpentines,** sometimes in crystalline limestones or schists. Found in the Urals, South Africa, Canada, and in the United States in California and Pennsylvania. Andradite, calcium-iron garnet, $Ca_3Fe_2(SiO_4)_3$, is of variable composition and may be red, yellow, brown, green, or black, or of intermediate shades. The subvarieties topazolite, yellow or green, demantoid, green, and melanite, a black sort, are recognized. Andradite is found both in deep-seated igneous rocks like syenite as well as in serpentines, schists, and crystalline limetones Demantoid has been called the "emerald of the Urals" from its occurrence there. Varieties of andradite are found in many localities in Europe; Italy, Switzerland, Norway, Saxony, etc., and in the United States at Franklin, New Jersey; Magnet Cove, Arkansas; and elsewhere. (E.S.C.S)

GAS ABSORPTION. Gas absorption is a process whereby one gas or several gases are removed from a gaseous mixture by causing the desired gas or gases to be dissolved in some liquid, thus leaving undissolved the inert or undesired gases. An example is the removal of ammonia (NH_3) from an air-ammonia mixture by bringing the mixture into contact with water. The ammonia will dissolve into the water but the air will not.

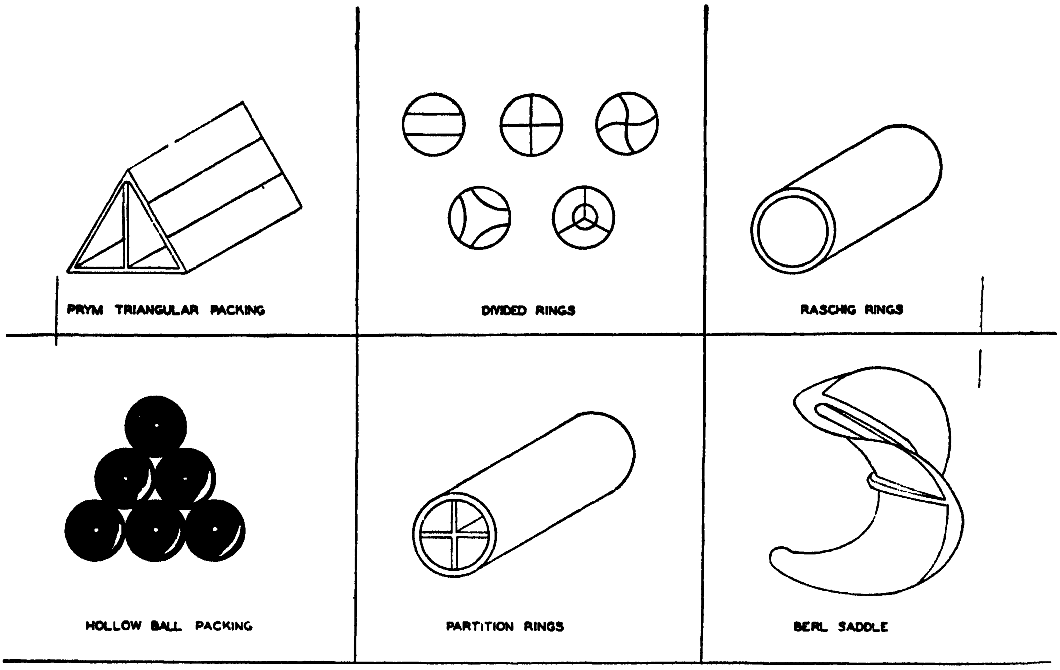
The operation of absorption is ordinarily accomplished in an *absorption tower.* The tower is usually cylindrical and packed with coke, broken rock, or specially shaped forms. The most usual special packing is the *Raschig ring.* These rings are short tubular pieces with length about equal to the diameter. They are dumped into the tower and lie in a random fashion. Liquid is allowed to trickle down over the packing while the gas is pumped up through the tower where it swirls about the packing on its way up. In this way there is an intimate intermingling of the gas and the liquid. The tower must be tall enough so that there is sufficient time of contact between the gas and the liquid, and large enough in cross-sectional area so that the required volume of flow can be accommodated. If too much liquid is run down for the size of the tower, then the upward-moving gas will hold up the liquid, causing the tower to choke or *flood.*

The amount of gas which a liquid can dissolve at a given temperature is determined by Henry's Law, which states that the partial pressure of a gas in equilibrium with a solution is equal to a constant times its concentration in the solution, or

$$p = cx.$$

The constant, c, is different for each system and for each temperature, and it must be determined experimentally.

The concentration of the absorbable gas in the effluent from the tower must be somewhat less than the equilibrium concentration of the gas in the liquid. The difference between the two, i.e., the difference between the actual concentration and the equilibrium concentra-



TYPES OF TOWER PACKING

tion, is necessary in order that there be a *driving force* to cause absorption to take place.

For each tower and set of operating conditions there is a specific absorption coefficient, *K*. *K* depends on the type and composition of the materials being operated on, the type of packing, the temperature, and the gas and liquid flow rates. The coefficient is defined as the amount of material absorbed per unit time per unit of contact area per unit of driving force. The area of contact through which the gas is being absorbed cannot be measured, therefore this unknown area is included with the coefficient, *K*, and determined experimentally as coefficient times the area, *Ka*. After the amount of material absorbed per unit time is determined for the whole tower by direct measurement, it is divided by the tower volume and by the driving force, giving the final form

$$Ka = \frac{\text{lb.}}{(\text{hr.})(\text{cu. ft.})(\Delta x)}$$

where Δx is the driving force. The Δx driving force is the difference between the concentration the liquid actually has and that which it would have if it were in equilibrium with the gas. Since Δx may vary throughout the tower, an average value must be used.

For any given installation the absorption coefficient depends on the liquid-flow rate, the gas-flow rate, the temperature and concentration of the liquid and the gas. Because the open cross-sectional area of the packed tower is not known, the gas and liquid rates are usually given in terms of superficial velocities. The superficial velocity is defined as the velocity the fluid would have if it were flowing through and completely filling the tower when empty of packing.

If slightly soluble gases are being absorbed (say oxygen into water) then turbulence in the liquid is essential but turbulence in the gas is not important. In this case the gas-flow rate has been found not to affect the absorption coefficient. When the gas is very soluble (say ammonia into water) the reverse is true, that is, the liquid rate is not important and the coefficient is affected greatly by the gas rate.

Typical examples of gas absorptions are: removal of SO_2 from flue gas, recovery of carbon dioxide from combustion gases, gasoline from natural gas, ammonia from coke oven gas, and the drying of air.

The reverse of absorption, where a dissolved gas is removed from a liquid by contacting the liquid with an inert gas, is called *stripping*.

Gas absorption need not necessarily be performed in a packed tower. It may be done in a bubble-cap tower (see **Distillation**), or in a tank where the gas is bubbled through a liquid. In order to obtain a good dispersion of the gas in the liquid it is common practice either to agitate the liquid violently with a stirrer (see **Mixing**) or to introduce the gas into the liquid through a porous plate. (D.E.M.)

GAS CALORIMETER. Fuel Calorimeter.

GAS ENGINE. Internal Combustion Engine.

GAS EQUATION FOR AIR. Equation of State for Air.

GAS GANGRENE. Infection of tissues around a wound by certain anaerobic bacteria which grow best deep in tissues away from the air. The infection is necrotic and rapidly spreading; it is accompanied by massive edema, gaseous infiltration and discoloration of the tissues. The organisms liberate a toxin which destroys tissue, particularly muscle, and they produce gas by fermenting muscle sugars.

Most of the information on gas gangrene was obtained during World War I. Many of the war wounds were infected with gas-producing organisms and from contamination either directly or indirectly with fecally contaminated soil. Gas gangrene is occasionally seen in civil medical practice in extensive wounds with considerable crushing of tissue, particularly in compound fractures.

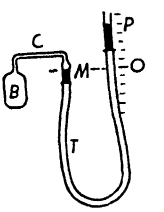
The most common organism found in gas gangrene infections is *Bacillus Welchii.* It, as well as other of the gas-forming group, is a normal inhabitant of the human and animal intestinal tract and is present in soil with great constancy. In war and in some civilian injuries, organisms are carried into the depths of tissues by foreign bodies or bits of projectiles. In these types of

injury variable amounts of tissue are destroyed or devitalized, thus furnishing the dead or necrotic material that gas organisms thrive upon. It is for this reason that debridement (excision of all devitalized or contaminated tissue) is immediately carried out as soon as the patient is hospitalized. This is one of the best methods of preventing this serious complication of wounds.

Good results have been obtained by injection of a polyvalent antitoxic serum against the common gas-gangrene organisms, both prophylactically and therapeutically. The **sulfanamides** and **penicillin,** used in conjunction with anti-serum and adequate surgery, are also effective in the treatment of gas-bacillus infection. (R.S.M.)

GAS OIL. Gas oil is the residual oil left after **gasoline** and kerosene are distilled from certain crude petroleums. (See **Fuels** and **Hydrocarbons, Paraffinic.**) (R.K.S.)

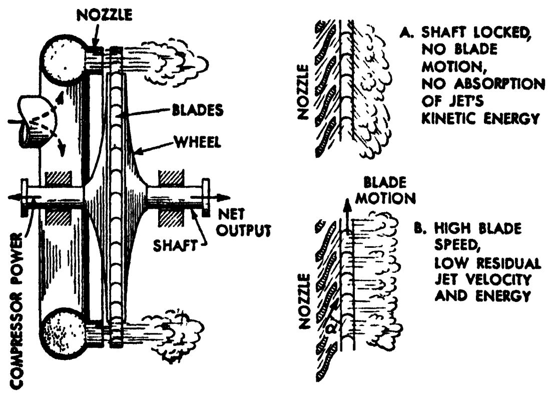
GAS THERMOMETER. When the standard measure of **temperature** was fixed upon as the pressure of a gas kept at constant volume, the constant-volume gas thermometer became the final arbiter of temperature measurement. (See **Thermometry.**) In this instrument the gas (preferably hydrogen or helium) is enclosed in a glass or fused quartz bulb that is connected to a mercury manometer, and facilities are provided to bring the gas always to the same volume and to indicate the gas pressure. The most common form, designed by Jolly (1874) is shown diagrammatically by the figure, in which *B* represents the bulb, *T* the flexible tube of the manometer, *M* the constant-volume mark at zero level, and *P* the level of the mercury indicating the pressure. The pressure is regulated by moving the right-hand mercury column up or down the scale. Slight corrections are necessary for the expansion of the bulb and for the difference of temperature between the gas in the bulb and that in the connecting tube *C*. The use of this thermometer depends upon the fact that changes of pressure are accurately proportional to the changes of temperature producing them. If a mercury thermometer is to be standardized between 0° and 100° C., for example, its bulb is placed along with the bulb *B* in a bath of adjustable temperature and the total pressure in *B* noted for each of these fixed points. The interval between these points is then divided into 100 parts, each of which corresponds to 0.01 of the whole change of pressure. Since the mercury at *P* is exposed to the atmosphere, the atmosphere pressure, taken from a good barometer, must be added to that measured by *OP*. The constant-pressure type of gas thermometer was perfected by Callendar and others, but proved somewhat impracticable and has fallen into disuse. (L.D.W.)



Sketch of essential parts of constant-volume gas thermometer.

GAS TURBINE. The gas turbine is a means of producing mechanical work from heat energy, using a gas as the working medium. Its advantages and limitations were little understood prior to 1930. However, since that time the gas turbine has been subjected to intensive research and development and has become a competitor of the internal combustion engine. Many successful installations of gas turbine power plants have been completed since 1935, and the field has broadened to include mobile as well as stationary power.

In the gas turbine a stationary nozzle discharges a jet of gas (usually products of combustion) against the blades on the periphery of a turbine wheel, as shown in Fig. 1. The jet is thereby deflected and slowed while the blades receive an impulse force which is transmitted as a mechanical torque to the shaft. The prospective jet speed is sometimes sufficiently high to warrant dividing the expansion into a series of *stages* with a set of nozzles and a row of blades in each stage, all blade wheels being mounted on the same shaft. By limiting the gas expansion per stage the blade speed and rpm of the shaft are suitably decreased. Were the blades themselves so shaped as to be virtual nozzles, some expansion would also take place in the gas as it went through the blading. The latter in consequence would receive a "reaction thrust" distinct from impulse action. Many gas turbine designs have employed the reaction principle.



PRINCIPLE OF THE GAS TURBINE
Fig. 1.

A properly designed nozzle can produce almost an ideal (isentropic) adiabatic expansion of the gas. Any failure of the gas turbine to convert all the ideal available energy into work at the shaft is mainly attributable to the blading—its clearance, friction, leakage, and residual gas velocity.

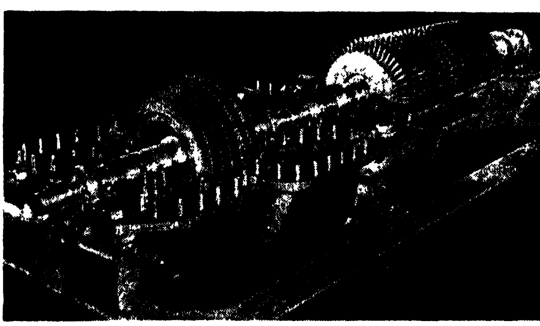


Fig. 2. Axial compressor unit for 23,000 cfm gas flow. Top half of casing removed. Turbine unit is in the foreground. (*Allis Chalmers Mfg. Co.*)

The term "engine efficiency" is frequently applied both to engine and turbine prime movers to denote perfection of thermodynamic design, using the ideal available energy as a standard. So, if e_i is the ideal amount of energy made available by the possibility of expanding a fluid between specified initial and final states, and e is the energy actually developed by a gas turbine working between the same limits, then

$$\eta_e = e/e_i.$$

η_e is the so-called *engine efficiency,* sometimes called internal efficiency.

It is quite essential to the success of a gas turbine plant that η_e be as high as possible. The range of η_e is 80% to 90%, a remarkable modern achievement. Had the efficiency been better in early experimental gas turbine plants, some might possibly have turned out successfully.

Gas turbines present no new difficult problems to the manufacturer. For the same inlet temperature the gas turbine is probably easier to design than the steam turbine. Compared to the internal combustion engine the turbine is compact and high speed. Gas turbine speeds of 10,000 rpm are not uncommon. But because of the volume of the compressor and combustion chamber, and because much of the turbine output is absorbed in the turbine plant itself, the advantage of compact size is not so likely to be realized, and often it is the internal combustion engine that is the more compact. However, in *simplicity,* the gas turbine excels. (F.T.M.)

GAS TURBINE PLANT. There is a distinction between the **gas turbine** and the gas turbine plant. As in a steam system, the turbine is but one of several components whose combined action is the conversion of heat energy into work. In a few instances a supply of gas suitable for use in the gas turbine is created by an industrial process. This gas, if in sufficient quantity, can be utilized by the gas turbine. However, the greatest interest centers at present in the gas turbine plant which will manufacture its own supply of gas at a pressure by compressing air and burning fuel in it. Such a plant will consist at least of an air compressor driven by the gas turbine, a combustion chamber wherein a liquid fuel is injected and burned at constant pressure equivalent to that of the compressor discharge. The resulting products of combustion form the working medium of the gas turbine. It is the expansion of volume of the working medium during the process of combustion that enables an ideal turbine to produce more work than an ideal compressor would consume. If this difference is sufficient to more than offset the internal imperfections of an actual compressor and turbine, some surplus work will become available as a net plant output. This net plant output (in B.T.U.), divided by the heating value of the fuel burned in the compressed air, is the over-all thermal efficiency of the gas turbine plant.

An elementary plant of this type is shown in Fig. 1. Since the working medium is changed in chemical composition by the combustion process, it is discharged from the system after yielding up some of its energy in the turbine and fresh air is continuously drawn into the compressor. The cycle, if there could be said to be one, is therefore an "open" one, since in a closed cycle the air passes around the cycle and receives heat by conduction instead of combustion. The open cycle of operations, shown in Fig. 2, is sometimes called the Brayton cycle. It has been used in internal combustion engines without significant success, but is well adapted to a turbine cycle since the turbine can more readily produce complete expansion. Line *ab* represents compression of the air, *bc* the addition of heat at constant pressure. Expansion in the turbine is represented by *cd*, while *da* is imagined to be a constant pressure cooling of the air to ambient atmospheric temperature. It is this part of the cycle that is open in gas turbine plants.

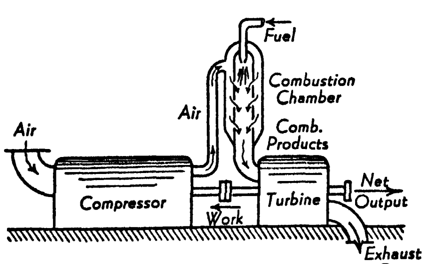

Fig. 1. Basic combustion gas turbine plant.

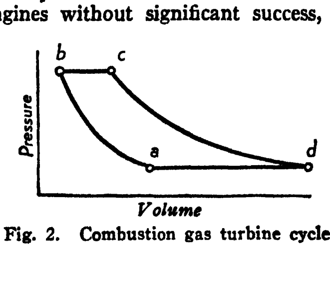

Fig. 2. Combustion gas turbine cycle.

This constant pressure combustion cycle is used in most gas turbine plants. Designating it the ***combustion gas turbine cycle*** is a means of distinguishing between it and the *explosion gas turbine cycle.* The latter type, which uses constant volume combustion, has been successfully constructed but is handicapped by the necessity of a mechanically operated valve system, like the internal combustion engine, and by operation with a fluctuating gas pressure.

Any liquid fuel which does not form corrosive products of combustion can be used in the open cycle. Since the products of combustion actually flow through the turbine, ash in them would be detrimental; consequently coal cannot be used as yet. Refined fuel oil and kerosene are used except where industry may have a gaseous fuel by-product to use.

The air standard efficiency of the Brayton cycle is the same as that of the Otto cycle, namely $1 - \frac{1}{r^{\gamma - 1}}$, in which r is the ratio of compression and γ the adiabatic polytropic gas exponent. In flow machines, such as the rotary compressor, the *pressure ratio* is often more useful than the volumetric compression ratio r. The theoretical cycle efficiency, using pressure ratio P_b/P_a as the variable, is

$$\eta_t = 1 - \frac{1}{\left(\frac{P_b}{P_a}\right)^{\frac{\nu-1}{\nu}}}.$$

This implies that an increase in pressure ratio increases cycle efficiency. The actual cycle efficiency also involves the internal machine efficiencies and a variable air-fuel ratio, since for a given temperature at point c in the cycle the higher the pressure ratio the greater the air-fuel ratio needed. For operation with a limiting maximum temperature in the combustion chamber (a practical criterion) the efficiency increases with pressure ratio up to a certain *optimum ratio,* then decreases with further increase of pressure ratio. This is shown in Fig. 3. The actual efficiency of an open cycle combustion gas turbine plant is approximately

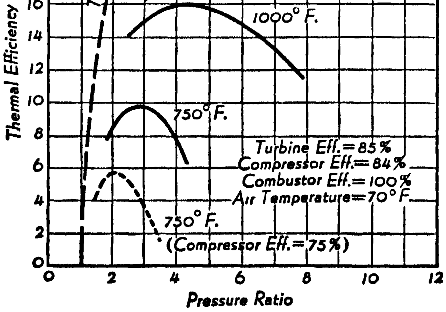

Fig. 3.

$$\eta = \frac{W_t \eta_t \eta_c - W_c}{\eta_c H_f}$$

W_c and W_t are the ideal amounts of work involved in processes *ab* and *cd*, respectively—in heat units. η_t and η_c are the internal efficiencies of turbine and compressor. H_f is the heating value of the fuel burned per cycle.

The two terms in the numerator of the above equation are of approximately the same magnitude, therefore small changes of η_t or η_c will cause η to vary widely. Since η is not particularly high anyway (on account of a limiting maximum temperature of about 1200° F. imposed by metallurgical considerations), this emphasizes the need for refinement of construction to secure the very highest actual efficiencies possible in the compressor and turbine, or else the W_c term equaling $W_t \eta_t \eta_c$ will leave zero efficiency and no net output for the plant. Illustrating the results possible in practice, η_t might, optimistically, be as high as 85%, η_c 80%. Then, using a pressure ratio of 4 and a maximum cycle temperature of 1000° F., the efficiency works out to be 13%, and somewhat more than 100 lbs. of air must be drawn into the compressor for each horsepower hour net work output. This is a contrast with the 9 lbs. used by a gasoline engine for the same output, but it should be remembered that the latter is a displacement machine whereas the gas turbine plant is a flow system, much better adapted to handle large volumes of the working medium. It should also be noted that the more of the turbine output the compressor requires the greater is the bulk of the equipment for a given *net* output. In its present stage of development, as much as 3/5 of the gross turbine output is required by the compressor.

The data quoted above might well dash the hope that the combustion gas turbine will actively compete with the steam and internal combustion prime movers. Although nearly perfect operation is assumed for the machines, the efficiency is so low that our gas turbine is surpassed by everything else except the non-condensing steam plant. However there are possibilities of improving the performance by metallurgical progress permitting higher maximum temperatures (1500° F. is being contemplated), and by thermodynamic schemes that reduce compressor demands and salvage part of the exhaust heat. Pushing up the maximum temperature limits will depend on developments in other fields of technology. But the thermodynamic modifications, called *intercooling, regeneration,* and *reheating,* may be applied at present. At the cost of complicating the flow pattern of a plant, whose virtue has always been simplicity, efficiencies may be raised until this prime mover becomes a practical competitor with the others, for over-all efficiencies of 20% to 30% seem to be possible, using today's maximum practical temperatures.

The intercooling principle consists of compounding the compression and intercooling between sections. This lowers the air temperature at constant pressure, reducing the volume and the compression work required in the following compressor stages. It requires a surface type intercooler with a coolant, air or water. Regeneration is effected by transferring heat energy from the exhaust gases to the compressed air after it leaves the compressor but before it enters the combustion chamber. This again requires a surface heat exchanger, one capable of standing up under high temperatures. The gain here is due to the smaller quantity of fuel which has to be injected to reach the same maximum gas temperature. Reheating is the process of burning the fuel in steps, the amount of fuel being proportioned to reach the maximum allowable temperature in each stage of combustion. For this the turbine must be compounded, with a combustion chamber inserted in the flow between the high and low pressure sections.

These principles are illustrated diagrammatically in Fig. 4. A marine gas turbine plant recently built, and incorporating intercooling, regeneration, and reheat, is

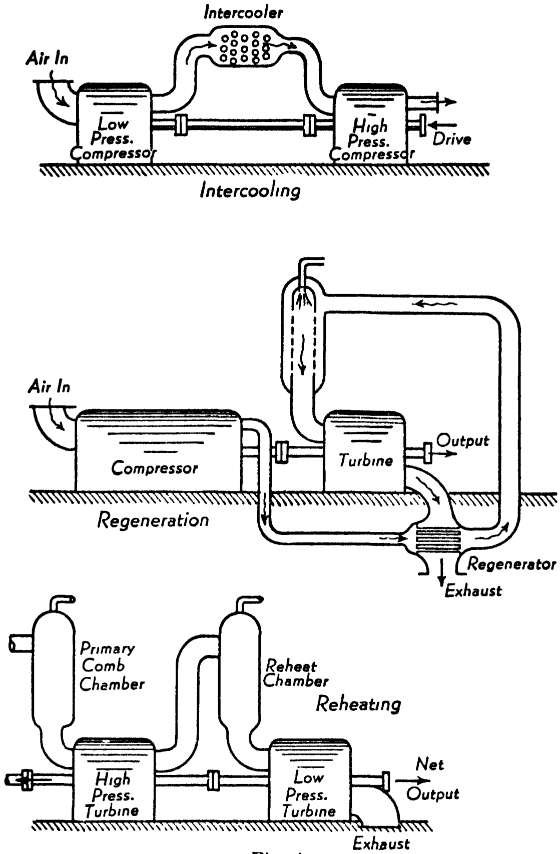

Fig. 4.

shown schematically in Fig. 5, with attendant temperatures noted. This plant is characterized by the use of a positive displacement rotary compressor rather

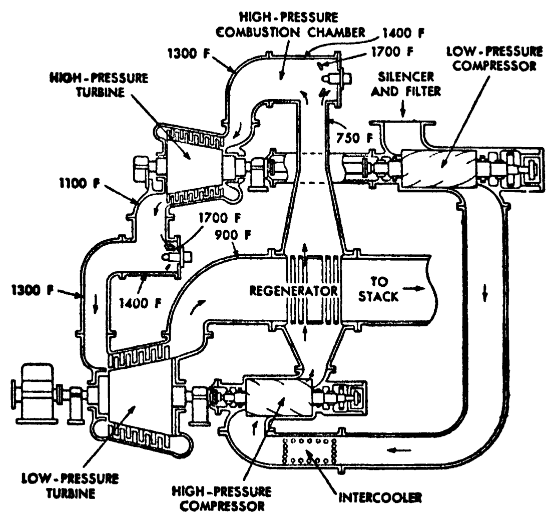

Fig. 5. An intercooled, regenerative-reheating gas turbine plant in schematic arrangement. (*Elliott Co.*)

than the axial flow type usually encountered. With a pressure ratio of 6.5 and a maximum throttle temperature of 1230° F., it is said to achieve an over-all effi-

ciency of 29% when producing the rated net output of 2500 hp. The high-pressure section of the turbine drives the low-pressure section of the compressor, these

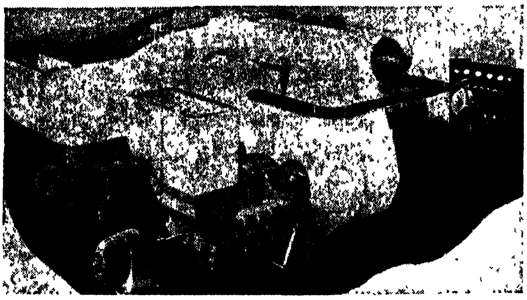

Fig. 6. View of the gas turbine plant for operation on the plan shown in Fig. 5.

being proportioned so that there is no surplus power. After intercooling, the air is further compressed in the high-pressure compressor, then heated by being passed through the regenerator. Fuel is next injected into it and burned. Plenty of oxygen remains in the products due to the great quantity of excess air used to hold down the temperature rise. After expansion through the high-pressure turbine more fuel is burned with some of the remaining oxygen, again raising the temperature to the limiting value. Next the products expand through the low-pressure turbine, after which they pass into the regenerator and thence to the exhaust stack. As this was designed for marine service, the net output of the low-pressure turbine is delivered to the propeller shaft at the output coupling of a speed-reducing gear box.

To date, the gas turbine has been used in the following fields:

1. Stationary power plant. Economical for stand-by service and possibly (in the future) for regular service.
2. Locomotive. An experimental unit was successful but not particularly impressive in performance. However, subsequent development may raise performance to competitive levels.
3. The Houdry process. In this gasoline cracking process compressed air must be provided for burning deposits from the catalyst. This process is accompanied by considerable increase in temperature and only a small drop of pressure. The gases discharged from process are put through a gas turbine, whose output supplies the necessary compression power. Here no net power is made, but as otherwise 2500 hp. would be required to drive the Houdry process compressors, the turbine-compressor combination is highly successful.
4. Supercharging of both spark and compressor ignition engines, using turbine-driven centrifugal compressors.
5. Marine power plant. Claimed to be as efficient and more compact than the steam plant.
6. Jet-driven airplanes. (See **Airplane, Jet Propelled.**)

Summarizing the comparative features of the gas turbine as a prime mover:

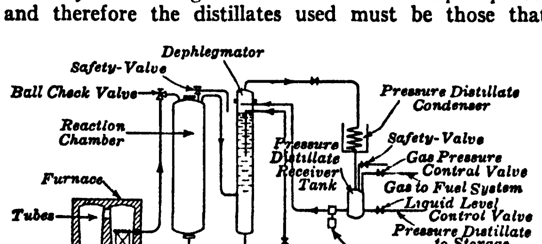
1. Mechanically it is simple compared to steam and I.C. plants, but in the endeavor to reach competitive efficiencies some of this advantage is lost.
2. An electric motor or I.C. engine is required to start the gas turbine plant. As the starter must bring the compressor well up toward operating speed, starting is not as simple as S.I. engines, but many compare favorably with C.I. engines and steam.
3. Like steam turbines, the gas turbine is not readily reversible. Steam engines and 2-cycle I.C. engines are best in this respect.
4. Turbine plants have less vibration than engine plants of similar size.
5. The gas turbine uses high temperatures. Even though the pressures are moderate, service life will be shortened by high temperatures.
6. With certain types of compressors, efficiency of the gas turbine plant is not as well maintained at part load as with steam or the I.C. engine. (F.T.M.)

GASES. **States of Matter; Dynamics of Gases; Kinetic Theory; Ideal Gas Law; Characteristic Equations; Avogadro's Law; Boyle's Law; Charles' Law; Joule-Thomson Effect; Dalton's Law; Poisons.**

GASKET. The gasket is a layer of packing material firmly held between contact surfaces on two pieces whose joint is to be sealed with the gasket. Gaskets are made in many different shapes to suit the shapes of the various mating pieces. The simplest type of gasket is that used to seal the joint between two circular **flanges**, as might be used in making a joint in piping. The gasket is made of a thin sheet of material, satisfactory for the service, having through it a hole corresponding to the internal diameter of the **pipe**. After being inserted between the flanges, flange bolts draw the latter tightly together, compressing the gasket material until it tightly seals the joint. Some gaskets are **toroidal** in shape, but most are flat. The services they perform range from that of sealing against leakage of the liquids in water lines to rendering gas-tight such high-temperature joints as those in engine exhaust manifolds. Naturally, a variety of materials would be required for these different conditions. In general, gasket material is rubber for water, corrugated copper for saturated steam, soft corrugated steel for superheated steam, asbestos for hot gas. (F.T.M.)

GASOLINE. A liquid hydrocarbon mixture obtained from four main sources: (1) natural gas or casing-head gasoline, by condensation under pressure or by adsorption of the liquefiable constituents of natural gas, (2) straight-run gasoline, by the fractional distillation of crude petroleum, (3) cracked gasoline by (a) thermal (heat-pressure) or (b) catalytic decomposition of crude petroleum or its distillate fractions, (4) synthetic gasoline by such reactions as (a) polymerization of hydrocarbons of lower, to those of higher, molecular weight, (b) hydrogenation of producer gas (Fischer-Tropsch), of petroleum or coal-tar distillate fractions, or of coal (Bergius). Cracked and synthetic gasolines show distinct and remarkable increases in production with resulting economy in the utilization of crude petroleum.

Catalytic cracking is conducted in the vapor phase, and therefore the distillates used must be those that

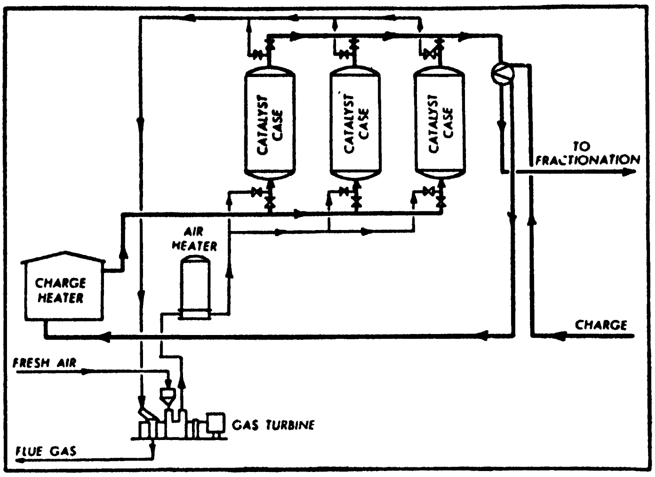


Dubbs thermal cracking process flow chart. (*Universal Oil Products Co.*)

can be vaporized at the operating temperature of the process. Steam is usually introduced simultaneously with the charging stock to facilitate the vaporization of the higher boiling portion. The chemical principles are

similar in all three of the following processes, although the mechanical arrangements differ radically.

The fixed-bed catalytic process has been in commercial operation since 1936 by the Houdry Process Corporation, Socony-Vacuum Oil Company, and Sun Oil Company,

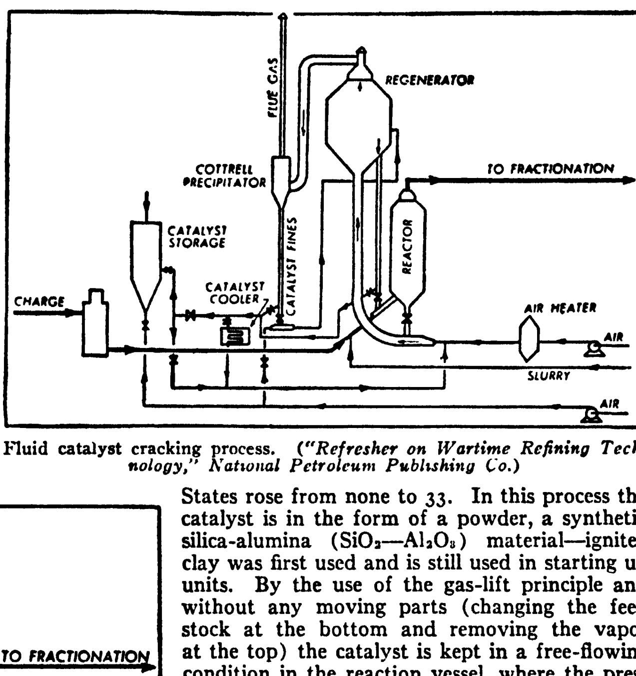


Houdry catalytic cracking process. (*"Refresher on Wartime Refining Technology," National Petroleum Publishing Co.*)

producing high-quality motor fuel. In this process, alternate periods of cracking the distillate and regenerating the catalyst occur in each reaction compartment, these being arranged in a series so that the input and output of the system as a whole is continuous. The usual compartments are about 40′ in height and about 10′ in diameter. The feed stock is fed from below, and the resulting vapor removed at the top. There is considerable latitude in the choice of feed stock, and a corresponding flexibility in the range of product obtained. Early yields ranged around 45% gasoline of octane number 77 to 81.

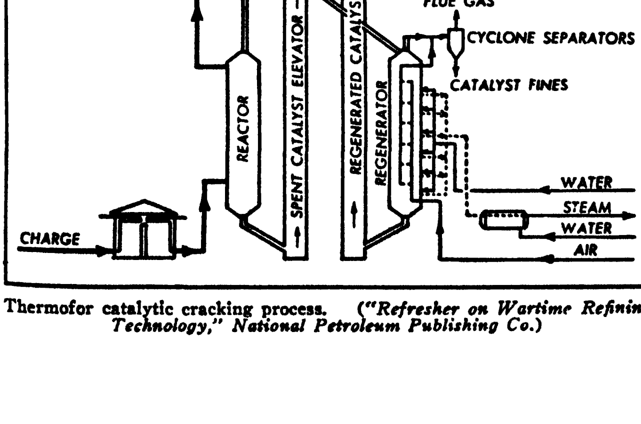
The moving-bed catalytic process is one developed by Socony-Vacuum Oil Company—called "Thermofor"—from the type of clay-burning kiln originally used in regenerating the catalyst. Some 30 units of this type were constructed in the United States during the war. The process is distinguished by having the reaction and regeneration zones separated, although there is a continuous movement of the catalyst through each zone. The counter-current principle is frequently employed, wherein the vaporized feed stock is admitted near the bottom of the reaction zone and the catalyst near the top, so that the fresh catalyst near the top meets first the more resistant portion of the oil vapor, and the partially spent catalyst near the bottom carries out the initial cracking. The concurrent principle is used in some installations, one advantage being that the operating pressure is less than in the counter-current type. The spent catalyst is purged of oil vapors by superheated steam and then moved in an elevator to the top of the regenerating kiln. Here the deposit of carbon on the catalyst is burned off by careful regulation of the air supply. The process yields 35 to 45% gasoline of **octane number** 85 to 93. A notable advance in the process has been the production of a specially active "bead" catalyst (1943) in the form of translucent spheres about 3.5 mm. in diameter which have superior crushing resistance and which increase the yields of product 15 to 30% compared to clay pellets.

Fluid catalyst cracking is also an outcome of World War II, although the Standard Oil Company of New Jersey was engaged in developing this process before the war. During the period 1941 to 1945 the number of fluid catalyst-cracking units operating in the United



Fluid catalyst cracking process. (*"Refresher on Wartime Refining Technology," National Petroleum Publishing Co.*)

States rose from none to 33. In this process the catalyst is in the form of a powder, a synthetic silica-alumina (SiO_2—Al_2O_3) material—ignited clay was first used and is still used in starting up units. By the use of the gas-lift principle and without any moving parts (changing the feed stock at the bottom and removing the vapor at the top) the catalyst is kept in a free-flowing condition in the reaction vessel, where the pressure is only about one atmosphere above the normal atmospheric pressure. The reaction vessel is a long cylindrical tank standing on end, say 50′ in vertical height and 25′ in diameter. The temperature in the reacting compartment is maintained between 425° C. (800° F.) and 525° C. (975° F.). On feed stock of 400° C. (750° F.) distillation dry-point the yields reported are about 43–46% of aviation gasoline having a distillation dry-point of 200° C. (400° F.) and octane rating of 91 to 94 without the addition of lead tetraethyl. The catalyst is recovered continuously from the bottom of the reaction compartment, and then the carbon, which is deposited on it in use, is carefully burned off by heated air, regulated so that the



Thermofor catalytic cracking process. (*"Refresher on Wartime Refining Technology," National Petroleum Publishing Co.*)

temperature of burning is maintained between 540° C. (1000° F.) and 650° C. (1200° F.).

Specifications for various types of gasoline more or less commonly used in commerce are laid down involving color, odor, gums, distillation range, doctor test (for certain sulfur compounds), corrosion (of copper) test, acidity, and sulfur (total). Of these, the most important is the distillation test, which is a measure of the volatility and the range of volatility of the gasoline. Various grades, based upon different distillation ranges, are recognized. The necessity for such specifications is demanded by the extensive use of gasoline in internal combustion engines for motive power in automobiles, trucks, and airplanes.

The knocking power of gasoline is an important consideration. The knocking sound, or **detonation**, is produced in high-compression engines or in ordinary **internal combustion engines** when under heavy load ascending grades or when accelerating rapidly. The knocking property is dependent upon the composition of the **fuel**. Knocking indicates that the combustion of the fuel vapor in the cylinder is taking place too rapidly for complete utilization of the power by the cylinder of the engine. Benzene and branched-chain paraffins (such as 2,2,4-trimethylpentane or isoöctane) are non-knocking under prevailing engine pressures, straight-chain paraffins are most conducive to knocking, while olefins and cycloparaffins are intermediate in effect. Benzene is blended with gasoline to improve the anti-knocking quality, and the addition of very small amounts of tetraethyl lead (which acts to retard the speed of combustion) is also utilized to produce the same result.

The knock characteristics of motor fuels are compared in a standard motor under standard test conditions of operation, using a standard test fuel, and the rating is reported in terms of octane number. The standard test fuel is composed of definite mixtures of "anti-knock" isoöctane

$$\left(\text{2,2,4-trimethylpentane, } CH_3\underset{\displaystyle CH_3}{\underset{|}{C}}H{-}CH_2{-}\underset{\displaystyle CH_3}{\underset{|}{\overset{\displaystyle CH_3}{\overset{|}{C}}}}{-}CH_3\right),$$

commonly referred to as octane, plus "knock," normal-heptane ($CH_3(CH_2)_5CH_3$). The octane number of a motor fuel is the same number as the percentage of isöoctane in the standard test fuel which matches the tested fuel in knock characteristics.

Federal Specification for United States Government Motor Gasoline includes *Distillation range*. A.S.T.M.*[2] method D86–30. When the thermometer reads 75° C. (167° F.) not less than 10% shall be evaporated. When the thermometer reads 200° C. (392° F.) not less than 90% shall be evaporated. The residue shall not exceed 2%. (R.K.S.)

GASTEROPODA, GASTROPODA. The **snails**, **slugs**, and allied forms, constituting a class of the phylum **Mollusca**. This group includes a large number of marine and fresh-water species and many that are terrestrial.

The chief structural characteristics of the gasteropods are these: 1. Most species have a dorsal visceral hump which is often spirally twisted. 2. A head is present, bearing eyes and tentacles. 3. The mouth is provided with a toothed organ called the radula. 4. The foot is usually a broad creeping organ. 5. Respiratory ctenidia lie in the mantle cavity of some species and in others the walls of the cavity are the respiratory organ. 6. In many species a shell, conical or spirally coiled, encloses the visceral hump.

Gasteropods are of relatively little economic importance. Snails are eaten in Europe and the abalones of the Pacific Coast are also used as food. The shell of the abalones furnishes beautifully iridescent mother-of-pearl for costume jewelry and there is an extensive traffic in the shells of many species among collectors.

The group is classified as follows:

Subclass **Streptoneura**. Usually with a shell closed by a horny shield, the **operculum**, when the animal is retracted.

Order **Diotocardia** (Aspidobranchiata). **Abalones**, **limpets**, and other marine species. A few fresh-water forms.

Order Monotocardia (Pectinibranchiata). **Whelk**, **periwinkle**, and many other marine forms and a few fresh-water species.

Subclass Opisthobranchiata. Shell small and internal, sometimes lacking.

Order Tectibranchiata. **Sea hare, sea butterflies** or pteropods with the foot expanded into wing-like lobes. All marine.

Order Nudibranchiata. Marine species without shells. Often with complex dorsal processes. **Sea lemon**; nudibranchs.

Subclass Pulmonata. Shell usually present but without an operculum. Mantle cavity sometimes the only respiratory organ. Mostly fresh-water and terrestrial species, a few marine.

Order **Basommatophora.** Eyes at the bases of the posterior tentacles. Many common **snails.**

Order Stylommatophora. Eyes at the tips of the posterior tentacles. Common snails and **slugs.** (See also **Invertebrate Paleontology.**) (A.W.L.)

GASTEROSTOMATA. **Trematoda.**

GASTRIC FILAMENT. Slender projections on the floor of the stomach of a **jellyfish**, containing stinging cells which kill living prey taken into the stomach. (A.W.L.)

GASTRIC SHIELD. A plate in the stomach of **bivalve** mollusks against which the **crystalline style** is worn away. (A.W.L.)

GASTRITIS. An inflammation of the lining membrane of the stomach occurring in an acute or chronic form. The common causes of gastritis are alcoholism, errors in diet, food poisoning, and irritant or corrosive poisons. (R.S.M.)

GASTRO-ENTERITIS. An inflammation or irritated condition of the gastrointestinal tract, due to errors in diet, infection or food poisoning, irritant poisons or alcohol. (R.S.M.)

GASTRO-ENTEROLOGY. The study of the diseases and functions of the **stomach** and **intestines**. A gastro-enterologist is a specialist in the diagnosis and treatment of the disorders of the stomach and intestines. (R.S.M.)

GASTROSTOMY. An artificial, and usually permanent, opening made through the abdominal wall into the stomach. This is done to prevent starvation when there is an obstruction in the **oesophagus** from a malignant growth, or scarring after drinking a corrosive chemical, etc., thus making it impossible for the normal passage of food into the stomach. (R.S.M.)

GASTROTRICHA. A group of minute animals found in fresh and salt water on the bottom and among the debris accumulated there. They move chiefly by means of cilia and have cement glands whose secretion attaches them temporarily to supports. They have a tubular alimentary tract and an excretory system consisting of two tubules with flame cells. The group is ranked by

some writers as a class in the same phylum as the **rotifers** and by others as of uncertain relationship.

Two orders are recognized: **Macrodasyoidea,** made up of marine species with numerous cement glands, and **Chaetonotoidea,** made up of marine and fresh-water species with a single pair of cement glands at the caudal end of the body, or none. (A.W.L.)

GASTROVASCULAR SPACE. The central cavity (**enteron**) of **coelenterates** and **ctenophores.** (A.W.L.)

GASTROZOOID. A form of individual in **hydrozoan** colonies whose function is to digest food for the colony. (A.W.L.)

GASTRULA. The stage in embryonic development in which the initial differentiation of tissues is evident. The gastrula is typically a sac whose wall is composed of the two germ layers, an outer ectoderm and an inner endoderm. The cavity lined by the endoderm is the archenteron and the opening to the exterior is the blastopore.

The gastrula is formed from the **blastula** by the process of gastrulation. Typically the wall of the spherical blastula caves in on one side and the invagination progresses until this side is in contact with the opposite wall. In some **coelenterates,** however, the two germ layers appear as a solid mass of endoderm surrounded by a layer of ectoderm, and the archenteron forms by the splitting of the inner mass. In animals with abundant yolk, modifications also appear. In birds, for example, the stage approximating the blastula is a disk of cells on the surface of the yolk and the endoderm may be formed by the folding under of this layer at one point on the margin or by a more diffuse process of polyinvagination, recently discovered. Later the folded edge undergoes a concrescent growth until it doubles on itself and fuses to form the primitive streak, equivalent to a closed blastopore.

The mesodermal layer also appears in the gastrula of **triploblastic** animals. Its formation is extremely variable but it usually grows out from the indeterminate zone about the blastopore where ectoderm and endoderm join. (A.W.L.)

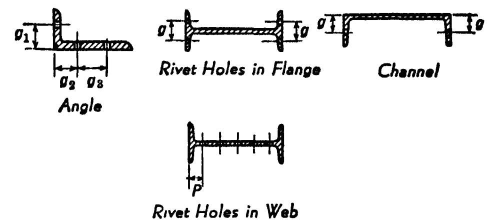
GATES. Sluices through a dam are conduits cast in the concrete and equipped with controls called sluice gates. The common types of sluice gates are the plain sliding, the gate, the butterfly, and the needle valve. The purpose of the sluice is to empty the reservoir if necessary, to control the head level, and to aid in passing floods. (See **Crest Gate.**)

In foundry practice, the pouring spout casting, which comes from the mold attached to the casting, is called a gate. (F.T.M.)

GAUGE. An instrument or device for measuring or comparing some physical characteristic, such as size, pressure, temperature, water level, force, etc. In the machine field, the term is usually applied to measuring tools (see **Measurement**). Electrical measuring devices are usually called instruments. (See **Pressure Gauge, Instruments, Electrical.**) (H.C.H.)

GAUGE BLOCK. Measurement.

GAUGE LINE. A gauge line marks the limits of any standard distance used repeatedly. Structural steel shapes are punched or drilled for rivets on lines called gauge lines as indicated in the accompanying figure. Structural handbooks contain tables giving the numerical value of these gauges for different sizes of structural shapes. The gauge lines may be varied to suit the details as long as the minimum required edge distance and clearance for punching, drilling, or riveting are maintained. In some fabricating shops the rivet holes in the webs of beams and channels are made with multiple punches or drills. (C.W.C., F.T.M.)



Standard rivet gauges.

GAUGE NUMBER. In the sheet metal industry, the term gauge is used to describe or define the thickness of sheet metal. Systems of gauge numbers are also in use for wire, rods, machine screws, and twist drills. A representative selection of gauge numbers is shown in the accompanying table. The United States Standard Gauge is the recognized commercial standard for all uncoated sheet and plate iron and steel, and is the legal standard to be used in determining duties and taxes levied by the United States under act of Congress approved March 3, 1893. The American or Brown & Sharpe gauge is the recognized standard in the United States for wire and sheet metal of copper and other non-ferrous metals. The Washburn and Moen or American Steel and Wire Company gauge is the recognized standard for steel and iron wire, and is also called the U. S. Steel Wire Gauge. The Birmingham or Stubs Iron Wire gauge is nearly obsolete but is still used for specifying the thickness of brass and aluminum tubing, and by the Treasury Department of the United States in connection with the importation of wire. The Music Wire gauge designated by the American Steel and Wire Company has been adopted as the standard for piano and music wire upon the recommendation of the United States Bureau of Standards. The British Imperial Wire gauge is the official standard for Great Britain. The table of twist drill sizes is known as the Manufacturers' Standard, since all numbered sizes of twist drills are made in accordance with its specifications. The last column shows a few representative numbered machine screw diameters. (H.C.H.)

Number of Gage	U.S Standard for Sheets and Plates	American or Brown & Sharpe	Birmingham Wire (BWG) or Stubs Iron Wire	Washburn and Moen	Music Wire	British Imperial Wire (SWG)	Twist Drills	Machine Screws
000	375	4096	425	3625	007	372		
0	.3125	.3249	340	3065	009	.3240		
2	.2656	.2576	.284	2625	011	2760	.2210	086
4	.2344	.2043	.238	2253	.013	2320	2090	.112
6	.2031	1620	203	1920	.016	1920	.2040	138
8	.1719	.1285	.165	.1620	.020	.1600	1990	164
10	.1406	.1019	.134	.1350	.024	.1280	.1935	194

Gauge number. (*Hesse's Engineering Tools and Process, Van Nostrand.*)

GAUGE, TRACK. Railway Track.

GAUR. Mammalia, Artiodactyla. A large wild **ox,** *Bibos gauras,* of India, Burma, and the Malay Peninsula. It has been domesticated to a very limited extent. (A.W.L.)

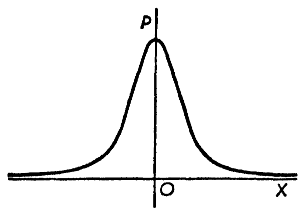
GAUSS. The gauss, as now defined, is the practical c.g.s. unit of magnetic induction (see **Magnetism**). If

a straight wire is passed across a region under magnetic influence so as to cut it with a speed of 1 cm. per sec. perpendicular to the direction of the induction, the value of the induction necessary to set up an electromotive force of 1 abvolt (0.00000001 volt) per cm. length of wire is 1 gauss. Or, if the induction is 100,000,000 gausses, the resulting electromotive force is 1 volt per cm. length of this moving wire. The induction in gausses is commonly represented by the number of "lines," or maxwells, per sq. cm. of normal cross-section.

For many years prior to 1932 the term gauss was used to designate that unit of magnetic field intensity which is now known as the **oersted.** This change in terminology was introduced to distinguish between magnetic induction and magnetic intensity as physical magnitudes. (L.D.W.)

GAUSS' THEOREM. **Green's Theorem in Space.**

GAUSSIAN DISTRIBUTION. Wherever statistical analysis has a part in physical theory or in the treatment of chance or accidental **errors of measurement,** frequency distributions and distribution functions are of importance. One of the most common types of distribution function is the so-called Gaussian distribution whose graphical representation gives rise to the "bell-shaped" figure so frequently met with in the treatment



Typical Gaussian distribution curve.

of errors of measurement and the theory of **least squares.** It may be illustrated by a study of the distribution of a large number of shots on a target ruled with parallel, equidistant, vertical lines, the line bisecting the middle compartment being the "bull's eye" aimed at. The distribution of the shots may be tabulated by counting the shots and recording the percentages corresponding to the numbers found in the several vertical compartments numbered out both ways from the central (or zero) compartment. The outstanding characteristics of such a distribution are the tendency to a maximum at the center (zero mode), the progressive decrease of frequency with distance from the center, and the symmetry of the distribution with respect to this modal zero. In dealing with all such problems we are assuming that merely chance or accidental errors are involved, i.e., that the marksman honestly tried to hit the "bull's eye" and that his sights were properly adjusted, wind effects were properly compensated for, etc.

The mathematical analysis of the probability for distributions having the characteristics of pure chance or accident, carried out by Gauss and by Hagen along quite different lines of reasoning, result in the following form of distribution function:

$$p = \frac{k}{\sqrt{\pi}} e^{-k^2x^2}.$$

In this expression p is the probability that any one of the statistical elements chosen at random (e.g., one of the shots on the target) will be found in the statistical interval numbered x from the modal zero (e.g., the xth vertical compartment from the center of the target). Or, it is the approximate percentage of all the elements which in the long run are found in the xth interval. k is a constant which depends upon the degree of concentration about the mode; its value being greater, the greater this concentration, as indicated by the fact that $\frac{k}{\sqrt{\pi}}$ is the probability of the element lying in the zero or modal interval (i.e., is the value of p for $x = 0$). In the target example k measures the excellence of marksmanship. In the language of statistics k is equal to about 0.95 of the reciprocal of the interquartile range, that is, the range of variation within which the central half of the elements lie.

Perhaps the most common example of the Gaussian distribution is that of the distribution of the accidental errors of varying size in measurements; in which case x is the size of the accidental error and k is the measure of precision. Again the components, parallel to any one axis, of the velocities of molecules in a pure gas (gravity and convection currents excluded) are distributed in like manner; though the actual speeds of the molecules follow the unsymmetrical and distinctly different **Maxwell distribution law.** Here k is dependent upon the temperature and molecular mass of the gas. Other examples are numerous in statistical physics. (L.D.W., W.K.G., L.L.S.)

GAUSSIAN FUNCTION. **Normal Probability Function.**

GAVIAL. **Garial.**

GAVIIFORMES. The loons. An order of large birds (**Aves**) with elongate bodies, short legs with webbed feet, and a long sharp beak. They are powerful swimmers and divers, and are named divers as well as loons. (A.W.L.)

GAYAL. Mammalia, Artiodactyla. A wild **ox** of northeastern India, related to the **gaur** but smaller and with less flattened horns. Domesticated to a limited extent. (A.W.L.)

GAY-LUSSAC LAW. **Charles Law.**

GAZELLE. Mammalia, Artiodactyla. **Antelopes** of moderate size which live in Africa and Asia. The numerous species are mostly inhabitants of deserts. They constitute the genus *Gazella* and with few exceptions are named gazelles. Among these exceptions are the **springbok,** the korin, and the aoul. (A.W.L.)

GEANTICLINE. **Anticlinorium.**

GEAR TOOTH FORMING. This is one of the most important processes in present-day engineering practice. Gears with cast teeth from sand molds, permanent molds, or metal dies are extensively used at the present time for comparatively slow-speed operation. Practically all watch and clock gearing is stamped from sheet metal and gives excellent results for the duty it must perform. Plastic molded gearing is also used to some extent. Gearing for precise operation, or for installation where high speeds and heavy loads prevail, is usually made with cut teeth which are often finished by various processes to attain high accuracy and comparatively noiseless operation.

Cutting gear teeth by using a form-type cutter is still an important and extensively used process. Mass-production spur gear form-cutting is generally performed on automatic gear-cutting machines. Two form-type cutters, one roughing and one finishing, are used and the process is analogous to cutting spur gears on the milling machine. The cutter slide advances to the work, feeds through for the cut and returns rapidly to starting position. The work then indexes and the cycle of operations is repeated. The roughing cutter

has stepped teeth to break up the chips and removes most of the material, leaving just enough metal for the finishing cut.

Gears with teeth of almost any form can be used to generate conjugate teeth in a plastic blank by rolling the master gear and the blank together at the proper speed ratio equal to the ratio of their pitch diameters. This principle is used in producing hot-rolled gears, in which a master gear is rolled with a heated gear blank. (Good results are obtained but the process is not yet extensively used.) Involute teeth, however, will generate conjugate teeth of involute form in the application of this principle. Since a rack is an involute gear with a pitch diameter that approaches infinity as a limit, it will also generate involute teeth in a circular blank. This application is made use of in the gear hobbing process in which a **hob** whose tooth profile is of rack form is used for cutting spur and helical gears.

The conjugate generating principle is also employed in the widely used process of gear-shaping. A cutter is carried on a vertical reciprocating ram, and is similar to a spur pinion; it cuts on its upward stroke, backs away from the work, moves down to starting position, and then moves forward for a second vertical cut. Both the cutter and the work rotate slightly as the cutter descends, at a speed ratio inversely proportional to their pitch diameters. The gear shaping process has several advantages over other methods of gear tooth cutting. One cutter can be used for cutting all spur gears of the same pitch; the cutter has a very accurate profile, since it is possible to generate its tooth profiles after hardening by grinding; the cutter automatically corrects any tooth interference in the blank; and the finished gear has a generated profile. Another advantage of the gear-shaping process is that it can be used to cut internal gears.

Another type of machine which operates on an essentially similar principle is used for cutting herringbone gears with continuous teeth that have sharp apices.

Precision bevel gear tooth profiles may be cut by a single-point tool guided by a master template. A cutter that can pass through the small end of the tooth space is used, and moves along straight lines which intersect at a point corresponding to the apex of the gear. These cutter strokes are straight lines and the tool oscillates about the axis of the blank so that profiles of the correct form are generated. These two methods produce bevel gears with correct profiles over the entire face of the gear to the same degree of accuracy that spur gears are manufactured.

Spiral bevel and hypoid gear teeth are generated on special machines built for that purpose, by means of a rotating side-cutter tool that simulates the form of a mating gear. The rotating cutter machines one tooth space at a time and the work is then withdrawn and indexed for the next series of cuts.

Worm gear teeth are generated either by an infeed hob, or by a tapered hob that feeds tangentially to the gear to be cut. Both types of hobs are generally employed in conjunction with automatic gear-cutting machinery in which the gear blank rotates at a speed proportional to the speed of the hob.

Gear teeth may be finished after heat treatment by burnishing, shaving, lapping, and grinding.

Shaving processes are extensively employed for gear tooth finishing. A rotary cutting tool is provided with a series of serrations on the faces of the teeth, which act as cutting edges. The blank to be finished is mounted on an arbor or on a mandrel between centers. The cutting tool rotates at high speed and is at the same time rapidly reciprocated across the work.

Lapping is recognized as a highly efficient method of finishing gear teeth after hardening. One method uses a cast iron internal gear lap for finishing external spur gears by a reciprocating motion across the gear face, employing a rotary motion of both the lap and the blank to distribute the abrasive lapping compound. The tooth shape of the lap conforms to the tooth shape of the gear. Another method of lapping employs abrasive lapping wheels in which helical teeth are cut. (H.C.H.)

GEAR TRAIN. Two or more gears, transmitting motion from one shaft to another, constitute a gear train. If spur, bevel, or worm gears are used, the velocity ratio is inversely proportional to the numbers of teeth in the gears. A pair of spur gears, directly connected, result in a reversal of direction; if the driving gear drives an intermediate idler, which in turn drives the driven gear, the only effect of the idler is to cause the driven gear to rotate in the same direction as the driver. (The same effect can also be obtained by using an internal gear and a pinion.) If a two-gear idler, or compound gear, in which both idlers are fastened either to the idler shaft or to each other, is used, and where the driver engages one of the compound gears, and the driven gear the other compound gear, the velocity ratio is equal to the product of the two trains. The back gearing of a lathe or a milling machine is a familiar example of a compound gear train; a gear attached to the driving pulley drives a large gear mounted on the back gear shaft; a small gear on this shaft in turn drives the spindle gear. (See also **Differential, Epicyclic Train.** (H.C.H.)

GEARING. In the past, the term gear or gearing included mechanisms of all types (see **Valve Gear**), but modern terminology confines its usage to toothed wheels for transmitting rotary or reciprocating motion from one machine element to another. The principal forms of toothed gearing are **spur gearing, helical gearing, bevel gearing,** and **worm gearing.** (H.C.H.)

GEARMOTOR. Speed Reducers.

GEASTERS. Basidiomycetes.

GECKO Reptilia, Sauria. Small **lizards** of many species inhabiting the warmer regions of both hemispheres. Most geckos have adhesive disks on the toes. Several species are found in southern Florida and the southwestern states. (A.W.L.)

GEE NAVIGATION. Gee navigation is that type of **hyperbolic navigation** which was most effectively used by the Royal Air Force and the American Air Forces when operating against Europe from the British Isles.

For the transmission of the signals one master and two or more slave stations are used. The distance between stations is about 75 miles and the stations are located approximately on a circle with the master station between the slaves. The **frequencies** used are between 20 and 88 megacycles and the length of the pulses are of the order of magnitude of six microseconds.

The receiving equipment, frequently referred to by air navigators as the "Gee Box," contains a viewing **cathode ray tube** on which four fast sweeps can be exhibited simultaneously. These four sweeps appear as two pairs of parallel lines and on one of each pair a marker corresponding to the master pulse is shown. On each of the parallel sweeps a marker from one of the slave stations is shown, with its direction opposite to that of the master station. Fig. 1(a) indicates the appearance of the view scope showing the two recordings of the master station at M, and of two slave stations at S_1 and S_2, respectively. The operator next brings the slave "blips" into coincidence with those from the master and increases the velocity of the scope sweep to give

more detail to the blips and hence closer setting. Fig. 1(b) shows the appearance of the scope when this adjustment has been made. Then time markers are thrown

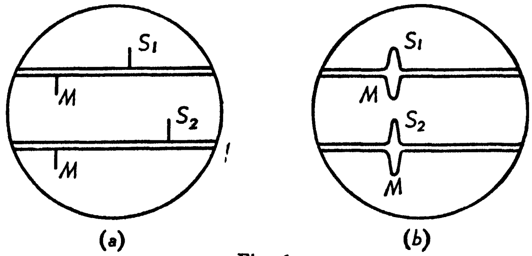


Fig. 1.

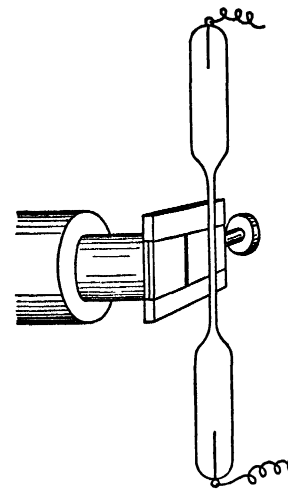
onto the scope and the differences of the time of arrival of each slave from the time of arrival of the master are read. The accuracy of the **lines of position** determined by Gee navigation varies with the square of the distance of the ship from the base lines between stations. On this line the accuracy is of the order of magnitude of 200 yds., when the navigator is on the base line, and about 1 mile at a distance of 400 miles from the base. Since time differences can be read simultaneously from the master and 2 slave stations, the **fix** can be determined by simultaneous observations without the necessity of using the running fix method. In practice between 2 and 3 min. is required to obtain the fix without any presetting of the instrument.

One of the most important uses of Gee hyperbolic navigation is for "homing" on a particular objective. A study of the chart will provide two lines of position, one from the master and one slave station and the other from the master and a second slave that intersect at the objective. The operator then sets the proper time differences on his Gee Box and proceeds until the markers for one line correspond. He then heads his plane so that this coincidence is maintained and knows that he is flying along one of the desired hyperbolic lines of position. This will be a true track, unaffected by drift, compass errors, or any other cause. A study of the rate of approach of the markers for the other line will give him the ground speed at which he is approaching his objective. When these two markers coincide he will know that he is at destination. If it is realized that the readings are independent of visibility—i.e., that they can be made in darkness as accurately as in daylight, or in thick fog as well as with unlimited visibility—the value of Gee navigation will be thoroughly appreciated. (W.K.G.)

GEGENSCHEIN. The gegenschein is a slight increase in intensity of the **zodiacal light** at a point on the **ecliptic** opposite to the position of the sun. The gegenschein appears as a soft glow against the sky, oval in shape, a few degrees wide and 10–15° in length. It is so faint that it cannot be observed on a night when there is any moon or when the patch falls in the vicinity of the **milky way.** (W.K.G.)

GEIGER-MÜLLER COUNTER. Counting Tube.

GEISSLER TUBE. Geissler manufactured a variety of gas discharge tubes at moderate exhaustion, which exhibited bright glow discharges and sometimes marked **fluorescence** effects. A form very useful in **spectroscopy** consists of two elongated bulbs, one containing the **cathode** and one the **anode,** and connected by a straight capillary section. The glow is most intense in the capillary, which is by its shape especially adapted to be placed in front of a spectroscope slit. Such tubes may be conveniently operated by an induction coil or a small transformer; though the latter is likely to overheat them and may even fuse the electrodes. (L.D.W.)



Common form of Geissler tube, in front of spectroscope slit.

GELADA BABOON. Mammalia, Primates. An Abyssinian **monkey,** *Theropithecus gelada,* of rather large size and chiefly black color, with a large mane. It resembles the true **baboons** in its elongate muzzle but differs in having the nostrils set well back from the tip. (A.W.L.)

GELATIN. Aminoacids, Polypeptides, and Proteins.

GEM, GEM STONES. A gem stone is a mineral substance which because of its beauty or rarity is in demand for ornamental purposes, chiefly personal adornment. The origin of such use for what we now call gem minerals is lost in the dim vistas of early human history. Ancient records describe the various gem stones, and archeologists find them in their investigations of bygone peoples. When we look at a collection of minerals with their bright colors and varying degrees of transparency or light-reflecting power, we cannot doubt that primitive man was much attracted by them and valued them greatly. We may imagine, too, that the occasionally found crystals with their regular geometric forms were more highly prized than broken fragments of the same minerals. Later they learned to polish them. Apparently the oldest form into which stones were shaped is that known as *en cabochon,* a French term derived from the Latin word for head and referring to its rounded shape. The forms were either hemispherical or hemiellipsoidal. The Emperor Nero is supposed to have had a large **emerald** cut en cabochon, and indeed for several centuries after his time this seems to have been the only sort of cutting employed. The supposedly accidental discovery in 1475 that diamonds would mutually scratch each other began the era of modern gem cutting. Previously it had been believed that diamonds were so hard that they could not be artificially shaped. At first, however, little progress was made in fashioning gems other than polishing a number of facets without any definite arrangement.

We owe to Vicenzio Peruzzi, a Venetian, the credit for devising the so-called "brilliant cut," the style of the modern **diamond** cutting, which, except for certain refinements due to a more thorough understanding of the behavior of minerals toward light, remains the same as in Peruzzi's day. At the present time transparent stones of all sorts are usually "brilliant cut," while translucent or opaque are cut en cabochon.

Since time immemorial, dealers in gems have used as the unit of weight the carat, undoubtedly introduced from the east. The word is derived from the Greek

meaning a small horn, referring to the pods of the locust tree, *Ceratonia siliqua,* a common Mediterranean tree whose seeds were said to have been taken as the unit of weight in buying and selling gems. In the 19th century the actual weight of the carat differed slightly in different countries of Europe, from a little under to somewhat over ⅕ of a gram. The uniform use of the metric carat, exactly ⅕ of a gram, has been urged and to some extent adopted. (E.S.C.S.)

GEMINI. (The twins.) (Map, page 380.) This constellation, which marks the third sign of the zodiac, has been recognized as a pair of twins from remote antiquity. The twins have not always been human, however, the Egyptians considering them as a pair of kids, and the Arabians as a pair of peacocks. By far the most familiar names for the two bright stars of this constellation are the names of the warrior brothers, Castor and Pollux, sons of Jupiter and Leda. Both of these stars are interesting objects in a 3-in. telescope, Castor being a fine **binary** and Pollux being a multiple star of at least six components. There is also a fine star **cluster** in this constellation which can easily be seen with a field glass and can be detected with the unaided eye on a clear moonless night. (W.K.G.)

GEMMULE. Reproductive bodies of **sponges** enclosed in protective capsules which enable them to withstand severe conditions of temperature and drought. (A.W.L.)

GEMSBOK. Mammalia, Artiodactyla. A South African **antelope** related to the **beisa.** *Oryx gazella.* (A.W.L.)

GENE. A minute body or zone in a **chromosome** which governs the hereditary transmission and the development of a specific character of the individual.

The gene is regarded as a hypothetical unit of **heredity** and as such its existence has been judged by indirect evidence from the study of hereditary processes. In recent years the study of giant chromosomes of the salivary glands of the fruit flies has revealed fine details of structure which may be the genes. These chromosomes are differentiated longitudinally into many zones whose nature and arrangement appear to be constant, barring recognized types of change, and many of these transverse bands or zones have been identified as the points occupied by the hypothetical genes of other studies.

The action of genes is not definitely known, but they have been interpreted as self-perpetuating bodies that produce **enzymes** capable of influencing the action of other parts of the cell. (A.W.L.)

GENERAL CIRCULATION. **Circulation of the Atmosphere.**

GENERAL SOLUTION OF A DIFFERENTIAL EQUATION. **Ordinary Differential Equations.**

GENERATOR. A generator is any equipment wherein originates a vital or chemical process. The two generators most frequently met are gas generators and electric generators. The method of generating the gas varies greatly, and there are several different kinds of gas generators. The acetylene generator, for example, has a chamber containing calcium carbide, into which water falls drop by drop, wetting the carbide, and reacting with it to produce acetylene.

Electric generators are built in all capacities, to suit the smallest and the largest installations. They can produce **alternating current** or **direct current,** depending on the design, but the origin of the electrical energy is the same, whether the final product be a.c. or d.c. To understand the action of the generator, examine Fig. 1, which represents a soft iron core rotating between the poles of a permanent magnet, and having the slots on the surface, in which is embedded a coil of wire. It is apparent that as the coil rotates, carried by the soft-arm armature, it will cut across the **flux** lines extending from pole to pole. When this apparatus is connected to stationary leads through the medium of slip rings, and brushes resting thereon, it becomes an elementary **alternator.** If, instead of slip rings, a split segment, such as that shown in Fig. 2, is connected to the ends

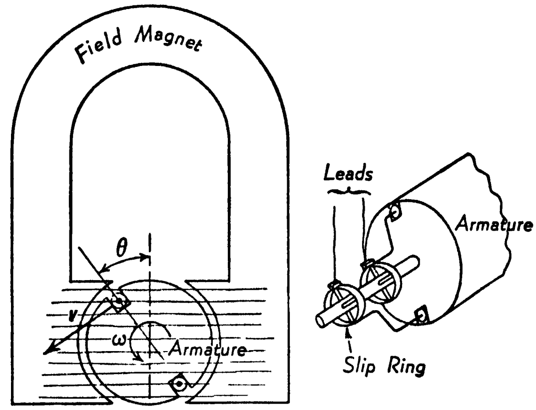


Fig. 1. Elementary generator.

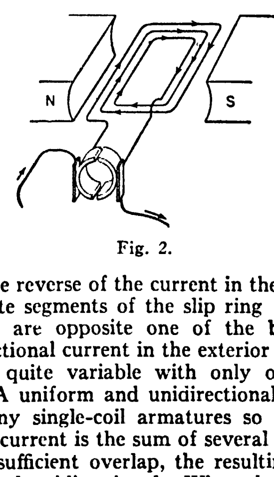

Fig. 2.

of the coil, the reverse of the current in the coil will occur when alternate segments of the slip ring (an elementary commutator) are opposite one of the **brushes.** This gives unidirectional current in the exterior leads, although it would be quite variable with only one coil in the **armature.** A uniform and unidirectional current is the result of many single-coil armatures so connected that the resultant current is the sum of several individual outputs. With sufficient overlap, the resulting current will be uniform and unidirectional. When the coil is revolving at a speed of ω radians per minute, at the position indicated, the speed of cutting vertically across flux lines is $v \cos \omega t$. The time is measured from the vertical position of the coil, and angle θ is ωt. When a wire cuts a magnetic field having a flux density represented by b and has a length and velocity represented by l and v, the voltage generated is $\frac{blv}{10^8}$ volts, thus the voltage generated any instant t, t being measured from the point of minimum generated voltage, is $\frac{blv}{10^8} \sin \omega t$.

The d-c generator is an ordinary dynamo machine having a multiple-coil winding, the ends of the coils of which are connected to a multiple-segment commutator. The armature is usually rotating, and the field stationary. The field sets up magnetic lines of force, which are cut by the conductors on the revolving armature, giving rise to a generated voltage, which is led through the commutator to a unidirectional external circuit. The iron core is built of laminations of iron insulated from each other by mill scale, or lacquer, or japanning, so that eddy currents which can be generated

in the iron core, will be a minimum. The field windings are usually stationary, and the armature rotating; hence low voltage is the usual condition of use of d-c generators. The common d-c generator is classified on the basis of the connection of the field current circuit to the armature circuit. If the field is so connected that the armature current flows through it, it is known as a series field. In a series machine, all of the armature current flows through the field. This type of generator is sometimes used to supply series street lamp circuits. The more the armature current, the higher the generated voltage in this type of machine. This characteristic serves to overcome the voltage drop in a series light circuit. A shunt-wound generator is a type in which the field winding has a high resistance, and is composed of a large number of coils of fine wire. The terminals of the shunt field are connected across the commutator. The shunt-wound generator has definitely drooping voltage characteristics, for the current in the field is dependent on the generated voltage in the armature. A compound-wound generator, having both a shunt and a series field, partakes of the best features of both of the other types. When the shunt field is connected across the commutator, only, the compounding is called short shunt; when the shunt field is connected across the series field and the commutator, it is a long shunt generator.

The d-c generator may be adapted to the Edison three-wire system, in which there are 220 volts between outside wires and 110 volts between an outside and a neutral wire. This dual voltage arrangement is obtained by bringing out the neutral point of the coil through slip rings mounted on the armature shaft. (See **Balance Coil.**)

A d-c generator cannot be operated without certain losses, both mechanical and electrical. The efficiency of the generator is simply the output in electrical energy divided by the same output, to which have been added these losses: mechanical friction, resistance heating, core loss due to hysteresis and eddy currents. In a well designed generator, the efficiency is very high. It can be of the order of 95%. (F.T.M.)

GENET. Mammalia, Carnivora. *Genetta.* Animals related to the **civets** but with more slender bodies and shorter legs. The several species are found in Africa, Asia, and Europe. (A.W.L.)

GENETICS. Heredity.

GENITAL BURSA. A cavity lined with ciliated ectoderm at the base of each arm of the brittle stars (**Asteroidea**) into which the reproductive glands discharge. (A.W.L.)

GENITAL OPERCULUM. A small plate formed of the united vestiges of a pair of appendages, which covers the openings of the genital ducts of **scorpions.** (A.W.L.)

GENITAL PORE. An external opening on the ventral surface of a flatworm, communicating with the genital **atrium** into which the reproductive ducts discharge. (A.W.L.)

GENITAL RACHIS. A ring of tissue in the starfishes and sea urchins (**Echinoidea**) whose branches bear the reproductive organs. (A.W.L.)

GENITAL STOLON. A mass of cells associated with the **axial organ** of echinoderms. (See **Echinodermata.**) (A.W.L.)

GENITALIA. The organs of reproduction. (See **Reproductive System.**) (A.W.L.)

GENOTYPE. Heredity.

GENUS. A minor subdivision of the animal or plant kingdom composed of related **species.** Genera are subdivisions of **families** and subfamilies.

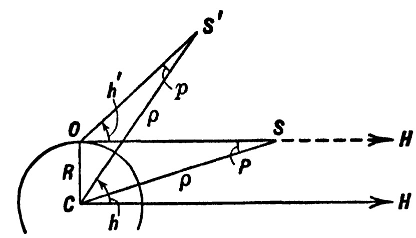
Genera are usually based on minor structural relations but in some cases superficial characters of color and pattern are made the basis of generic separation in groups of uniform structure. The distinctive characters of a genus are those of a type species (genotype) which should be stated in the original description of the genus and is determined in other cases by established rules of **taxonomy.** (A.W.L.)

GEOBENTHOS. All organisms that live on the surface of land masses. Aerial benthos. (See **Distribution.**) (A.W.L.)

GEOCENTRIC COORDINATES. Any system of coordinates on the **celestial sphere** which uses for its origin, or reference point, the center of the earth is known as a system of geocentric coordinates. Practically all cordinates published in an **ephemeris** or **almanac** are geocentric in character. (W.K.G.)

GEOCENTRIC PARALLAX. The origin of the apparent systems of **spherical coordinates** is a point on the surface of the earth, while the origin of the **geocentric** systems is at the center of the earth. For obvious reasons, all observations must be taken in the apparent system. For the solution of most problems, geocentric coordinates are desired. The transfer from one system to the other is made by applying a correction for geocentric **parallax.**

In the figure we have C the center of the earth of radius R, and O the position of an observer on the sur-



Geocentric parallax in altitude.

face. OC is the direction of gravity at O. OH is the direction of the astronomical **horizon** and CH is a parallel direction drawn through the center of the earth. S and S' represent two positions of an object at distance ρ from the center of the earth. S being the position when the object is on the horizon. At S' the object has an apparent **altitude** h' and a geocentric altitude h. P is defined as the horizontal parallax of the object and is the angle subtended at the object by the radius of the earth. For rigor the quantity usually defined is the mean equatorial horizontal parallax which is the angle subtended by an equatorial radius of the earth at the object, when the object is on the horizon, and at its mean, or average, distance from the earth. The equatorial horizontal parallax is tabulated in **Ephemerides** for all members of the solar system for selected dates. Inspection of the figure indicates that $\sin P = R/\rho$.

The geocentric altitude h is greater than the apparent altitude h by the angle p which is defined as the geocentric parallax in altitude. In the oblique plane triangle COS' we have $\frac{R}{\rho} = \frac{\sin p}{\cos h'}$ but we have already seen that $R/\rho = \sin P$ whence $\sin P \cos h' = \sin p$. Now both P and p are such small angles that, without sensible errors for most problems, except those dealing with the moon, we have $p = P \cos h'$ giving the geocentric parallax in altitude in terms of the equatorial horizontal parallax and the apparent altitude of the object. For objects outside of the solar system the value of P is far too

small to be appreciable in even the most refined observations.

In case other spherical coordinates than altitude are to be used, the geocentric parallax in altitude may be transformed to the desired quantities by solution of the **astronomical triangle** or other triangles on the **celestial sphere.** (W.K.G.)

GEOCHEMISTRY. Geochemistry is that branch of the science of chemistry which deals with the **chemical composition** of and the past and present chemical changes in the earth. The subject matter is for convenience divided into three parts:

1. Atmosphere. (See **Air; Atmosphere.**)
2. Hydrosphere. (See **Water.**)
3. Lithosphere. (See **Lithosphere.**)

The chemical and physical weathering and transport of rock materials furnishes the inorganic portion of soils for crops. Local concentration of various minerals in the crust of the earth is a matter of great economic importance. (R.K.S.)

GEOCRONITE. A mineral sulfide of **lead, antimony** and **arsenic**, $Pb_5(Sb, AS)_2S_8$. Crystallizes in the orthorhombic system. Hardness, 2.5; specific gravity, 6.4±; color, gray to blue with metallic luster; opaque. (R.M.F.)

GEODE. A geode is a hollow concretion or nodule whose inside walls are lined with crystals, commonly of **quartz** or **calcite.** (R.M.F.)

GEODESY. Geophysics.

GEODETIC SURVEYING. Surveying.

GEODUCK. Mollusca, Lamellibranchiata. A giant clam found on the Pacific coast of North America. It attains a weight of more than 6 lbs. and is edible. (A.W.L.)

GEOGALE. Mammalia, Insectivora. *Geosale.* A small animal of Madagascar which resembles the mice (**mouse**). (A.W.L.)

GEOGRAPHICAL COORDINATES. Geographical coordinates provide a method for determining the position of a point on the surface of the earth by means of a system of **spherical coordinates.** Because of the fact that the earth is not a sphere but is in reality an oblate spheroid, technically the system of coordinates cannot be strictly spherical. The geographical method of representation of the position of points on a spherical earth by means of **latitude** and **longitude** was first applied by Ptolemy in the construction of his atlas of the world during the second century of the Christian era. (W.K.G.)

GEOGRAPHY. Literally, the study, description and mapping of the surface phenomena of the earth without, necessarily, a consideration of the origin of the phenomena. Compare and contrast with **geomorphology, geodesy** (cartography), **geology, geophysics, meteorology, hydrology, oceanology (oceanography)** and biology, of the **geosciences**; and history, economics and politics of the so-called social "sciences." (R.M.F.)

GEOLOGY. The study of the composition, structure, and history of the earth. The term is derived from the Latin, *geologia*, coined by Bishop Richard de Bury in 1473 to distinguish lawyers who study "earthy things" from theologians. First consistently used in its present sense in the latter part of the 17th century. The great mass of detail that constitutes geology is classified under a number of subdivisions which, in turn, depend upon the fundamental sciences, physics, chemistry and biology. The principal subdivisions of geology are: **Mineralogy, Petrology, Structural Geology, Physiography** (Geomorphology), usually grouped under **Physical** or **Dynamical Geology**; and **Paleontology, Stratigraphy,** and **Paleogeography,** grouped under **Historical Geology.** The term **Economic Geology** usually refers to the study of valuable mineral (ore) deposits, including coal and oil. The economic aspects of geology are, however, much more embracive, including many subjects associated with Civil Engineering, Economic Geography and Conservation. Some of the more important of these subjects are: **Meteorology, Hydrology, Agriculture** and **Seismology.** Subjects which are also distinctly allied to geology are **Geophysics, Geochemistry** and **Cosmogony.** (R.M.F.)

GEOMETRIC MEAN. The geometric mean, G, of N positive **variates** is the Nth root of the product of the N variates.

$$G = (x_1x_2x_3\cdots x_N)^{\frac{1}{N}}$$

It is found by use of logarithms.

$$\log G = \frac{\log x_1 + \log x_2 + \cdots + \log x_N}{N}.$$

The geometric mean is useful if the variates form an exponential or are approximately in a geometric progression. The geometric mean is occasionally useful in **index numbers.** It is another measure of central tendency. (See **Harmonic Mean; Arithmetic Mean.**) (L.A.A.)

GEOMETRIC MEANS. Geometric Progressions.

GEOMETRIC PROGRESSION. A geometric progression is a succession of numbers in which each term has a constant **ratio** to the preceding term; this ratio is called the common ratio. The terms "geometric progression" are often abbreviated by G.P.

There are two fundamental formulas for geometric progressions—one for the general term and one for the sum of any number of terms.

The general term or n^{th} term of the geometric progression whose first term is a and whose common ratio is r is given by the formula

$$l = a\cdot r^{n-1}.$$

The sum of the first n terms of this progression is given by

$$s = \frac{a(1 - r^n)}{1 - r} = \frac{a(r^n - 1)}{r - 1} = \frac{rl - a}{r - 1} \quad (\text{if } r \neq 1)$$

The terms of a geometric progression between the first and last are called geometric means.

The geometric mean of two numbers is the middle term of a geometric progression whose first and last terms are the given numbers. It is given by the square root of the product of the given numbers.

If in a geometric progression $a, ar, ar^2, \cdots, ar^n, \cdots$, the common ratio r is <1 in absolute value, the sum s_n of the first n terms approaches $\frac{a}{1 - r}$ as a limit when n increases beyond all bounds ($n \to \infty$). In this case, we speak of the geometric progression as an **infinite geometric series**, and we say that its sum is $\frac{a}{1 - r}$. (L.L.S.)

GEOMETRIC SERIES. The infinite series $\sum_{n=0}^{\infty} r^n$ is called a geometric series. It is **convergent** when $|r| < 1$ with sum $\frac{1}{1 - r}$; but is **divergent** for other values of r. (L.L.S.)

GEOMETRICAL OPTICS. This branch of physics treats light as if it were actually composed of "rays" diverging in various directions from the source and abruptly bent by **refraction** or turned back by **reflection** into paths determined by well-known laws. The idea that light travels in straight lines is here uppermost, while its wave character and other physical aspects are lost sight of. Thus the image of a point *A*, if "real," is simply another point *B* through which the rays diverging from *A* ultimately pass after the several reflections or refractions produced by the mirrors, lenses, etc., of the optical system. If the image *B* is "virtual," the rays appear to be diverging from it, but only because their direction has been so changed that if produced backward, the lines along which they now travel would intersect at *B*. A real image of a lamp may easily be formed by a reading glass; a virtual image, by a plane mirror.

The chief advantage of this mode of visualizing the behavior of light is the simplicity with which problems may be solved by geometrical constructions. The same formulae which are deduced by the methods of geometrical optics may be arrived at, but often with much more labor, by treating light as composed of waves and studying the changes of wave front. (See **Mirrors and Lenses, Optical Instruments, Eyepieces, Spherical Aberration,** etc.) (L.D.W.)

GEOMETRY. Geometry may be said to be a study of the properties of geometric figures. Elementary plane geometry deals with figures composed of points, straight lines and circles; elementary solid geometry deals with figures composed of points, planes, straight lines, and spherical, cylindrical and conical surfaces. **Analytic geometry** is an analytic (algebraic) treatment of geometric problems. There are other branches of geometry, such as **projective geometry,** differential geometry, etc. (L.L.S.)

GEOMORPHOLOGY. This term is gradually replacing the earlier term physiography to denote the full scientific interpretation of the origin of topographic features, or the purely physical attributes of scenery. This relatively distinct department of the earth sciences includes the study of the origin of all topographic features in terms of process, or processes of erosion and in their relation to geologic structure. (R.M.F.)

GEOPHYSICS. The term "geophysics," derived from the Greek, meaning the Physics of the Earth, was probably first used by the Germans. According to Dr. G. Angenheister, Director of the Geophysical Institute of the University of Göttingen, the word *"Geophysik"* appeared in Meyer's *"Conversationslexikon,"* published in 1853. The term must have been in use sometime before. Both A. Mühry (1863), and K. Löppritz, Sr., aided in procuring its general acceptance. (See A. Sieberg, *"Geologische Einführung in der Geophysik,"* 1927, p. 1.) Among the first comprehensive treatises in the English language on this subject is "Physics of the Earth's Crust," by Osmund Fisher, published in 1881 (O. T. Jones). The scope of geophysics is broad and difficult to define, especially in relation to geology. During recent years geophysical techniques have been highly developed, particularly in relation to prospecting for petroleum through the mapping of sub-surface geological structures, the traces of which may, or may not, be exposed at the surface of the earth. By 1925, the general field of geophysics is defined in the *"Zeitschrift für Geophysik"* as follows:

1. Motion and Constitution of the **Earth.**

a. Rotation; revolution; precession; mutation; fluctuation of the poles. (Subjects which are also directly related to astronomy and physical geography.)

b. Mass, weight, figure, density, and elasticity of the earth (frequently classified under the subject of **geodesy**).

c. Distribution of mass in the earth's interior; **isostasy.** (Intimately related to fundamental problems in geodesy, **geology,** and **cosmogony.**)

2. Deformations; drifts and vibrations.

a. Elevations and depressions of the crust, folding and mountain building, glaciation and glacier-movement; vulcanism. (Primarily geological problems.)

b. Tides of the **atmosphere,** of the oceans, and of the earth. (Problems in meteorology, physical oceanography and structural geology.)

c. Wave-motions and currents in air and water. (Meteorology and physical oceanography.)

d. Elastic deformation and seismic behavior of the earth. (Usually classified under seismology, and related to structural geology.)

3. **Electric and Magnetic Field** of the Earth.

a. The internal permanent magnetic field; its distribution and secular variation.

b. The external magnetic field and its periodic variation.

c. Earth-currents and **aurora.**

d. Atmospheric electricity; **radioactivity** of the earth, the oceans, and the atmosphere. (All of the above problems are included under the subject of **terrestrial magnetism,** a distinct and important branch of geophysics; it should be noted that the **compass** is the earliest type of geophysical apparatus.)

4. Cosmic Physics in its Relation to the Earth and its Atmosphere.

a. History of the earth; determination of the origin and age of the earth as a whole, and of its crust. (Usually considered under the subjects of cosmogony and historical geology)

b. Solar constants; radiation of the earth and the atmosphere for light, heat, and wireless waves.

c. Relation of solar activity to terrestrial radiation and to the earth's electric and magnetic field.

d. Climatic changes (meteorology).

e. Cosmic radiation (discovered since 1925).

In terms of geophysics meteorology, hydrology, physical geography, physical oceanography, structural-inorganic-historical geology and cosmogony are allied subjects. In terms, however, of each of the "allied subjects," geophysical methods are included, among others, as contributary techniques.

The greatest field for the application of geophysical methods has been in geology, both from the point of view of fundamental science and economics. In the field of applied geophysics the many methods and techniques are classified as either gravitational, seismic, magnetic, electric or radioactive. (Mathematics and physical chemistry are directly allied to geophysics only through experimental physics.) In its purest sense, therefore, geophysics is a branch of experimental physics dealing, particularly, with the structure and, to a certain extent, the mass-composition of the earth, including its atmosphere and hydrosphere. Geophysics bridges the gap between physics and geology in its broadest sense. (R.M.F.)

GEOPOTENTIAL. If a unit mass is lifted above sea level to a given height, the geopotential of that level is given by the potential energy of the mass at that level. Unit geopotential is equal to the potential of unit mass lifted a unit distance in a force field of unit strength. Distance upward can be measured in terms of differences in geopotential. (P.E.K.)

GEOSCIENCE. A term proposed by R. M. Field in 1933 to include all the overlapping departments (divisions) of the physical and chemical earth sciences such

as: **geology, geophysics, geochemistry, geodesy, meteorology, hydrology, glaciology, oceanography, vulcanology** (volcanology), **seismology, geomagnetology** (geomagnetism) and their numerous subdivisions and important interscientific and intertechnological relations. Later (1939) still further defined so as to include the relation of **natural resources** (their national and international geographic distribution and technological development) to human affairs. In contradistinction to geoeconomics and geopolitics which emphasize the "monetary" and "legal" rather than the scientific and technological environment of man. (R.M.F.)

GEOSTROPHIC WIND. The wind that is the result of a balanced pressure gradient and Coriolis Force. Geostrophic winds blow in straight or nearly straight lines. Low pressure is to the left of the wind direction in the northern hemisphere when the observer stands with back to the wind. (P.E.K.)

GEOSYNCLINE. Dana's definition of a geosyncline (1873) is a depression which has been produced by lateral compression and which is filled with **sediments.** Although Dana, in his original definition, suggested that subordinate ridges might be formed in the bottom of the geosyncline during its formation, it remained for Emile Haug, in his *"Traité de Geologie,"* to emphasize these ridges (geanticlines) in relation to the tectonics of the Alps. According to L. W. Collet, "A geosyncline is situated between two continental masses and is destined to be filled with sediments, some of which are derived from the **geanticlines** which develop in it." According to R. M. Field, "A geosyncline originates in a continental block as a great trough, the locus for the accumulation of marine and terrestrial sediments, which are derived from concomitant geanticlines formed in or on the margins of the geosyncline." The geophysical and geological study of the great island arcs, such as the East Indies and West Indies (1927-1937), strongly intimates that the foredeeps in front of the arcs represent geosynclines which have not been filled with sediments while they were being formed. The pronounced deficiency of gravity associated with these foredeeps suggests great down buckle of the crustal or continental type of rocks called Sial into the more basic subcrustal couch called **Sima.** (See also **Tectogene.**) (R.M.F.)

GEOTECTOCLINE. Term proposed by H. H. Hess and R. M. Field (1938) for the deformed prism of sediments in (of) the geosyncline. (See also **Synclinorium** as originally defined. See also relation of geotectocline to **Tectogene.**) (R.M.F.)

GEOTROPISM. Tropism, and also **Movement in Plants.**

GEPHYREA. Large marine worms. As adults they are not segmented but since the young show evidence of metameric segmentation they are placed with the segmented worms in the phylum **Annelida.** They have a large body cavity, one pair of **nephridia,** and in some species a few **setae.** The internal organs are not metamerically arranged.

This class is divided into three orders:

Order Echiurida. With a pair of setae near the anterior end. Body cylindrical with a slender anterior protuberance, the **prostomium.**

Order Sipunculida. No setae. Body slender, with a protrusible proboscis and a group of tentacles near the mouth.

Order Priapulida. No setae or tentacles. (A.W.L.)

GERANIOL. Alcohols and Ethers.

GERANIUM OIL. Volatile Oils.

GERBIL. Mammalia, Rodentia. Small burrowing animals of Asia and Africa. They resemble **rats** but have long hind legs and large eyes and move about by jumping. In these points they resemble the **jerboas** but they are less extreme. (A.W.L.)

GERENUK. Mammalia, Artiodactyla. An **antelope,** *Lithocranius walleri,* of eastern Africa with a very long neck and moderate spiral horns, turned forward sharply at the tips. Also called Waller's gazelle but not a true gazelle. (A.W.L.)

GERM. 1. Any microbe or **bacterium.** 2. A spore. 3. The substance from which the embryo develops. (R.S.M.)

GERM CELL. A sexual reproductive cell. **Gamete.** (A.W.L.)

GERM LAYER. The three tissues resulting from the first differentiation in the embryonic development of multicellular animals. They are formed from the presumptive areas of the blastula during gastrulation by a redistribution which results in three layers. The three are an outer ectoderm, an inner endoderm, and between the two the mesoderm.

Animals of the phyla **Porifera, Coelenterata,** and according to one interpretation the **Ctenophora,** develop only the first two germ layers and are said to be diploblastic. Multicellular forms of all other phyla have all three and are therefore **triploblastic.**

The chief parts of the body formed from the various germ layers are as follows (in these lists the terms are chosen to embrace both vertebrates and invertebrates and so do not all apply to the same animal):

Ectoderm: Outer cellular layers of the integument, their glandular derivatives, and the cuticula. Exoskeleton and exoskeletal structures such as setae, scales, feathers, hair, claws, hoofs and nails. Parts of sensory organs including the cornea and lenses of all types of eyes, external and internal ears of vertebrates. Lining of oral cavities and salivary glands, and in vertebrates the enamel of the teeth. Lining of the posterior part of the alimentary tract. The entire nervous system of most animals, including the nervous structures in the sense organs. A limited amount of muscular tissue. Organs of reproduction of some animals. Lining or covering of organs of respiration of many invertebrates.

Mesoderm: Lining of body cavity, circulatory system, water vascular system of echinoderms, and parts of excretory system. Muscular tissue. Bone. Teeth, except the enamel. The mesenchymal tissues such as cartilage, connective tissue, adipose tissue, and tendon. Blood. A limited part of the nervous system of starfishes. Reproductive organs.

Endoderm: Lining of the enteric cavity, including most of the alimentary tract of vertebrates and the limited mid-intestine of arthropods. Respiratory epithelium of vertebrates. Lining of parts of vertebrate excretory system. Reproductive organs and cells. (A.W.L.)

GERM PLASM. The essential reproductive tissue and the germ cells that it produces

The concept of the germ plasm has been emphasized chiefly in the field of organic **evolution.** Since the germ cells of one generation produce both the body (soma, somatoplasm) and the germ plasm of the next, the continuity of this material is evident. It has been interpreted as the perpetual living substance, while the material of the body appears as an offshoot in each generation. In the 1-celled animals, however, there is no differentiation. (A.W.L.)

GERMAN MEASLES. Rubella.

GERMAN SILVER. Alloys; Brass and Bronze.

GERMANIUM. Symbol: Ge. Atomic number: 32. Atomic weight: 72.60. Density: 5.46. Melting point: 958.5° C. (**Isotopes**: page 290.)

Germanium is a silver-white, lustrous, hard, brittle metal; when heated in oxygen to 730° C. is partially oxidized to dioxide; unaffected by solutions of acids and bases but soluble in fused **sodium** hydroxide; in the form of powder is of dull gray color; combines with **chlorine** to form volatile tetrachloride. Discovered by Winkler in 1886, but predicted by Mendeléeff in 1871 as an element to be discovered with properties resembling **silicon**.

Germanium occurs in very small amount in many **sulfide** ores, such as American zinc ores (0.25% GeO_2), and the rare mineral **argyrodite** (silver germanium sulfide) of Saxony, and Bolivia. Separated from accompanying metals by fractional **distillation** of volatile germanium tetrachloride, then converted to dioxide, and then reduced to germanium metal by heating with **hydrogen, carbon,** or **aluminum.** Chemically related to **silicon** and **tin.**

Chlorides: Germanium dichloride ($GeCl_2$), white solid; germanium tetrachloride ($GeCl_4$), colorless liquid, boiling point 86° C., from the acid solution zinc metal precipitates germanium metal.

Hydroxide: Germanous hydroxide ($Ge(OH)_2$), yellow precipitate turning red on heating, formed by reaction of sodium hydroxide solution and germanous salt solutions, soluble in excess sodium hydroxide; germanic hydroxide not known.

Oxides: Germanous oxide (GeO), gray-black solid, soluble in hydrochloric acid, or sodium hydroxide solution; germanic oxide (GeO_2), white solid, by ignition of germanium metal or sulfide.

Sulfides: Germanous sulfide (GeS), brown to red precipitate; germanic sulfide (GeS_2), white precipitate; both by hydrogen sulfide with the respective salt solutions.

Germanomethane (GeH_4), melting point −165° C., boiling point −90° C.; germanoethane (Ge_2H_6), melting point −109° C., boiling point 29° C.

Germanium tetramethyl ($Ge(CH_3)_4$), boiling point 43° C.; germanium tetraethyl ($Ge(C_2H_5)_4$), boiling point 163° C.

Germanochloroform ($GeHCl_3$), boiling point 75° C. (R.K.S.)

GERMARIUM. 1. A division of the ovary (see **Gonad**) of **rotifers** in which the eggs are formed. 2. A division of the follicles in the testes of insects in which the germ cells are formed but not completely differentiated. (A.W.L.)

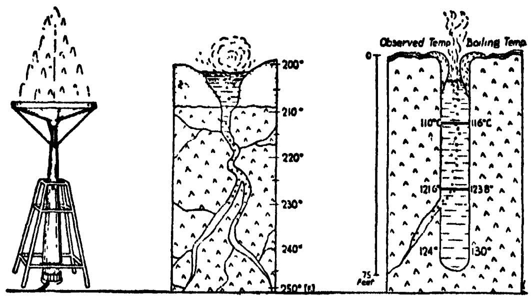
GERMICIDE. Any substance or agent, physical or chemical, which is destructive to germs (**bacteria**). (R.S.M.)

GERMINATION. **Seed.**

GERSDORFFITE. A mineral related to **cobaltite** and ullmannite in the cobaltite group. A nickel, iron, cobalt, arsenic sulfide, (Ni, Fe, Co)AsS. Crystallizes in the isometric system. Hardness, 5.5; specific gravity, 5.9; color, white to gray with metallic luster; opaque. Named after von Gersdoffs (1842) at Schladming. (R.M.F.)

GESTATION. **Pregnancy.**

GEYSER. Derived from the Icelandic word *geysa*, meaning gush and descriptive of hot springs which at regular, or irregular, intervals throw a column of steam and hot water into the air. Geyser waters usually build up tubes or conduits of **siliceous** sinter. Geyser waters have been proved to be mainly **vadose** with approximately 10% of juvenile or magmatic water. Geyser action is the result of vadose water coming in contact with steam arising from the solidifying **magma,** and periodically returning to the surface through the geyser tube, for the same reason that water is suddenly expelled from a test tube when heated too rapidly. The mechanics of geyser action are illustrated. The principal



The mechanics of geyser action, as illustrated by laboratory experiment, and the hypothetical cross-sections of natural geysers. (*Field, Outline of Geology, Barnes & Noble.*)

geyser fields are in Wyoming (Yellowstone Park), New Zealand, and Iceland. (R.M.F.)

GEYSERITE. A loose or compact, sometimes concretionary, **siliceous** deposit, formed by geysers and hot springs from the material held in solution by the thermal waters. (R.M.F.)

GHOSTS. **Diffraction Grating.**

GIANT AND DWARF STARS. With the absolute **magnitudes** and **spectral classes** of a number of stars known, a diagram may be plotted showing absolute magnitudes as ordinates against spectral classes as abscissae. Such a diagram was first published by Russell of Princeton in 1913. He found a number of stars of approximately the same absolute magnitude running as a horizontal line across the top of the diagram and a series of stars of progressively decreasing absolute magnitude with spectral class changing from *B* to *M*. From the shape of the original diagram it became known as the "figure 7 diagram." In 1905, Hertzsprung noticed that there was a sharp distinction between *M*-type stars of high and low luminosity and he referred to them as

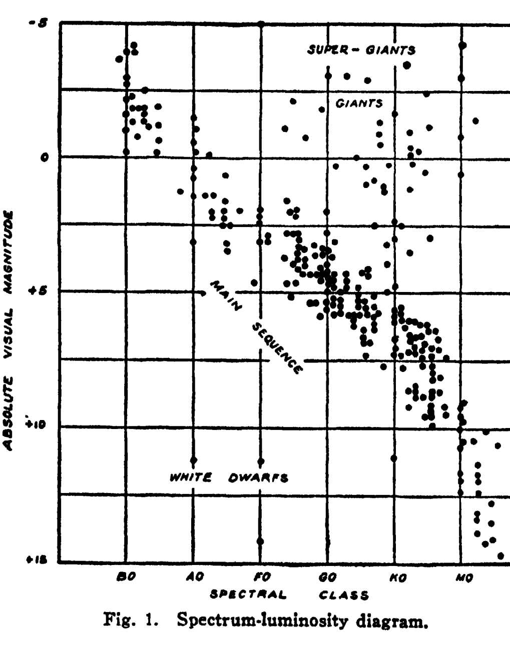


Fig. 1. Spectrum-luminosity diagram.

giant and dwarf stars. With the publication of the figure 7 diagram it became evident that the distinction between giant and dwarf classification could be extended to all spectral classes. However, the difference between the giant and dwarfs becomes less and less striking as we proceed from the *M*-type stars toward the *B*-types.

As the number of **parallax** determinations increased, and more and more stars were added to the figure 7 diagram, it became evident that the distinction between the giants and dwarfs was sharply indicated only for the *M*-types. Fig. 1 indicates such a diagram for a moderately large number of stars. It will be noted that the majority of the stars are found in a narrow region extending diagonally across the figure from the *B* to *M* spectral class. This is known as the main sequence.

The stars which appear on the diagram above the main sequence are known as the giant stars. It will be noted that the scattering of the points in the giant classification is far greater than for those along the main sequence and at present the term super-giant is applied to these giants with the greatest luminosity. Those stars which are found below the main sequence are known as the **white dwarfs.**

The **sun** is a main sequence star of G_0 spectral class and absolute magnitude about 4.9. Its luminousity is about 100 times greater than that of a main sequence *M*-type star, and about 100 times less than that of a *B*-type star in the same sequence.

Although the term giant was first used solely for indicating the relative brightness of these objects, the term has a far more striking meaning. The temperatures of all *M*-type stars are of the same order of magnitude; hence, the brightness per unit area must be approximately the same for both the giants and the dwarfs of the same class. Since the total luminosity of the giant *M* is about a million times that of the dwarf star, the areas of the two stars must be in that same ratio. This indicates that the diameter of a giant *M* star must be about 1000 times that of the dwarf and we see that the terms giant and dwarf indicate size characteristics as well as brightness.

Calculations of the relative diameters of stars of differing spectral classes is a complicated process, but approximate values may be computed for all of the stars in terms of the known diameter of the sun. By means of the **interferometer** the actual diameters of a few of the stars can be measured and the agreement between the values derived on the basis of giant and dwarf classification and those obtained by observation provides a striking example of the validity of modern astrophysical theory.

Detailed studies of the individual stars, from purely dynamical considerations, indicate that the range of mass is probably not greater than 1000. Since we have seen that the ratio of diameter is of this same order of magnitude, the range of densities between the giant and dwarf stars may be as great as a million for the extreme cases. Such differences in density would produce important differences in the characteristics of the **absorption lines** observed in giants and dwarfs of the same spectral class. These differences have been observed and form the basis for the determination of **spectroscopic parallaxes,** and physical characteristics of the stars.

The table indicates approximate physical characteristics of stars of different classifications. (W.K.G.)

PHYSICAL CHARACTERISTICS OF TYPICAL STARS

GIB. Bearings.

GIB HEAD KEY. Key.

GIBBER. Glyptolith.

GIBBON. Mammalia, Primates. Several species of man-like **apes,** highly adapted for arboreal life. They live in the forests of southeastern Asia, especially in the region of the Malay Peninsula.

Gibbons are smaller and of more slender build than the other apes and are among the most agile of all primates in the trees They have extremely long arms with which they swing long distances from bough to

bough, and their movements are said to be very rapid. They differ from the other anthropoid apes in the presence of ischial callosities.

Three of the species are known as the siamang, *Symphalangus syndactylus,* hoolock, *Hylobates hulock,* and the wou-wou, *H. leuciscus.* (A.W.L.)

GIBRALTAR SKULL. **Paleontology of Man.**

GILA MONSTER. Reptilia, Sauria. A poisonous **lizard,** *Heloderma suspectum,* of the southwestern deserts. It attains a length of 18″ and is thick-bodied, with a stubby tail. The skin bears rounded tubercles instead of flat scales and is black or blackish with pink to yellow markings. (A.W.L.)

GILBERT. **Magnetic Circuit.**

GILL. A respiratory organ for the extraction of oxygen from the water and for the liberation of carbon dioxide.

Many small aquatic animals absorb oxygen through the surface of the body generally but the more complex forms have localized respiratory organs formed to present an adequate surface. They are usually thin plates of tissue or slender tufted processes and, with the exception of some aquatic insects, they contain blood or coelomic fluid which absorbs oxygen through their thin walls. In the insects a unique type of respiratory organ is the tracheal gill which contains air tubes. The oxygen of these tubes is renewed in the gills.

Gills are developed in starfishes and sea urchins (see **Echinoidea**) as thin protuberances on the surface of the body containing diverticula of the water vascular system. In the **crustaceans, mollusks,** and some **insects** they are tufted or plate-like structures at the surface of the body in which blood circulates. The gills of other insects are of the **tracheal** type and also include both thin plates and tufted structures, and in the larval dragon fly the wall of the caudal end of the alimentary tract (rectum) is richly supplied with tracheae as a rectal gill. Water pumped into and out of the rectum supplies oxygen to the closed tracheae.

Gills of vertebrates are developed in the walls of the **pharynx** along a series of gill slits opening to the exterior. Water taken into the mouth passes out of the slits, bathing the gills as it passes. Some fishes utilize the gills for the excretion of electrolytes. In some of the **amphibians** the gills occupy a similar position on the body but protrude as external tufts. (A.W.L.)

GILL BOOK. A series of many thin respiratory plates associated with the jointed appendages of the horseshoe crabs (see **Xiphosura**). (A.W.L.)

GILL CHAMBER. A partially enclosed space containing **gills.** In many invertebrates external gills project from the surface of the body. Such structures are very delicate and in many species are protected by folds of the body wall. The **crayfish** offers a good example, with the **carapace** extended down on each side of the body to form the outer wall of a chamber in which the gills lie. (A.W.L.)

GILL FILAMENT. A thread-like component of a gill. Also the ciliated ridges of the gills of **bivalve** mollusks. (A.W.L.)

GILL PLATE. The respiratory organ of some **bivalve** mollusks. It is formed of two thin plates or lamellae, each made up of united ctenidial filaments **(ctenidium),** and contains passages communicating with the mantle cavity and with the chamber above the **gills.** Water passes into these passages from the mantle cavity. (A.W.L.)

GILL RAKER. A comb-like structure along the inner margin of the gill arches of fishes **(Pisces).** These combs prevent the passage of food into the gill slits and direct it toward the **esophagus.** (A.W.L.)

GILL SLIT. A perforation of the body wall of **vertebrates** opening into the **pharynx.** In the fishes **(Pisces)** and **amphibians** the slits are associated with the **gills** but in terrestrial vertebrates they occur only in the embryo and in mammals they usually fail to open. The gill slits are paired, opening as a series on each side of the body. In the **lampreys** and most cartilaginous fishes (**sharks,** etc.) the openings are externally separate but in the bony fishes those of each side are covered by an **operculum.** (A.W.L.)

GILSONITE. **Uintaite.** The mineral Gilsonite, named for S. H. Gilson of Salt Lake City, is a variety of **asphaltum** that occurs in Uinta County, Utah. It is found in black lustrous masses which ignite easily. A less frequently used name for it is uintaite. (E.S.C.S.)

GILT-HEAD. Pisces, Teleostei. Marine fishes (**Pisces**) whose heads are marked with gold spots. (A.W.L.)

GINGER. *Zingiber officinale.* Zingiberaceae. Ginger is the dried **rhizome** of a perennial **monocotyledonous** plant, probably native to tropical Asia. The plant apparently no longer exists in the wild state, but is extensively cultivated in tropical countries and islands of both hemispheres. In China, the cultivation of ginger has been carried on since earliest times.

The plant has a fleshy, irregularly branched rhizome from which arise erect leafy stems 2–3′ in height. The leaves are grass-like; the flowers, borne on a separate stem, are yellow and of a distinctive shape resembling that of orchids. The inside tissues of the rhizome are white and richly spotted with resin dots. The plant is propagated by means of rhizome-cuttings, each cutting having an eye or bud which produces an erect stem.

When the leaves begin to turn yellow the plant is ready to harvest. The rhizomes are dug up and cleaned, then immersed in boiling water to kill the buds or eyes, and also to loosen the periderm or outer portion. The rhizomes are then peeled and dried.

Ginger is used principally as a condiment and as an aromatic stimulant. Several volatile oils are responsible for the characteristic odor, while a ketone, gingerol, or zingerone, produces the hot biting taste. Much ginger is used in preparing ginger ale. Formerly quantities of the rhizome were used in making Jamaica ginger. Ginger also appears on the market in another form, preserved ginger, a Chinese product made from uncured rhizomes. (R.M.W.)

GINGIVITIS. Inflammation of the gums due principally to dental pyorrhea, mouth infections (e.g. "trench mouth") and vitamin B deficiencies. (D.M.H.)

GINKGO. **Paleobotany; Maidenhair Tree.**

GINKGOALES. **Paleobotany.**

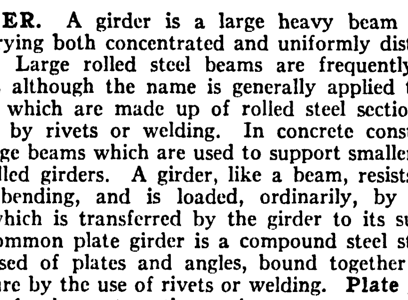
GINSENG. *Panax Ginseng* and *P. quinquelolium.* Araliaceae. The thick roots of the two species of ginseng, the first a native of Manchuria, the second of North America, are of curious interest because of the significance attached to their use. The plants are low-growing perennial herbs having compound leaves and compound **umbels** of small white flowers. They grow best in rich shady woods of hardwood trees. Even in cultivation they are usually grown in such localities. When mature, the thick fleshy roots are removed from the ground very carefully to avoid any damage. They

are then dried and marketed. Their chief users are the Chinese, who attribute to the roots wonderful curative properties, which modern research has failed to verify. Especially valuable, from the primitive viewpoint, are roots having the general form of the human body, two lateral branch roots near the top simulating the arms, and a **dichotomy** in the lower half resembling two legs. Formerly such a root would be worth its weight in gold, but today the Chinese are becoming gradually educated by modern science away from such beliefs. (R.M.W.)

GIRAFFE. Mammalia, Artiodactyla. *Giraffa.* Large African animals with unusually long necks and legs. The head bears a pair of stubby horn-like structures, covered with skin. Giraffes are marked with large irregular brown spots on a lighter ground but this pattern is said to be inconspicuous in their natural habitat. (A.W.L.)

GIRDER. A girder is a large heavy beam capable of carrying both concentrated and uniformly distributed loads. Large rolled steel beams are frequently called girders although the name is generally applied to large beams which are made up of rolled steel sections connected by rivets or welding. In concrete construction the large beams which are used to support smaller beams are called girders. A girder, like a beam, resists transverse bending, and is loaded, ordinarily, by gravity load which is transferred by the girder to its supports. The common plate girder is a compound steel structure composed of plates and angles, bound together in one structure by the use of rivets or welding. **Plate girders** are used where strength requirements cannot be met by the largest available rolled steel sections. Due to their adaptability, plate girders are to be found in almost every form of construction embodying steel. **Bridges, cranes,** and buildings, show many examples of the plate girder.

The built-up plate girder roughly resembles an **I-beam** in shape. Its area may be thought of as subdivided into area of flanges and area of web. The flange sections are most useful in withstanding the bending, and the web resists most of the **shear** to which a girder is subjected. The arrangement of plates and angles in a plate girder is shown in the accompanying figure.



Principal parts of a plate girder.

As shown in the figure, the girder is built up of a web plate whose depth is nearly equal to the full depth of the girder, flange angles which are riveted near the top and bottom of the web plate and cover plates that are riveted to the flange angles. Since the flange chiefly resists bending, and bending moment is greatest at the center of a girder (for ordinary load conditions) the cover plate could be of a thickness increasing from minimum at the abutment to maximum at midspan. It is not practicable to specify a tapered plate, but the same effect is achieved by subdividing the total maximum required cover plate area into a number of plates in laminar arrangement, and achieving the taper effect by cutting off the plates where reduction of bending stress permits. Localized buckling of the web must be resisted in order to permit the girder to develop its full strength. For this purpose stiffeners, consisting of angles arranged vertically, and riveted to the web and to the flange angles, are spaced periodically along the length of the girder. These are called *stiffener* angles, and may be smaller than the flange angles.

As the girder carries load by beam action, the **flexure** theory applies. The problem of design of plate girders begins with the computation of bending moment and shear. Generally, bending moment governs the design. A cross-section of the girder is then assumed, and the **moment of inertia** of the same computed. This moment of inertia must be such as to fit into the common flexure formula

$$\frac{M}{p} = \frac{I}{y}$$

and give a value of p which is within the safe working stress, but which is not uneconomically low. In the above equation, I is the moment of inertia of the section of the girder about its neutral axis, M is the bending moment, p is the working unit stress of the metal, and y is the distance from the neutral axis at the most stressed fiber of the girder, generally, at the extreme edge of the flange.

Most authorities require that the design of an important girder be carried through with an exact computation of the moment of inertia of some assumed section. If a determination of an economic section is made by trial and error, this moment of inertia method of design may become quite tedious. The number of trials can be greatly shortened if some approximation, which would guide the designer towards a correct selection of the proper structural shapes, could be employed. Such a method is outlined below. It is based on the assumption that a girder is made up of a simple rectangular web connecting rectangular flanges. Let the area of the web be w, and the area of each flange f, while the distance between the centers of gravity of the area of the flanges is h. The moment of inertia of this assumed area about the neutral axis which is taken to be on the axis of symmetry, is:

$$I = \frac{h^2}{2}(f + w/6).$$

If this expression be substituted in the flexure formula mentioned above, and note be taken of the fact that $y = \frac{h}{2}$, the flange area f is found to be given by the following equation:

$$f = \frac{M}{ph} - \frac{w}{6}.$$

As ordinarily given in structural texts, this formula represents the net flange area (area with rivet holes deducted). Consequently it has w divided by 8 instead of 6, the difference being accounted for by deduction of a certain amount of web area to account for rivet holes. If the flexure is obtained by some rapid estimating system, such as this flange area method, an arrangement of commercially procurable steel shapes can be set up, and the exact **moment of inertia** accurately established by the principles of **mechanics.**

The complete design of a steel plate girder includes also such problems as determining the riveting pitch in the flanges, the design of splices in the web plate, the spacing and riveting of stiffeners, and the strengthening of the ends by end stiffeners where the girder bears on its supports. (F.T.M.)

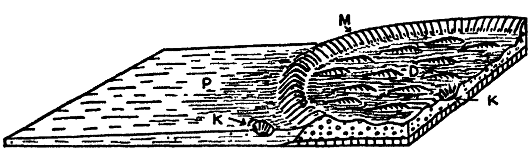
GIRDLE. 1. The part of the mantle of a chiton which surrounds the shell plates. 2. The skeletal structures of **vertebrates** by which the appendages are associated with the trunk. **Skeletal system.** (A W.L.)

GIRT. **Bent.**

GIZZARD. A region of the alimentary tract (see **Digestive system**) with thick muscular walls and some adaptation for grinding food. The gizzards of birds are the best known examples. They have a tough lining and their grinding action depends on the movements of hard particles such as gravel contained in them. One of the fishes, the **gizzard shad,** has a stomach of similar nature. Many insects also have a gizzard but in this organ the supposed grinding structures are chitinous folds and teeth projecting into the cavity. The grinding action of the organ has been questioned by some observers. (A.W.L.)

GIZZARD SHAD. Pisces, Teleostei. A widely distributed North American fish (**Pisces**) whose stomach is developed like the **gizzard** of a bird. It occurs in both fresh and salt water. (A.W.L.)

GLACIAL DEPOSITS. DRIFT. The general term for glacial deposits, or sands, gravels, boulders, etc., which are the result of mountain or continental glaciation, is drift. Drift is classified as either stratified drift, the result of deposition by waters from the melting glacier, or, till (unstratified drift) which is apt to be coarsely graded sediments composed of clay, sand, gravel and boulders. Till may grade, in places, into stratified drift, but is principally transported and deposited by the ice. Both stratified drift and till also form distinctive topographic features, to such an extent that both mountain ranges and even broad continental areas which have been subjected to glaciation cannot be described as having been subjected to the normal cycle of **erosion.** When a glacier advances over old drift it may form cigar-shaped hills, called **drumlins,** whose longer axes are relatively parallel with the movement of the ice. **Till,** which is built up into long mounds and ridges at the frontal margin of the ice sheet, forms significant topographic features called moraines. The waters coming off from the front of a



Block diagram showing a terminal moraine, *M*; an outwash plain, *P*; drumlins, *D*; and kettle holes, *K*. (*Modified after A. Penck.*)

melting ice-sheet deposit great sheets of stratified gravels, sands and clays. If ice-blocks have been covered by the outwash, when these ice-blocks finally melt they leave depressions in the outwash plain which fill with ground water to form ponds and lakes. These depressions are called kettle holes. (R.M.F.)

GLACIER. Wherever upon the earth's surface the temperature is sufficiently low and there is sufficient precipitation to produce a permanent snow field, there may glaciers be found. Other things being equal, perpetual snow is more likely to be found in high latitudes and high altitudes; as examples we have the extensive snow and ice field on Greenland and the Antarctic continent as well as valley glaciers of the Alps, of Alaska, the Rocky Mountains, the Andes, the Himalayas and elsewhere. Repeated thawing and freezing of the snow in perpetual snow fields permit the formation of coarse granular ice called nevé which passes into ice of the usual sort. On slopes, the accumulated ice will eventually begin to move, and as it fills a mountain valley, becoming literally a river of ice, it may be called a valley glacier. Even in the absence of great slopes ice will only accumulate to a limited thickness before it commences to spread out in all directions from its place of accumulation. Such a mass of ice is called a continental ice sheet or continental glacier; Greenland is an example of such a sheet of continental ice. The exact mechanics of ice movement is not definitely known. (R.M.F.)

GLAND. An organ of epithelial structure which produces secretions necessary to the body, or which excretes waste materials from the system. Glands vary greatly in form and complexity and in the nature of their products.

The simplest glands are unicellular. In the glandular lining of the intestine (see **Digestive System**), for example, are isolated cells which secrete mucus. They are known as goblet cells because the mucus accumulates in a clear ovoid mass above the constricted base of the cell, approximating the form of a goblet.

Multicellular glands develop from the epithelial layers by local increase of cells and consequent expansion of

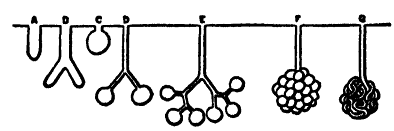


Diagram showing types of glands: *A*, simple tubular; *B*, branched tubular; *C*, simple acinous; *D* and *E*, branched acinous; *F*, compound acinous; *G*, compound tubular. (*From Kimber and Gray, Textbook of Anatomy and Physiology, Macmillan Co.*)

the layer into adjacent spaces or tissues. They include tubular, acinous, and alveolar structures. Tubular glands are slender tubes lined with glandular epithelium; acini are rounded groups of cells with a small central cavity; and alveoli are larger rounded chambers lined with glandular cells. Tubular glands may branch or coil. Many of the larger glands of the body, including the **pancreas** and **salivary glands,** are made up of great numbers of acini borne by complex branching ducts. These glands are said to be compound. In the most complex forms the secretion may leave the cells by minute canals, or similar canals between the cells may conduct it to the cavity of the acinus. This cavity empties into a short secretory duct lined with gland cells, and this in turn into the excretory duct. These smaller ducts join to form larger and larger passages, ultimately reaching the main duct which delivers the secretion of the entire gland to its destination.

Glands may be divided into three kinds:

1. Glands of external secretion whose products are discharged through ducts.
2. Glands of internal secretion, the endocrine or ductless glands.
3. Glands having both external and internal secretion.

Glands which produce cells are known as cytogenic glands. They include the reproductive glands (see **Gonad**) which produce germ cells and the **spleen, lymph** glands, and red bone marrow, in which blood cells develop.

Special glands are derived from all germ layers and are associated with all organic systems. They serve for hormone production, for lubrication, to prevent drying, for defense, in reproduction, and in many other ways. (See **Endocrine Glands.**) (A.W.L., D.M.H.)

GLAND, STEAM. **Fluid Seals.**

GLANDULAR FEVER. **Infectious Mononuncleosis.**

GLASS. Glass is defined as "a liquid whose rigidity is great enough to enable it to be put to certain useful purposes" (Morey). The term "rigid liquid" includes the naturally occurring rock glasses, such as **obsidianite,** and the industrially formed metallurgical **slags.** Glasses, glazes of pottery, enamels on steel, obsidianite,

fuzed quartz ware, and slags are all formed by rapidly cooling a previously molten mass without allowing sufficient time for crystallization to occur during the cooling process (undercooling). The viscosity characterizing liquids is absent, and the material appears to be solid.

Common glass is essentially a sodium calcium **silicate** in composition. In preparing the raw materials for the charge, **sodium** is supplied as soda ash (sodium carbonate, Na_2CO_3) or salt cake (sodium sulfate, Na_2SO_4), with **carbon** to reduce the **sulfate**, **calcium** as **limestone** (calcium carbonate, $CaCO_3$) or burnt lime (calcium oxide, CaO), and **silicon** as **quartz**, usually in the form of silica sand (silicon oxide, SiO_2), along with "cullet" or broken glass to assist in the fluxing and melting.

A representative charge for common glass is 100 parts by weight of silica sand, 35 of soda ash, 12 of lime, and 10 of niter (**sodium** nitrate, $NaNO_3$), which supplies some of the sodium and serves to oxidize ferrous to ferric. For plate glass one of the charges used is 100 parts by weight of silica sand, 32 of soda ash, 6 5 of salt cake, 0.3 of charcoal, and 32 of limestone. All materials of the charge that are not volatilized in the process remain in the glass produced. The green color due to the presence of ferrous iron, of much common glass is accounted for by the presence of **iron** in some of the materials of the charge. To produce colorless glass when iron is present, sodium nitrate or manganese dioxide is usually added. To produce colored glass small amounts of the desired coloring materials are added to the charge, for example, **cobalt** oxide for blue glass, **manganese** oxide for violet, **gold** or **selenium** for red, **uranium** oxide or **silver** for yellow, ferric oxide for brown. Addition of **calcium** fluoride, **arsenic** trioxide, **aluminum** oxide, **zinc** oxide, **calcium** phosphate, one or more, produces opalescent white glass, while black glass is produced by **iridium** oxide or mixtures of other oxides, such as those of cobalt, iron, nickel, manganese.

The raw materials are heated to a high temperature in a furnace either in individual pots or in hearth or tank furnaces. When the whole mass has been fused, time is allowed for the escape of gases, and then the liquid is withdrawn and worked. The working depends upon the unique property possessed by glass of being shaped while in a heated state, by blowing, mo'ding or rolling, and retaining the shape upon being cooled. The range of temperature through which glass is thus workable and its viscosity in this range are important considerations.

For special purposes the composition of glass may be varied considerably. **Potassium** may be substituted for **sodium, lead** or **barium** for **calcium;** the ratio of these to silicon may be decreased markedly; and, finally, **boron,** which functions somewhat as **silicon,** is available. Illustrative analysis of various glasses are the following:

ANALYSES OF VARIOUS GLASSES

Kind of Glass	Silicon Oxide	Sodium Oxide	Potassium Oxide	Calcium Oxide	Barium Oxide	Zinc Oxide	Lead Monoxide	Aluminum Oxide	Boron Oxide	Remainder

Blast furnace slag has an approximate analysis somewhat as follows: **calcium** oxide 43%, **magnesium** oxide 2%, **aluminum** oxide 15%, **silicon** oxide 35%, residue—chiefly **ferrous** oxide plus **maganous** oxide plus **calcium** sulfide—5%.

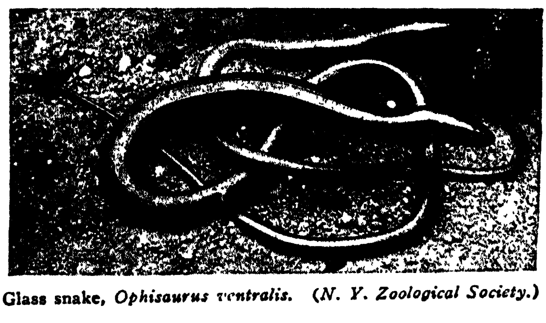
Obsidianite has the following approximate analysis: calcium oxide 1%, **sodium** oxide 4%, **potassium** oxide 4%, aluminum oxide 14%, silicon oxide 75%, **ferric** oxide 1%, ferrous oxide 0 5%, iron disulfide 0.5%, water 0.5%.

When glass is cooled rapidly strains are set up in it but up to a certain point the resistance to shock, and to rapid, moderate changes of temperature is increased; but on scratching it is subject to shattering. To increase this effect, glass is sometimes cooled rapidly by immersion in oil, as for lamp chimneys. To decrease this effect, glass is usually cooled slowly or annealed as for lenses. Very slow cooling and aging cause devitrification of glass. Such glass crystallizes and is readily shattered.

Quartz glass, unlike ordinary glass, is transparent to **ultra-violet rays,** and is, therefore, used in the **mercury-arc lamp.** Sodium vapor lamps require a boro-silicate glass. Heat-absorbing glass, useful for skylights, is made so that it is effective in removing one-half of the infra-red or heat rays of sunlight. Safety or laminated glass is made by cementing together sheets of hardened glass by a thin layer of **cellulose** acetate or some other plastic. Such glass does not scatter when it fractures.

The system sodium (or potassium) oxide—calcium oxide—silicon oxide has been determined by Morey and coworkers. The lowest melting mixture, namely 5% sodium oxide, 20% calcium oxide, 75% silicon oxide, was found by them to have a melting temperature of 725° C. The system calcium oxide—aluminum oxide—silicon oxide, has been determined by Rankin and coworkers. (See **Cement.**) (R.K.S.)

GLASS SNAKE. Reptilia, Sauria. A legless **lizard,** *Ophisaurus ventralis,* whose tail is exceptionally brittle.



Glass snake, ***Ophisaurus ventralis.*** *(N. Y. Zoological Society.)*

Although snake-like it may be recognized as a lizard by its small ventral scales and its eyelids. Central and southern states. (A.W.L.)

GLAUBER'S SALT. **Sodium** sulfate decahydrate.

GLAUCOMA. A common disease of the eye which usually occurs in middle and later life. The exact cause is unknown, but several predisposing factors have been observed. There is frequently an hereditary history. **Arteriosclerosis,** hyperopia, and abnormalities in the size of the eyeball and lens may play a rôle.

The symptoms of glaucoma are due to an increase of the pressure within the eyeball and the accompanying venous congestion. In the acute form there is diminished vision to blindness, pain in the eye and severe headache. The disease may be rapid or insidious in onset. Untreated, it terminates in blindness of both eyes. Treatment is with pupil-constricting drugs locally and, in advanced cases, surgery. (D.M.H.)

GLAUCONITE. Glauconite is a hydrous **silicate** of **potassium** and **iron** of somewhat variable composition. It has a dull green color and is often a constituent of marine deposits forming "green sand." It is believed to have been produced through the alteration of iron-bearing silicates chiefly **biotite** and possibly **augite** and **hornblende.** It occurs along the Coastal Plain of the Atlantic and Gulf States. Frequently found filling the interiors of the shells of globigerina, a common genus of the **foraminifera (Protozoa).** Since globigerina occurs as a deep-sea deposit many European geologists have claimed that glauconite is only found in deep water. On the other hand typical "green sands" occur associated with sand and clays which are certainly of shallow marine origin. Glauconite derives its name from the Greek word meaning bluish-green. (R.M.F.)

GLAUCOPHANE. Glaucophane, essentially a complex **silicate** of **sodium,** and **iron** or **aluminum** $Na(Al, Fe)(SiO_3)_2$, is a rather rare mineral although it has been noted from widely separated occurrences. It is **monoclinic** and ordinarily is fibrous or granular. It is brittle; hardness, 6–6.5; specific gravity, 3–3.1; color, azure blue, blackish-blue or gray; luster, vitreous to pearly; translucent to opaque. Glaucophane is found only in the **metamorphic** rocks sometimes forming glaucophane schists. It is found in Switzerland, Italy, Siberia, Japan and in the United States chiefly in the rocks of the Coast Ranges in California and Oregon. The name glaucophane is derived from the Greek words meaning *bluish green,* and *appear.* (E.S.C.S.)

GLIDER. The glider is an **aircraft** obtaining its sustention from **aerodynamic** forces created by a wing of **airfoil** section. Unlike the airplane, the glider has no engine, and must depend either on gravitational energy obtainable by gliding down a slope, or upon a tow furnished by a surface vehicle or an airplane. The sailplane, or soaring glider, a refinement of the glider, is a more expensive, less rugged, and aerodynamically more efficient craft. It is so light and is built with so low a wing loading, (i.e., lbs. per sq. ft. wing area) that in the presence of upwardly directed air currents, such as are present along the windward slopes of mountain ranges, its sinking speed being lower than the upward component of air velocity, it is able not only to remain aloft, but actually to mount upwards considerable distances.

The glider has several spheres of usefulness. First, like yachting, it furnishes, to a high degree, an entertainment of a sporting nature. This is especially true of the sport of soaring. Second, since its controls are the same as those of the conventional airplane, it offers a means of preliminary pilot training at a minimum cost. It is said that one unable to coordinate the controls in a glider, cannot master a power plane. Third, it has many commercial possibilities as a towed air-freighter. Fourth, the glider is of proved tactical value in airborne offensive warfare.

There are three classes of gliders, primary, secondary, and cargo. The primary glider is relatively heavy, and crudely constructed. It is built around a keel or backbone rather than a fuselage, and there is no attempt to streamline the pilot's seat. Due to its steep gliding angle, flights in it are necessarily short. This type of glider has but little usefulness, and is not frequently built nowadays. The secondary glider, sometimes called dual-purpose or trainer glider, is more ruggedly built than the sailplane, and stands rougher usage, but will soar when subjected to the best wind conditions. Usually it is constructed as a single-place high-wing monoplane, with steel tube or wooden fuselage covered with fabric. The forward end is smoothly rounded and a detachable cockpit cover is slipped into place before soaring flights. The landing gear may consist either of a skid or a single wheel, aided by skids fore and aft. The controls are exactly the same as those of an airplane, but the light wing loading makes the glider much more sensitive to wind currents. Consequently, it is provided with extra large control surfaces in the form of aileron, elevator, and rudder.

The cargo glider is built primarily for towing by an airplane. Although it is large, the cargo glider is also efficient, aerodynamically, and a multi-motored airplane can pull two or three cargo gliders simultaneously. Airborne warfare has given great impetus to the construction of this type of glider since personnel and heavy armament may be safely landed on sites where airplane landings are impossible. (F.T.M.)

GLOBIGERINA OOZE. **Oceanic Deposits.**

GLOBULINS. **Aminoacids, Polypeptides and Proteins.**

GLOCHIDIUM. A larval form of fresh-water **bivalve** mollusks which lives as a parasite in the **gills** or skin of fishes. (A.W.L.)

GLOMERATE. The textural term, proposed by R. M. Field, for a **sedimentary rock** with a coarse and poorly graded texture, when the origin of the shape of the larger constituents has either been undetermined or is indeterminable. (R.M.F.)

GLOSSA. **Labium.**

GLOSSITIS. Inflammation of the tongue. It is seen commonly in pernicious **anemia** and **vitamin B** deficiencies. (D.M.H.)

GLOSSOPTERIS. **Paleobotany.**

GLOTTIS. The opening from the **pharynx** or throat of vertebrates into the **trachea.** (A.W.L.)

GLOW DISCHARGE. **Ionized Gases.**

GLOW PLUG. **Hot Bulb.**

GLOW WORM. Insecta, Coleoptera. Wingless females of certain **beetles.** They resemble larvae throughout life and are luminous. (A.W.L.)

GLUCINUM. **Beryllium.**

GLUCOSE. **Carbohydrates.**

GLUCOSIDES. Glucosides are substances that by reaction with water, either in presence of certain **enzymes** or of dilute **acids** or **alkalis,** yield a **sugar,** commonly

glucose, as one of the products, plus a principle characteristic of the individual glucoside. Most glucosides are soluble in cold or hot water, and in alcohol (95% C_2H_5OH), and insoluble or slightly soluble in ether (used to separate from alcohol solution). Most optically active glucosides are laevo-rotatory. The di- and polysaccharides are to be considered as glucosides. Glucosides occur in plants, especially in leaves, buds, young shoots where **metabolism** is active, and in the bark and seeds. **Anthocyanins,** the plant colors of flowers, are glucosides, as are also some **tannins.**

GLUTELINS. Proteins.

GLUTTON. Wolverine.

GLYCEROL. Glycerol, propantriol, glycyl alcohol, "glycerine" ($CH_2OH \cdot CHOH \cdot CH_2OH$) is a colorless, viscous liquid, of sweetish taste, odorless, boiling point 290° C., or at 12 mm. pressure 170° C., gradually solidifies at 0° C. to solid, melting point 18° C., miscible in all proportions with water or alcohol, insoluble in ether or chloroform, absorbs water on exposure to the atmosphere. Glycerol reacts (1) with **phosphorus** pentachloride to form glyceryl trichloride ($CH_2Cl \cdot CHCl \cdot CH_2Cl$), (2) with **acids** to form **esters,** e.g. glycerol monoacetate ($CH_2OH \cdot CHOH \cdot CH_2OOCCH_3$), glycerol diacetate ($C_3H_5(OH)(OCOCH_3)_2$), glycerol triacetate, triacetin ($CH_2OOCCH_3 \cdot CHOOCCH_3 \cdot CH_2OOCCH_3$), glycerol mononitrates (alpha, $CH_2OH \cdot CHOH \cdot CH_2ONO_2$; beta, $CH_2OH \cdot CHONO_2 \cdot CH_2OH$),

GLUE. Glue is the product of **hydrolysis** of **proteins,** usually of animal origin. Waste products of slaughter-houses (i.e., hide clippings, hoofs, etc.) are the source of most commercial glue. (R.K.S.)

GLUME. A glume is an empty **bract,** often chaff-like, which occurs at the base of the **spikelet** in grasses. Usually there are two to each spikelet. (R.M.W.)

glycerol dinitrates (1,2, $CH_2OH\cdot CHONO_2\cdot CH_2ONO_2$; 1,3, $CH_2ONO_2\cdot CHOH\cdot CH_2ONO_2$), glyceryl trinitrate, "nitroglycerine" ($CH_2ONO_2\cdot CHONO_2\cdot CH_2ONO_2$), glyceryl tristearate, tristearin ($CH_2OOCC_{17}H_{35}\cdot CHOOCC_{17}H_{35}\cdot CH_2OOCC_{17}H_{35}$), indirectly, glycerol monophosphates (alpha, $CH_2OH\cdot CHOH\cdot CH_2OPO(OH)_2$, beta, $CH_2OH\cdot CHOPO(OH)_2\cdot CH_2OH$), (3) with oxidizing agents, e.g., dilute **nitric acid,** to form glyceric acid ($CH_2OH\cdot CHOH\cdot COOH$), tartronic acid ($COOH\cdot CHOH\cdot COOH$), mesoxalic acid ($COOH\cdot CO\cdot COOH$), (4) with **phosphorus** plus **iodine,** to form allyl iodide ($CH_2{:}CHCH_2I$), which with **hydrogen iodide** yields propylene ($CH_2{:}CHCH_3$) and then iso-propyl iodide (CH_3CHICH_3), (5) with **sodium** or sodium hydroxide to form alcoholates, (6) with **sodium** hydrogen sulfate or **phosphorus** pentoxide heated, to form **acrolein** ($CH_2{:}CHCHO$). Glycide alcohol ($CH_2OH\cdot\underbrace{CH\cdot CH_2}_{O}$) is obtained by treatment of glycerol alpha-monochlorohydrin ($CH_2OH\cdot CHOH\cdot CH_2Cl$), which is made by reaction of hypochlorous acid and allyl alcohol with barium hydroxide. With **hydrogen chloride,** glycide alcohol yields epichlorohydrin ($CH_2Cl\cdot\underbrace{CH\cdot CH_2}_{O}$).

Glycerol is obtained (1) from vegetable and animal oils and fats, most of which are mainly glycerol esters of **stearic, palmitic** and **oleic acids** by treatment with alkali (**sodium** hydroxide commonly used), **acid** (sulfobenzone—or naphthalene—stearic acid, "Twitchell's reagent"), superheated steam, or an **enzyme** (lipase of castor beans). Glycerol is recovered from the water solution by **evaporation** under diminished pressure, and purified by treatment with decolorizing **carbon** followed by **filtration,** (2) by **fermentation** of glucose in the presence of **yeast** and **sodium** sulfite.

Glycerol may be detected by the characteristic odor of **acrolein,** found on heating with **potassium** bisulfate.

Glycerol is used (1) in the manufacture of high **explosives,** e.g., glyceryl trinitrate ("nitroglycerine"), which is the main component of dynamite, (2) in antifreeze solutions, especially for automobile radiators,

% Glycerol by Weight	Specific Gravity, 60° F.	Freezing Point, °F.
20	1.049	23
40	1.103	4
60	1.158	−28

(3) to maintain a moist condition in fruits and tobacco, (4) in cosmetics and skin preparations, (5) to prepare glycerol phosphoric acid, used in medicine, and "boroglyceride" used as a preservative. (R.K.S.)

GLYCINE. **Aminoacids, Polypeptides, and Proteins.**

GLYCOCOLL. **Aminoacids, Polypeptides and Proteins.**

GLYCOGEN. **Carbohydrates.**

GLYCOL. Glycol, ethylene glycol, ethandiol, ($CH_2OH\cdot CH_2OH$) is a colorless, viscous liquid, of sweetish taste, odorless, boiling point 197° C., miscible in all proportions with water or alcohol, slightly soluble in ether. Glycol reacts (1) with **sodium** to form sodium glycol ($CH_2OH\cdot CH_2ONa$) and disodium glycol ($CH_2ONa\cdot CH_2ONa$), (2) with **phosphorous** pentachloride to form ethylene dichloride ($CH_2Cl\cdot CH_2Cl$), (3) with **carboxy acids** to form mono- and di- substituted esters, e.g., glycol monoacetate ($CH_2OH\cdot CH_2OCOCH_3$), glycol diacetate ($CH_3COOCH_2\cdot CH_2OOCCH_3$), (4) with nitric acid (with sulfuric acid), glycol mononitrate ($CH_2OH\cdot CH_2ONO_2$), glycol dinitrate ($CH_2ONO_2\cdot CH_2ONO_2$), (5) with **hydrogen chloride,** heated, to form glycol chlorohydrin (ethylene chlorohydrin, $CH_2OH\cdot CHCl$), (6) upon regulated oxidation to form glycollic aldehyde ($CH_2OH\cdot CHO$), glyoxal ($CHO\cdot CHO$), glycollic acid ($CH_2OH\cdot COOH$), glyoxalic acid ($CHO\cdot COOH$), **oxalic acid** ($COOH\cdot COOH$). In the preparation of glycol derivatives, important substances are (a) the sodium glycols, (b) ethylene dichloride (1,2-dichloroethane), best prepared by reaction of **ethylene** and **chlorine,** (c) ethylene chlorohydrin (1-hydroxy-2-chloroethane), best prepared by reaction of ethylene and **hypochlorous acid.** From these are readily made respectively, (a) **ethers,** e.g., glycol monoethyl ether ($CH_2OH\cdot CH_2OC_2H_5$), glycol diethyl ether ($CH_2OC_2H_5\cdot (CH_2OC_2H_5)$, (b) ethylene diamine ($CH_2NH_2\cdot CH_2NH_2$), ethylene dicyanide ($CH_2CN\cdot CH_2CN$), glycol itself, (c) hydroxyethylamine ($CH_2OH\cdot CH_2NH_2$), ethylene cyanhydrin ($CH_2OH\cdot CH_2CN$), ethylene oxide (by sodium hydroxide $\left(\begin{smallmatrix}CH_2\\|\\CH_2\end{smallmatrix}\!>\!O\right)$. Glycol is made by reaction of ethylene and chlorine or hypochlorous acid to form ethylene dichloride or ethylene chlorohydrin, respectively, followed by treatment of either of these with sodium carbonate solution heated under pressure. Glycol is also formed when ethylene is treated with **potassium** permanganate. Glycol is used (1) in antifreeze solutions, especially for automobile radiators, (2) in the preparation of **ethers** and **esters,** especially nitrate for explosive, (3) as a solvent, substitute for glycerol. (R.K.S.)

% Glycol by Volume	Specific Gravity, 60° F.	Freezing Point, °F.
17	1.026	20
32.5	1.048	0
44	1.063	−20

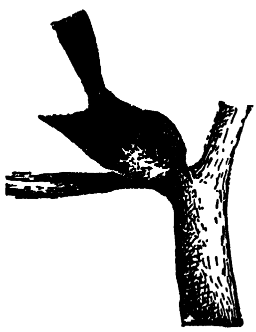
GLYCOLLIC ALDEHYDE. **Aldehydes, Ketones, and Related Compounds.**

GLYCOSURIA. The presence of excess **sugar** (glucose) in the **urine.** By far the commonest cause is **diabetes,** where as much as 200 grams may be excreted daily. The glycosuria of diabetes is always accompanied by a high blood sugar. In some people extreme emotional stress or fright may produce an excess of sugar in the urine. Another form of glycosuria occurs with injuries or tumors of certain parts of the brain. Still another form occurs in some individuals in whom, regardless of the sugar intake, a certain amount of sugar is passed into the urine. Here the kidneys are said to have a low threshold for sugar. The condition is called renal glycosuria and is without pathological significance. Glycosuria is also seen in normal pregnancy, and in certain disorders of the thyroid and pituitary glands. (D.M.H.)

GLYPTOLITH. **Dreikanter.**

GNAT. Insecta, Diptera. Loosely applied to many small 2-winged flies. In such names as **buffalo gnat, gall gnat,** and **fungus gnat** it applies to specific groups. (A.W.L.)

GNATCATCHER. Aves, Passeriformes. Small birds related to the **kinglets.** One, the blue-gray gnatcatcher, *Polioptila caerula,* ranges over North America east of the Rockies and two other species occur in the southwestern states. (A.W.L.)



Blue gray gnatcatcher.
Polioptila caerulea. Bluish gray above, grayish white below. Outer tailfeathers white; inner ones black. Narrow black border on front and sides of head. Four and one-half inches long.

GNATHOBASE. The base of an appendage of the **arthropods,** formed for crushing food. **Spiders,** horseshoe crabs, and **scorpions** chew their food by such means. The gnathobases of a pair of appendages act together like the **mandibles** of other arthropods. (A.W.L.)

GNATHOCHILARIUM. The posterior element of the mouth parts of **millipedes.** It is formed of a pair of appendages and is similar to the **labium** of insects (A.W.L.)

GNATHOPOD. Appendages of crustaceans (**Amphipoda**) used for grasping food. (A.W.L.)

GNATHOSTOMATA. A term applied collectively to the members of the subphylum Vertebrata which have hinged jaws, in contrast with the funnel-shaped mouth of the Class Cyclostomata. It embraces the fishes, amphibians, reptiles, birds and mammals. (A.W.L.)

GNEISS. The gneisses are common and widely distributed rocks which have been derived by **metamorphic** processes from pre-existing formations that were originally either **igneous** or **sedimentary** rocks. Gneissic rocks are coarsely laminated and largely recrystallized but do not carry excessive quantities of the **micas,** chlorite or other platy minerals. Gneisses that are metamorphosed igneous rocks or their equivalent are termed **granite** gneisses, **diorite** gneisses, etc.; however depending upon their mineralogical composition, they may be called **garnet** gneiss, **biotite** gneiss, **albite** gneiss and so on. Orthogneiss designates a gneiss derived from an igneous rock; paragneiss, one from a sedimentary rock. The word gneiss is from an old Saxon mining term which seems to have meant decayed or rotten, or possibly worthless material. (R.M.F.)

GNETALES. Paleobotany.

GNOMONIC PROJECTION. This type of projection is used in producing, especially for use in navigation, what are frequently referred to as great-circle charts, because of the fact that great circles (geodesic lines) on the surface of the earth are projected as straight lines. In the gnomonic projection the chart is constructed by placing a plane tangent to the surface of the earth at some selected point and then projecting the surface features by extending radii from the center of the earth out until they meet the plane.

In the gnomonic projection the distortion, both of shape and of size, is very severe except for a very limited area immediately about the point of tangency with the earth. The great value of the charts lies in the fact that the shortest distance, even between very widely separated points, will be projected as a straight line. The government issues a series of charts on this type of projection for all of the principal cruising areas of the world and they are of immense value to navigators for determining at a glance whether or not the following of the shortest course between two points (**great-circle course**) is practicable. (W.K.G.)

GNU. Mammalia, Artiodactyla. African **antelope,** *Connochaetes gnu,* of large size and ugly appearance. Also called wildebeests. These animals have a large head, strong curved horns, an erect bristly mane and a bristly muzz'e. The withers are high and the tail hairy throughout its length. (A.W.L.)

GOAT. Mammalia, Artiodactyla. Hoofed animals belonging to the same family as the cattle, sheep, and antelopes, and not sharply distinct from the sheep. The males are usually bearded. The group includes numerous species of the Old World. One species occurs in North America, two in northern Africa, and the remainder in Europe and the more northern parts of Asia. They are primarily mountain animals.

In addition to goats named as such, the group includes the turs of the Caucasus, the Persian pasang, the **ibexes,** the **markhor,** and the **tahr.** The American species is found in the Rockies and Cascades, north to Alaska. It is called the mountain goat, *Oreamnos americanus.*

Wild goats are fine game animals and the domestic goat, *Capra hircus,* is valuable for its milk and hide, and as a source of mohair. (A.W.L.)

GOATSUCKER. Aves, Caprimulgiformes. All birds (**Aves**) of this order characterized by weak legs, a short weak beak and very wide mouth, and crepuscular habits. They catch insects while on the wing. The **frog mouths, oil bird,** and **nightjars.** Generally distributed except in the Australian region.

The North American goatsuckers are the chuck-will's-widow, **poor-will, whip-poor-will, nighthawk,** and parauque. (A.W.L.)

GOBLET CELL. Gland.

GOBY. Pisces, Teleostei. Shore fishes (**Pisces**) of the tropics. Many species of which a few enter fresh water. Family Gobiidae. (A.W.L.)

GODWIT. Aves, Charadriiformes. *Limosa.* Wading birds (**Aves**) allied to the sandpipers, with long legs and a long slender beak. The several species nest in the far north but migrate to the southern hemisphere in winter. (A.W.L.)

GOETHITE. The mineral goethite is a hydroxide of **iron** corresponding to the formula FeO(OH) crystallizing in the **orthorhombic** system. It occurs in prisms, but is often found in **foliated** or other massive forms. When observable it shows one good **cleavage** parallel to the **prism;** fracture, uneven; hardness, 5–5.5; specific gravity, 4.28; luster adamantine to dull; color, yellowish, reddish, brownish to nearly black; translucent to opaque. It is found associated with **hematite** and **limonite,** being perhaps in part an alteration product of the latter mineral. Goethite is used as an ore of iron. There are many European localities, including Bohemia, Saxony, Westphalia, and Cornwall. In the United States it is found in the **hematite** mines of the Lake Superior region and in Colorado. This mineral was named in honor of the German poet Johannes Wolfgang von Goethe (E.S.C.S.)

GOITRE. Thyroid Gland.

GOLD. Symbol: Au (aurum). Atomic number: 79. Atomic weight: 197.2. Density: 19.3. Hardness: 2.5–3.

Melting point: 1063° C. Boiling point: 2600° C. No isotope, but of single atomic form: 197.

Gold is a yellow metal—the color is markedly affected by the presence of traces of other metals—very malleable and ductile—the ductility is diminished by the presence of other metals—soft—the softness is counteracted when desired by the addition of other metals—unattacked by air, water or **hydrogen sulfide,** not dissolved by **hydrochloric** or **nitric acid,** but soluble in **aqua regia** and converted into chloride by **chlorine** used either as gas or solution, soluble in solutions of cyanides in the presence of air. Very thin sheet gold is translucent and transmits greenish light. Discovery prehistoric.

Gold is one of the most ancient metals used in the arts, about ⅓ of the present output being so used, and the remaining ⅔ in coinage or in bars. The lettering of books and the decoration of porcelain utilize important amounts of gold. It occurs chiefly as native gold alloyed with silver, copper, lead, or other metals (60%–98% Au), in certain sands and quartz veins from which it is obtained (1) by mechanical methods, such as "washing," (2) by dissolving in sodium or potassium **cyanide** solution followed by precipitation of the gold by zinc metal, (3) by dissolving in **mercury** (quicksilver) and later distilling off the mercury.

Auricyanide: Potassium aurocyanide ($KAu(CN)_2$) and sodium aurocyanide ($NaAu(CN)_2$), by treatment of gold with **potassium** and **sodium** cyanide solutions, respectively, in the presence of air.

Bromide: Aurous bromide ($AuBr$) yellowish-gray solid, by heating auric bromide to a maximum temperature of 200° C.; auric bromide ($AuBr_3$) brownish-red soluble solid by reaction of gold with **bromine** solution.

Chloride: Aurous chloride ($AuCl$), yellow solid, by heating auric chloride to a maximum temperature of 175° C. for several days; auric chloride ($AuCl_3$), reddish-brown soluble solid, by reaction of gold with **chlorine** as gas or in solution, sublimes at 265° C. in a current of chlorine, is changed to aurous chloride as stated above, and when heated to temperature higher than 175° C. decomposes into gold metal and chlorine gas; chlorauric acid ($HAuCl_4 \cdot 3H_2O$), brown soluble solid, used in identifying certain organic bases.

Chloroaurates: Sodium chloroaurate, "sodio-gold chlorride" ($NaAuCl_4 \cdot 2H_2O$), yellowish-red crystals, soluble, as also lithium chloroaurate ($LiAuCl_4$) and potassium chloroaurate ($KAuCl_4$).

Hydroxide: Aurous hydroxide ($AuOH$), purple precipitate, by treating aurous bromide solution with **sodium** hydroxide solution in the cold; auric hydroxide ($Au(OH)_3$), brown precipitate, by treating auric chloride solution with sodium hydroxide solution.

Oxide: Aurous oxide (Au_2O), purple precipitate, by treating aurous bromide solution with a slight excess of sodium hydroxide and boiling the mixture; auric oxide (Au_2O_3), dark brown solid by heating auric hydroxide to 100° C.

Purple of cassius is precipitated when a solution of auric chloride is treated with a solution of **stannous** chloride of the proper concentration. The product is used in the preparation of ruby **glass.**

The occurrence of gold in sea water has attracted much attention. The various sources and reports show there is present from 5 to 250 parts by weight of gold per 100,000,000 of sea water. Although the *quantity* present is enormous, the cost of recovering the same has hitherto been greater than the value of the gold obtained. (R.K.S.)

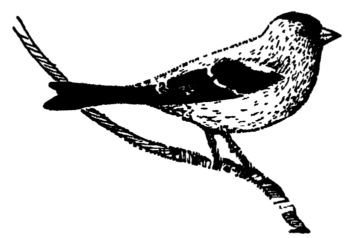
GOLD-AMALGAM. A mineral alloy of gold and mercury, occurs as small grains or lumps. Color, white to yellow with metallic luster. (R.M.F.)

GOLDCREST. Aves, Passeriformes. A European **kinglet.** (A.W.L.)

GOLDEN-EYE. 1. Insecta, Neuroptera. The lacewing, adult of the **aphis-lion.** These insects are small and delicate, with large many-veined wings of yellowish- or green color and shining eyes. They have a disagreeable odor. 2. Aves, Anseriformes. A North American **duck.** *Glaucionetta.* (A.W.L.)

GOLDENSEAL. Buttercup Family.

GOLDFINCH. Aves, Passeriformes. **Finches** of several species. The American goldfinches, *Astragalinus tristis,* are predominantly yellow in the male sex and



Goldfinch. *Astragalinus tristis.* Bright yellow, with top of head, wings, and tail black. Two white bands on wings. Female duller. Male also much duller in winter. Length, five inches.

mostly olive in the female, while the European species is more brilliantly colored, with a red face. The latter species has been introduced into the United States but is apparently not established. (A.W.L.)

GOLDFISH. Pisces, Teleostei. A species, *Carassius auratus,* related to the carp, often bright reddish-golden in captivity. It is a native of Europe and Asia and is now established in some of the lakes and streams of the eastern half of the United States. As an aquarium fish it is available in many varieties of different form. (A.W.L.)

GOLGI APPARATUS. Cell.

GOMPHOTHERIUM. Fossil Mammals

GONAD. An organ in which sexual reproductive cells (**gametes**) are produced. In some of the simpler animals, gonads develop as temporary organs during the breeding season and in more complex forms they are permanent. They are ectodermal in the fresh-water polyps (*Hydra*), endodermal in the jellyfishes, and mesodermal in the higher forms. The gonads which produce male germ cells are called testes and those which produce egg cells are ovaries. In some snails the gonad produces both kinds of cells and is called an ovotestis. (A.W.L.)

GONANGIUM. A term applied both to the reproductive members of hydroid colonies and to the sheath which envelops them. Usually the reproductive **polyp** is called a blastostyle and the sheath a gonotheca. (A.W.L.)

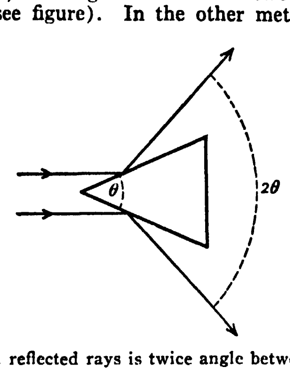
GONAPOPHYSIS. Appendages of the insect **abdomen** which serve as accessory organs of reproduction. Copulatory organs of the male and egg-laying organs of the female. They are probably derived from jointed appendages. (A.W.L.)

GONDWANA LAND. Permian.

GONIATITE. Invertebrate Paleontology.

GONIOMETER. An instrument for measuring the angles between the reflecting surfaces of a crystal or a prism. Parallel rays from a collimator, impinging upon the polished surfaces, are reflected in different directions.

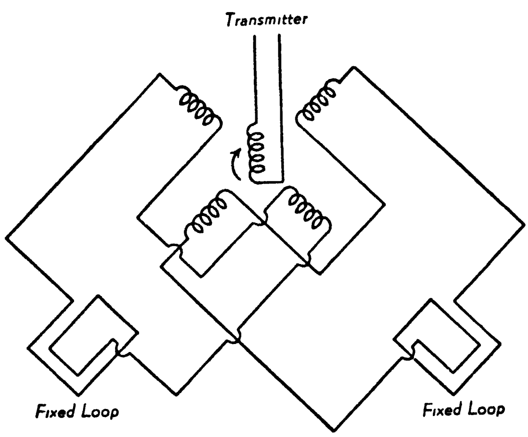
Two methods may be used. In one the crystal or prism is held stationary and the angle between the reflected beams from the two faces, received in succession by a telescope moving around a graduated circle, is measured on the circle; the angle between the two faces is then ½ of this (see figure). In the other method, the tele-



Angle between reflected rays is twice angle between prism faces.

scope is clamped in some convenient position and the crystal or prism is rotated so that first one and then the other face reflects light into it; the angle between the faces is the supplement of the angle through which the prism mounting is turned. An ordinary spectrometer may be used for the purpose (see **Spectroscope**). An instrument similar in geometrical principle, but employing **x-rays** instead of light and an ionization chamber instead of a telescope, is used for measuring angles between the atomic planes within crystals.

Sometimes in the use of a loop antenna for directional purposes (see **Directional Antenna**) it is inconvenient or impossible to rotate the loop. This is especially true for transmitting loops where the size becomes appreciable in order to improve the radiation efficiency. To overcome this difficulty the goniometer is used. As shown in the figure, the instrument consists of crossed sta-



Goniometer.

tionary coils feeding fixed, crossed (90°) loops with the coupling to the moving coil proportional to the cosine of the angle of rotation. The movable coil is fed from the transmitter. The amount of energy transferred from the rotating coil to the fixed coils and hence to their antennae is determined by the position of the moving coil with respect to the others. The effect as far as the resultant field pattern of the antennae is concerned is exactly the same as if a single-loop antenna had been physically rotated. An extension of this principle is used with two sets of crossed loops in many radio range systems. A further advantage of the goniometer is that the antennae may be connected through a transmission line and thus it is not necessary that the operating position be near the antenna. It may be used equally well for reception. (L.D.W., L.R.Q.)

GONOPOD. Modified jointed appendages of **centipedes**, used as accessory organs of reproduction. (A.W.L.)

GONORRHEA. An acute or chronic infectious disease, involving primarily the passages of the external genital organs and the **urethra.** Frequently, there is secondary involvement of more distant body structures, causing systemic manifestations.

Gonorrhea is the most common venereal disease. It is rarely a killing disease but due to its late complications, its obstinacy and its ability to cause permanent damage, it ranks next to syphilis as one of the most serious of infectious diseases.

Gonorrhea is as old as the human race. References to it are found in old Egyptian, Chinese and East Indian writings. It is mentioned in the Old Testament. Gonorrhea was not differentiated from syphilis until the early 19th century. Albert Neisser discovered the gonococcus as the causative organism in 1879. (See **Bacteria.**)

There are no figures as to the incidence of gonorrhea in the human race, as many infected never consult a physician and the disease is not ordinarily reported. At least 20% of those having gonorrhea suffer from complications.

The adult form of the disease results usually from sexual intercourse with an infected partner. Gonorrhea of the new-born results from infection of the eye at birth during passage through the infected vagina. It has always been the great cause of permanent blindness in the new-born, and for this reason prophylactic antiseptics are applied to the eyes of every new-born child. Accidental infection can occur through contaminated articles such as towels, etc., but is not especially common, although gonorrheal infection of the eyes in adults has occurred in this manner.

The primary infection involves the **mucous membrane** of the urethra in both male and female, and the mucous membrane of the **vagina** and cervix in the female. This lasts in its acute form for a relatively short time. It is marked by local swelling, burning, and pain of the regions involved. Urination is painful and frequent. There is a copious discharge of pus.

The serious complications of gonorrhea develop from direct spread of infection upward from the primarily infected local parts. In the male the upper portions of the urethra, the prostate, seminal vesicles and the testicles are commonly involved in the acute form. The infection in the prostate later becomes chronic and low-grade activity may remain for a considerable time. Later it may flare up and become acute. In the female, infection of the cervix, various local glands, uterus and ovary and fallopian tubes (salpingitis) are common. General peritonitis is a frequent complication of acute gonorrheal salpingitis. When the salpingitis becomes chronic operative procedures may be necessary. Salpingitis is frequently the cause of sterility.

Gonorrhea is also a systemic disease in some instances, the organism being carried to distant organs by the blood stream. Gonorrheal **septicemia** is rare and has a high mortality. Gonorrheal infection of the **heart** lining and valves (endocarditis) usually results fatally.

Gonorrheal arthritis is the most common complication, and may be a severe crippling disease. It sometimes appears long after the local disease seems to have been cured. Any or several joints may be involved. Fever is usually present with other constitutional symptoms. Pain is very acute. In a similar manner, tendon sheathes, muscles and bones may be involved. Neuritis and various neuralgia occur.

The treatment of gonorrhea involves local treatment of the primary disease and medical and surgical treatment for the various sequelae or complications. **Sulfonamides** are effective in a large per cent of cases.

Those organisms which are resistant to sulfonamides respond well to **penicillin**. (R.S.M.)

GONOSOME. The medusoid (see **Medusa**) of a hydrozoan (see **Hydrozoa**). This is the sexual stage in the alternation of sexual and asexual generations of these animals. (A.W.L.)

GONOTHECA. Gonangium.

GONOZOOID. 1. The attached medusoid (see **Medusa**) such as is borne by the **blastostyle** in some hydrozoan (see **Hydrozoa**) colonies. 2. Sexual individuals in the **salpian** colony. (A.W.L.)

GOOSANDER. Aves, Anseriformes. A merganser (**duck**) of the northern Hemisphere. *Mergus merganser.* (A.W.L.)

GOOSE. Aves, Anseriformes. Large swimming birds (**Aves**) with webbed feet and thick, strong beaks. They live chiefly on vegetation. Geese are found on all continents. They are strong fliers and some species migrate from their nesting grounds in the north to the southern hemisphere. Among the several North American species the Canada goose, *Branta canadensis,* is sometimes called brant and a related species is the black brant, *B. nigricans.*

Geese are excellent game birds and good food. The domestic goose is also valuable for its smaller feathers and down, which are preferred for filling pillows and cushions. (See **Die Casting.**) (A.W.L.)

GOOSEBERRY. Berry.

GOOSEBERRY STONE OR GROSSULARITE. Garnet.

GOPHER. Mammalia, Rodentia. 1. The pocket gophers. Stout-bodied burrowing animals of several species, found throughout the United States. They have fur-lined cheek pouches opening at the sides of the mouth. 2. Slender burrowing species of the central and western states, also called ground squirrels. The suslik or sisel is a European species.

Gophers are injurious to crops. The pocket gophers eat roots and the ground squirrels are more injurious to grain. In the prairie regions they are sometimes so abundant that they have to be destroyed by shooting or poison. (A.W.L.)

GORAL. Mammalia, Artiodactyla. *Urotragus.* Animals of several species related to the **goats**. They are slender and beardless and have small curved horns. They are distributed from the Himalayas to northern China. (A.W.L.)

GORDIACEA. Nematomorpha.

GORDIOIDEA. Nematomorpha.

GORILLA. Mammalia, Primates. The largest of the man-like **apes**. The gorillas are terrestrial animals with an enormous trunk, short bent legs, and long powerful arms. In walking they rest partly on the backs of the bent fingers. According to Akeley's observations they are poor climbers. The head of the gorilla is distinguished by the strong jaws and large teeth, the heavy ridges over the eye sockets, and the small ears. There are two species, the common gorilla, *Gorilla gorilla* and the mountain gorilla *G. beringei.*

Gorillas live in the forests of Africa and our knowledge of them has come mostly from field observations. They are apparently less intelligent than the chimpanzee.

Specimens formerly brought into captivity proved to be delicate and soon died. This difficulty has evidently been mastered by careful attention to diet and by protecting them from the respiratory diseases of man, to which they are very susceptible. The London Zoo, prior to the second World War, had a magnificent pair, Mok and Moina, which had been reared from infancy in captivity. Fine examples are owned also by various zoos in our own country.

The male gorilla was long regarded as a creature of the utmost ferocity. Since he may reach a height of more than 5′ and a weight of 400 lbs. he would, indeed, be a formidable opponent, but Akeley reported the gorillas of his experience to be very shy and difficult to approach so the older idea must be abandoned. (A.W.L.)

GOSSAN. This term is applied to the decomposed upper parts of mineral veins and ore deposits. It usually consists chiefly of hydrated **iron oxide** resulting from the weathering of **pyrite, chalcopyrite,** etc. Gossans have been important sources for the release of the relatively insoluble precious metals and gems which are washed away to form **placer** deposits. Many valuable gold ore bodies have been traced to their source by means of their derived placers. Also **secondarily enriched** sulfide ores of copper have been discovered beneath gossans which were originally prospected for the more precious metals. (R.M.F.)

GOUGE. Used by miners to designate soft or claylike material between the sides of a mineral **vein** or **ore** deposit and the wall rock; also (structural geology), a layer of finely comminuted material between the walls of a **fault**. (See **Lathe, Woodworking.**) (R.M.F.)

GOUJON. Pisces, Teleostei. A large **catfish,** *Opladelus olivaris,* common in the larger streams of the Mississippi basin. Also called the mud cat. It sometimes attains a weight of 100 lbs. (A.W.L.)

GOURAMI. Pisces, Teleostei. *Osphromenus.* Brightly colored fishes (**Pisces**) of the fresh waters of the Old World tropics. The pelvic fins bear a long slender filament, apparently sensory. One species is valued as food and several small species are kept in aquaria. (A.W.L.)

GOURD FAMILY. Cucurbitaceae. A small family, largely restricted to tropical or warm climates, with representatives in both the Old and the New Worlds. Most of its 650 species are climbing or trailing herbaceous plants which grow very rapidly. They are mostly annuals. The stems are hollow and in most species abundantly supplied with stiff bristly hairs. The large leaves are borne alternately on the stem, have a distinct, often long, **petiole,** and show a variety of shapes. The **tendrils,** which are a conspicuous feature of many members of this family, appear in the **axils** of the leaves and are interpreted as stems modified greatly. They are very sensitive organs, responding to the lightest touch of any solid substance, and often show a change in the direction of twining in the middle of a single tendril. In many species the nutating or circling movement of the tendril is very rapid. The flowers are axillary, either borne singly or in various types of **inflorescence,** and are usually yellow or white. The plants are either **monoecious** or **dioecious.** The **calyx** is adnate to the inferior **ovary,** the **corolla** is 5-lobed and inserted on the calyx. The **stamens** are typically five, but show great variation in number through fusions. The inferior ovary is 1- to 3-celled and usually contains many flattened seeds. The latter lack **endosperm.** The fruit is a variety of berry called a **pepo,** differing from a berry in that the receptacle enters into the formation of the rind or outer wall. The germination of the seeds of the commonly grown members of this family exhibits one rather striking peculiarity. When the arched **hypocotyl** emerges from the seedcoats a small peg forms on its lower end. This peg prevents the seedcoats from sticking to the **cotyledons,** which

are withdrawn and carried into the air by the straightening of the arched hypocotyl. Many members of this family are grown in cultivation, as for example squashes, pumpkins, and cucumbers, and certain ornamental species, like *Echinocystis, Momordica,* and some of the gourds.

Cucurbita, pumpkins and squashes. These are rather coarse annual vines having very rough bristly stems, large, long-stalked leaves and axillary (**axil**) flowers of two kinds. The staminate (**stamen**) flowers have long stalks while the pistillate flower stalks, or **peduncles,** are short. Staminate flowers have a rudimentary **ovary** while pistillate flowers have three staminodia, or vestigial stamens; in both kinds of flowers the 5-lobed yellow **corolla** is conspicuous. **Insect-pollination** is usual. It is probable that these plants are native to tropical America, where they have been long cultivated. Cultivation is now widespread in both the New World and the Old.

Pumpkins, *Cucurbita Pepo,* are of many varieties, sizes and shapes. Included here are the Field Pumpkin, Sugar Pumpkin, Pie Pumpkin and Mammoth Pumpkin, Fordhook, Scallop (Petty-pans), Crookneck Squashes, and Marrow Squashes. In this group the stems are prickly as a rule, and more or less 5-angled.

Squashes, *Cucurbita maxima,* are plants having cylindrical stems which are hairy rather than bristly. Here are found Hubbard squashes, turban squashes and mammoth squashes, the latter often of immense size and frequent occurrence, sometimes weighing over 100 lbs. *Cucurbita moschata* includes cushaw and cheese types of squashes.

Cucumis, Muskmelons, Cantaloupes and Cucumbers. The plants in this genus are considered to be natives of tropical Asia and Africa and the East Indian Islands, where they have been in cultivation for many centuries. In these plants the tendrils are unbranched, the staminate flowers are borne in small clusters in the axils of the leaves, while the pistillate flowers are solitary. Many more staminate flowers are formed than pistillate, to insure successful pollination, which is almost entirely by insects.

Cucumis Melo includes melons of various kinds, among them muskmelons and cantaloupes. Many varieties bear inedible fruits, some of which may be used in making preserves. Few of these are cultivated in American gardens. The fruits have a warted or ribbed skin, but never hairy or spiny. They are probably native to southern Asia.

Cucumis sativus is the cucumber. This is a native of the East Indies. There, and in Asia, cucumbers have been cultivated since earliest times. Many varieties have been developed. Certain varieties, grown under glass, are often seedless. Others are largely grown for pickling. The best pickling fruits are grown in regions having a cool climate. For pickling, the fruits are picked while still young and small. They are first salted in brine, after which they are bottled in vinegar, often with the addition of various spices or other flavorings, such as dill, or mustard, or peppers.

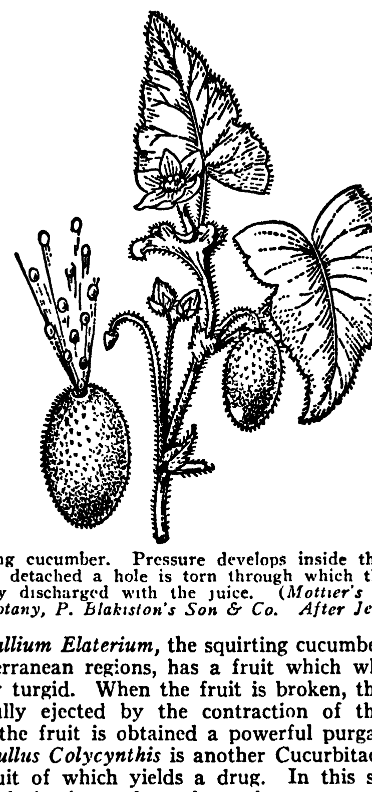
Gherkins, *Cucumis Anguria,* are native to the West Indies. Small cucumbers are also frequently called gherkins.

Citrullus. Watermelons, Citron and Colocynth. These are natives of Asia, Africa and southern Europe. They are coarse trailing vines with branched tendrils and lobed leaves.

Citrullus vulgaris includes the watermelon and citron as varieties. It is native to Africa, where it has been cultivated since the time of Egyptian supremacy. Watermelons are grown for the juicy tender flesh. In contrast to them, the flesh of the citron is firm and inedible when raw. It is grown largely for preserving or for pickling. Preserved citron is used in cakes and in the making of certain kinds of bread. Because the juice of the citron is rich in pectin, it is much used in making jellies, especially with fruits naturally lacking in pectin and hence not capable of "jelling." Another kind of citron is made from the fruit of **Citrus media.**

Many members of this family are grown as ornamentals or for their curious and sometimes useful fruits. Many such are classed as gourds. One of these, *Lagenaria vulgaris,* a native of the Old World tropics, is known as the calabash gourd or bottle gourd, from the shape of its fruit. Excellent flasks are made from the woody pericarp.

Luffa cylindrica, the "bath sponge," is frequently seen in gardens. The **vascular** tissues of the **pericarp** form an intricate net which is sometimes used as a sponge. Many species of *Luffa* have edible fruits. Mostly they are natives of the Old World. Another gourd, a native of tropical America, is *Sechium edule,* grown for its edible fruit. Many other species of guords have curiously ornamental fruits.



Squirting cucumber. Pressure develops inside the fruit, and as it is detached a hole is torn through which the seeds are violently discharged with the juice. (*Mottier's Textbook of Botany, P. Blakiston's Son & Co. After Jenkins.*)

Ecballium Elaterium, the squirting cucumber, found in Mediterranean regions, has a fruit which when mature is very turgid. When the fruit is broken, the seeds are forcefully ejected by the contraction of the pericarp. From the fruit is obtained a powerful purgative.

Citrullus Colycynthis is another Cucurbitaceous plant, the fruit of which yields a drug. In this species pulp of the fruit gives colocynth, used as a general tonic, an insecticide, a fungicide, a cathartic and as a treatment for certain forms of dropsy.

Echinocystis lobata, a native American plant, is frequently grown for ornament, and as a vine to cover unsightly places quickly. Its small white flowers are pleasantly fragrant. The staminate flowers are borne in long-stalked many-flowered inflorescences, while the pistillate are borne singly and are very short-stalked. The tendrils of this plant are especially sensitive to touch and move very rapidly. (R.M.W.)

GOUT. An hereditary constitutional disease characterized by recurrent attacks of acute **arthritis.** 95% of cases occur in males, and the disease usually comes on in middle life. Its cause is unknown, but a fundamental defect in **uric-acid metabolism** is involved. There is some difficulty in the disposal of uric acid. The blood level is high, but excretion by the kidneys is diminished. There is a popular conception that gout is more prevalent in men whose occupations are conducive to overindulgence in food and drink. This is not

borne out by available statistics, nor is the idea that dietary and alcoholic excesses precipitate attacks in gouty individuals.

The onset of acute gout is dramatic. A healthy-appearing middle-aged man experiences sudden, severe pain usually in the metatarsal-phalangeal joint of the great toe. Within a few hours the affected joint is red, swollen and exquisitely tender. The pain is often excruciating, especially at night. Other joints—particularly in the foot—may be involved. During the acute attack, the blood uric-acid content is high. The attack subsides spontaneously usually within 10 days, with complete restoration of normal joint function. After the acute episode is over, the patient remains well until the disease recurs. The recurrences may be scattered over a period of years, and then cease altogether. In some instances the attacks recur frequently and persist for longer and longer periods. In these cases of chronic gout and "gouty arthritis" degenerative changes occur in the joints, demonstrated by x-ray as punched-out areas near the joint surfaces. The large as well as the small joints may be affected.

The manifestations of gout are dependent upon the **pathology** which is the deposition of sodium urate in various tissues. The characteristic joint signs are the result of such deposition in the joints, surrounded by an **inflammation** and a foreign body tissue reaction. When the urates are present in the subcutaneous tissues as small nodules, they are called tophi. Tophi occur in 50% of patients with gout; they are seen commonly on the ears, or over the affected joints. They are pathognomonic of the disease.

Treatment with colchicine, an **alkaloid** obtained from the seeds of the autumn crocus, is specific during the acute attack. It relieves the pain and results in rapid improvement of the joints. There is no way of preventing the recurrence of gout, although an attack can be aborted by colchicine taken immediately at the onset of symptoms. The orthodox diet for gout is low in fat and low in **purines**, the latter being the chief source of uric acid. The modern therapist has discarded this diet which is poorly balanced and deficient in the necessary foods; but it is suggested that patients avoid certain foods such as anchovies, sardines, sweetbreads, liver, kidney and brains, which are exceedingly high in purine content. (D.M.H.)

GOVERNOR. Ordinary governing consists of varying the power of a prime mover in accordance with the demands made upon it by the power user. By governor is generally understood the mechanical governor, used to effect a change of throttle position, spark advance, etc. The **centrifugal** force of rotating masses is the most common principle underlying governors. Fluid pressure produced by fans or centrifugal pumps, the rotors of which revolve with the prime mover shaft, have also been used, but greater dependence is laid upon the principle of rotating masses. A governor of this type is diagrammed in Fig. 1. The rotating fork R carries in its ends the pivots upon which are mounted the weights MM. By means of the bell-crank linkage and the sliding yoke S, the weight W tends to keep the flyballs in equilibrium in the position shown under the influence of the mass of the weight, transmitted through the connecting links, and the centrifugal force acting at the center of the gravity of the governor weight. Considering that the rotative speed of the governor is ω, the magnitude of this centrifugal force in weight units is:

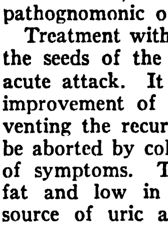


Fig. 1.
Fly-ball governor.

$$\frac{Wr\omega^2}{g}.$$

Heavier, slower speed governors are constructed with the heavier masses arranged as shown in Fig. 2, this type being known as the pendulum governor. In general, the higher the rotative speed of the prime mover being governed, the lighter will the governor weights be.

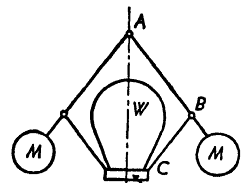

Fig. 2.
Pendulum governor.

Governor action on **internal combustion engines** for the purpose of regulating the speed to some normal value is undertaken in a number of ways. For example, the governor may hold the exhaust valve open, preventing any power stroke from being accomplished, or it may interrupt the ignition circuit, causing explosions to be missed by failure to ignite. Or the passage supplying the inflammable fuel air mixture may be throttled mechanically by a valve to vary the amount of fuel with which the cylinder is charged. In **Diesel engines,** governing is accomplished by varying the amount of oil pumped into a cylinder during that portion of the power stroke given over to the combustion of a fuel. This is done by a governor which either regulates the stroke of the fuel oil pump, or operates a variable by-pass in the discharge from the fuel oil pump. The steam engine may be governed with mass governors of two types, depending on the particular system of governing employed. The smaller, cheaper engines are governed by altering the throttle pressure through imposing an artificial pressure drop created by a governor valve between the boiler and the cylinder. This is known as a throttling governor, and is simplest, but least efficient. Governing of a **steam engine** consists of varying the amount of steam admitted to the cylinder per stroke. As just indicated, this can be done by throttling the steam pressure entering, but it can be accomplished, still allowing full pressure steam to enter, by varying the portion of the stroke during which the admission valve remains open. This is governing by changing the point of cut-off, and is known as cut-off governing. It is more efficient, but more complicated than the throttled governing. A throttling governor may be simply a flyball type, as already described, arranged so that the motion of the sleeve at a can be transmitted through a forked lever to the stem of the governor valve in the steam line. The automatic cut-off is usually built into the flywheel. It is a weight on the end of an arm which is pivoted to one of the flywheel spokes. Any motion of this arm in the direction of the centrifugal pull is opposed by a leaf or coil spring built into the governor. A mechanical link connects the governor with the eccentric, which drives the steam valve. Motion of the governor under varying centrifugal forces set up by variable power alters the position of the eccentric driving the valves, and thus alters the timing of the event of admission of steam to the cylinder. It can do this, for the various events of the steam engine cycle are under the control of the slide valve.

Governing of **steam turbines** is accomplished by three methods, viz.: (1) throttling at inlet, (2) varying number of inlet nozzles in action, (3) varying duration of full pressure puffs (blasts), of which there are several per second. In addition, some turbines are provided with hand-operated by-pass valves which, by admitting high-pressure steam to low-pressure stages, enable the turbine to carry more overload, though, of course, at reduced economy.

The basic actuation of governors will usually be found to employ a change brought about by change of centrifugal force during change of speed, the latter brought about by increasing or decreasing load. Usually the centrifugal force is opposed, mechanically, by governor springs which give the turbine a drooping speed characteristic. A single turbo-alternator not parallel with

any other, and not expected to be paralleled with another, may have this curve as flat as is consistent with governor hunting—a fault induced by an oversensitive governor. The unit would operate back and forth over its range of load from $P = O$ to $P =$ full load with a speed regulation of $(s_1 - s_2)/s_2$. The speed regulation should, in no case, exceed 4%. But if the alternators are to be paralleled, their characteristics should have considerable droop, as too flat a characteristic would exaggerate the effect of slight variations in the slopes and make apportionment of the load a difficult matter. Shifting of tension on governor springs (usually done by remote control) has the effect of shifting the speed-load characteristic nearly parallel to itself.

To permit speed adjustment, the speed of a turbine at no load should be adjustable within 5% above or below the rated no-load speed. Within this range the emergency governor should be inoperative. Furthermore, the governing characteristic of a turbine should be such as to hold the speed rise upon instantaneous drop of full load within the operating limit of the emergency overspeed trip.

The gates of the **hydraulic turbine** require an operating force for their movement that is far greater than in the steam turbine, so the mechanism of a hydraulic turbine governor does not bear any resemblance to the delicate parts of the steam-driven machine. Indeed, the force is so large that the hydraulic governors are rated on the basis of the foot-pounds of energy they will produce in completing an operating stroke. A 30,000-foot-pound capacity is a small governor. Large ones may develop as much as 200,000 foot-pounds. Naturally, the force developed by sensitive flyballs operated by centrifugal force can be used only to control a relay which, in turn, will control the actual gate-shifting mechanism. An oil pressure governor consists of a governor proper and an oil-supply system. An oil pump, a pressure storage tank, a sump into which released oil can be drained and into which the suction of the pump dips, and suitable strainers to keep the oil clean, are the principal elements of the oil-supply system. The governor consists of the flyballs, the control valve, the servomotor, and such accessories as overspeed trips, and load-limit blocks.

The operation of a governor can be understood by reference to Fig. 3, which is a simplified diagram of the governor mechanism. The servomotor piston rod is the operating rod of the turbine gate-shifting ring. Oil is admitted to and drained from the servomotor by the control valve. This control valve is connected to the governing flyballs, and also indirectly to the servomotor rod. The operation is as follows: The change in speed of the turbine resulting from change of load is communicated to the governor through the drive belt. The flyballs seek a new position of equilibrium and move the control valve from closed position. Oil pressure is then admitted to the servomotor piston and it completes the motion required to adjust the gates to the new operating position. While completing this motion, the servomotor, through the medium of the bell-crank and connected rod, closes the control valve. Some large governors have a pilot valve to control the main control valve. Quick governor action is secured through using as large control valve lifts and oil passages as possible, and using heavy oil pressure. The natural tendency is then to cause the servomotor to override its correct position and leave the gates too far open or closed; consequently, there must be another movement of the whole system in search of the equilibrium point. Resonant conditions may be set up and a steady speed impossible to maintain. Stability of the system is unsatisfactory if the governors are too sensitive, yet there is need for close regulation so that the frequency will not suffer. Ordinary governors will complete a closing stroke, upon sudden release from full load, in from 2 sec. to 5 sec. (F.T.M.)

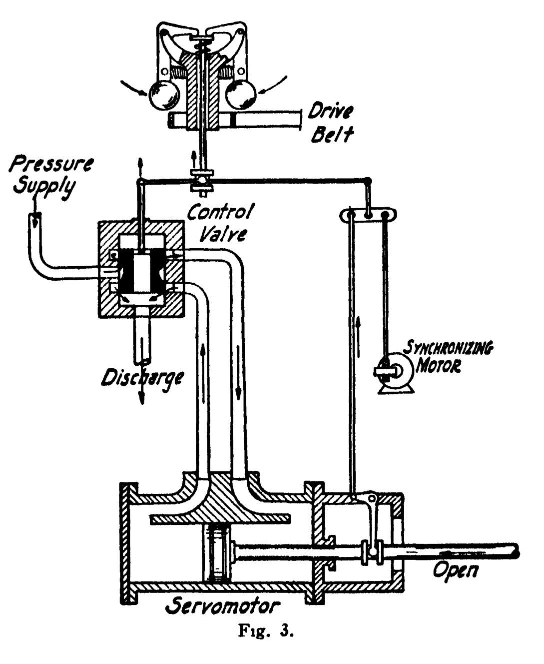

Fig. 3.

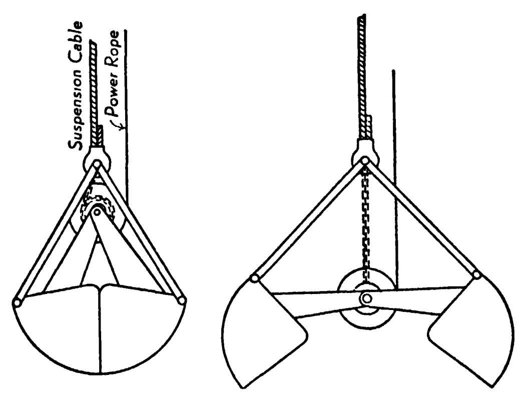
GRAB BUCKET. A grab bucket is an apparatus which is able to pick up a load of a bulk material by "biting" into the surface of the material. The particular usefulness of the grab bucket is that it may be lowered from the end of a **boom** onto the surface of the material to be moved, where it is operated to bite into this material, picking up a load, which can then be raised and deposited where wanted. The figure shows a grab bucket in open and closed positions. The procedure by which this bucket is caused to close upon a load of material is based on the differential action of a two-step drum. A rope, to which power may be applied by winding it around a drum, passes to the bucket and has its end wrapped around the larger drum of the bucket. After power is applied to this rope, it unwraps from the drum on the bucket, turning that drum and wrapping the chain on the smaller diameter portion. The added leverage thus attained is sufficient to enable the drum to wind itself up on the chain, thus closing the bucket. The axis of the drum is pivoted to the center arms of the bucket. The digging power of a grab bucket of this kind is a function of the weight of the bucket, the sharpness of its cutting edges, the power applied to the operating rope, and the resistance of the material which it digs. Buckets of this type are not suitable for hard-packed material such as earth in origi-



Grab bucket. (Hayward type.)

nal embankment, but are suited to handling grain, coal, ore, etc. They are built in capacities varying from ½ to 5 cu. yds. (F.T.M.)

GRABEN. Fault.

GRACKLE. Aves, Passeriformes. In North America, several species of birds (**Aves**) with black plumage and iridescent metallic luster, related to the orioles and blackbirds. The great-tailed grackle, *Cassidix mexicanus*, which ranges from Texas into South America, is also called the jackdaw. It should not be confused with the European jackdaw. In India the hill mynas and related species are called grackles. (A.W.L.)

GRADE. In geology, the term refers to the slope of the bed of a stream such that the water has just velocity enough to carry its load without either **erosion** or deposition. A stream valley is said to have become graded when its longitudinal profile is a smooth curve without waterfalls or rapids. The term grade is also used by students of **sedimentary rocks,** in a textural sense, to designate those grains of any sediment or sedimentary rock which are of the same size. The classification of grade-sizes is as follows:

Name of Grade		Range of Diameters
Pebbles		Greater than 10 mm.
Gravel		10 mm. to 2 mm.
Sand	Very Coarse	2 mm. to 1 mm.
	Coarse	1 mm. to 0.5 mm.
	Medium	0.5 mm. to 0.25 mm.
	Fine	0.25 mm. to 0.1 mm.
Silt		0.1 mm. to 0.01 mm.
Clay		Less than 0.01 mm.

In highway, railway or municipal engineering the **slope of a line** is called the grade. Grades are usually expressed as percentages preceded by a plus or minus sign. As an example, a +2% grade indicates a rise of 2′ in every 100′ measured horizontally in the direction of travel; a −2% grade indicates a drop of 2′ in every 100′. A curve known as a vertical curve is used to make the transition at a point of change in the grade of a highway or railroad. A second-degree **parabola** is used because it is the only curve in which the rate of change of slope is constant. The length is a function of the difference of the connected grades and the allowable rate of change of slope of the parabola per hundred feet measured horizontally. In the case of highways the length of a vertical curve, at a point where the grade changes from plus to minus (at the crest of a hill), is governed by the safe sight distance. (See **Grinding.**) (R.M.F., C.W.C.)

GRADE ROD. Earthwork.

GRADED BEDDING. A geological term denoting a type of bedding or stratification characterized by a cyclic or rhythmic deposition of coarse to fine sediments. A helpful criterion for determining the original position of the strata after they have been deformed. Graded bedding is generally supposed to be characteristic of offshore rather than in-shore deposition. (R.M.F.)

GRADIENT. In any field of atmospheric property, temperature for instance, lines of equal value can be drawn. Thus it is possible to draw isolines such as isotherms (lines of equal temperature). The gradient of the property is the maximum rate of change of the property with distance or space and is measured from the highest numerical values to the lowest.

In geology, this term is applied to streams to refer to the slope of their beds, as steep, gentle, or in terms of so many ft. per mile. (R.M.F., P.E.K.)

GRADIENT OF A SCALAR FUNCTION. The gradient of a scalar function is a type of mathematical expression which occurs frequently in mathematical physics.

Let $\phi(x, y, z)$ be a **scalar function** of position. Form the **partial derivatives** $\frac{\partial\phi}{\partial x}, \frac{\partial\phi}{\partial y}, \frac{\partial\phi}{\partial z}$; they may be regarded as the rectangular components of a **vector.** This vector is defined as the gradient of ϕ, and is denoted by grad ϕ.

In terms of the unit vectors $\hat{\mathbf{i}}, \hat{\mathbf{j}}, \hat{\mathbf{k}}$, the gradient may be represented by

$$\operatorname{grad}\phi = \hat{\mathbf{i}}\frac{\partial\phi}{\partial x} + \hat{\mathbf{j}}\frac{\partial\phi}{\partial y} + \hat{\mathbf{k}}\frac{\partial\phi}{\partial z}.$$

This may be written symbolically:

$$\operatorname{grad}\phi = \left(\hat{\mathbf{i}}\frac{\partial}{\partial x} + \hat{\mathbf{j}}\frac{\partial}{\partial y} + \hat{\mathbf{k}}\frac{\partial}{\partial z}\right)\phi.$$

If we consider the expression $\hat{\mathbf{i}}\frac{\partial}{\partial x} + \hat{\mathbf{j}}\frac{\partial}{\partial y} + \hat{\mathbf{k}}\frac{\partial}{\partial z}$ as a symbolic vector, denoted by ∇, we may write

$$\operatorname{grad}\phi = \nabla\phi.$$

This symbolic vector ∇ is often called "del," (sometimes "nabla").

Grad ϕ represents both in magnitude and direction the greatest space rate of change of the function ϕ; or in other words, it has the direction and magnitude of the maximum **directional derivative** of ϕ.

The vector grad ϕ is normal to the ("level" or "equipotential") **surfaces** $\phi(x, y, z) = c$, where c is any constant.

Let $\hat{\mathbf{r}}$ be a unit vector with **direction cosines** l, m, n, so that $\hat{\mathbf{r}} = l\hat{\mathbf{i}} + m\hat{\mathbf{j}} + n\hat{\mathbf{k}}$. The component of grad$\phi$ (or $\nabla\phi$) in the direction of $\hat{\mathbf{r}}$ is

$$\hat{\mathbf{r}}\cdot\nabla\phi = l\frac{\partial\phi}{\partial x} + m\frac{\partial\phi}{\partial y} + n\frac{\partial\phi}{\partial z},$$

a scalar, which is the directional derivative of ϕ in the direction of $\hat{\mathbf{r}}$.

If $\mathbf{r} = x\hat{\mathbf{i}} + y\hat{\mathbf{j}} + z\hat{\mathbf{k}}$ and $\nabla = \hat{\mathbf{i}}\frac{\partial}{\partial x} + \hat{\mathbf{j}}\frac{\partial}{\partial y} + \hat{\mathbf{k}}\frac{\partial}{\partial z}$, we have

$$\nabla r = \operatorname{grad} r = \hat{\mathbf{r}}, \quad \nabla\left(\frac{1}{r}\right) = \operatorname{grad}\left(\frac{1}{r}\right) = -\frac{\hat{\mathbf{r}}}{r^2},$$

$$\nabla r^n = \operatorname{grad} r^n = nr^{n-1}\hat{\mathbf{r}}.$$

If $\mathbf{r}$ is a variable vector, $\mathbf{r} = x\hat{\mathbf{i}} + y\hat{\mathbf{j}} + z\hat{\mathbf{k}}$, and if $\mathbf{a}$ is a constant vector, then

$$\operatorname{grad}(\mathbf{r}\cdot\mathbf{a}) = \nabla(\mathbf{r}\cdot\mathbf{a}) = \mathbf{a},$$

$$\mathbf{a}\cdot(\operatorname{grad} r) = (\mathbf{a}\cdot\nabla)r = \frac{\mathbf{a}\cdot\mathbf{r}}{r}.$$

If u and v are scalar functions of position, then

$$\operatorname{grad}(u + v) = \nabla(u + v) = \nabla u + \nabla v = \operatorname{grad} u + u \operatorname{grad} v,$$

$$\operatorname{grad}(uv) = \nabla(uv) = v(\nabla u) + u(\nabla v) = v \operatorname{grad} u + u \operatorname{grad} v.$$

If $\mathbf{u}$ and $\mathbf{v}$ are vector functions of position, then

$$\operatorname{grad}(\mathbf{u}\cdot\mathbf{v}) = \nabla(\mathbf{u}\cdot\mathbf{v}) = (\mathbf{u}\cdot\nabla)\mathbf{v} + (\mathbf{v}\cdot\nabla)\mathbf{u} + \mathbf{u}\times(\nabla\times\mathbf{v}) + \mathbf{v}\times(\nabla\times\mathbf{u}).$$

In **spherical coordinates** if $\hat{\mathbf{r}}$, $\hat{\boldsymbol{\theta}}$ and $\hat{\boldsymbol{\phi}}$ denote unit vectors in the direction of increasing r, θ, ϕ, we have

$$\nabla = \hat{\mathbf{r}}\frac{\partial}{\partial r} + \hat{\boldsymbol{\theta}}\frac{1}{r}\frac{\partial}{\partial\theta} + \hat{\boldsymbol{\phi}}\frac{1}{r\sin\theta}\frac{\partial}{\partial\phi}.$$

An alternative definition of the gradient is the following:

Let ϕ be a scalar function of position, let δ be a small region of space and also its volume, surrounding a point P, and let ω be the bounding closed surface of δ, and let $d\sigma$ be an element on ω; let $\hat{\mathbf{n}}$ be a unit normal to ω (outward drawn) at any point of ω. Then the gradient of ϕ at the point P may be defined by

$$\operatorname{grad}\phi = \lim_{\delta\to 0}\frac{1}{\delta}\int_\omega \hat{\mathbf{n}}\phi d\sigma.$$

(L.L.S.)

GRADIENT WIND. The wind which blows when the pressure gradient, **Coriolis Force,** and centrifugal force are balanced, and when there is no acceleration. In clockwise systems in the northern hemisphere Coriolis Force balances both centrifugal force and the pressure gradient; in the counterclockwise system, the pressure gradient balances both centrifugal force and Coriolis Force. Gradient wind velocity depends on the latitude, the pressure gradient and the radius of curvature of the isobars. (P.E.K.)

GRAFTING AND BUDDING. Grafting is the process of inserting a part of one plant into another in such manner that the two unite and the inserted piece continues to grow. The part which is inserted is called the scion, the plant into which it is inserted is the stock. Budding is a similar process in which the part inserted consists of a bud with some of the bark adjoining it.

This process is possible because of the **cambium** cells. The successful union of the two pieces is caused by the formation of callus tissue by the cambium cells. Callus tissue is composed of a mass of **parenchyma** cells which fill in or grow over wounds, thus repairing the injury. In graft unions, the cells of the **callus** tissue soon begin maturing into cells of various types, as **xylem** and **phloem** cells, while others become typical cambium cells joining the cambium layer of stock and scion. In grafting, the cambium layers of the two parts are to be brought as closely together as is possible.

There are several methods of grafting. A very common method is known as cleft grafting. In this method a small twig having several buds is removed from the plant which is selected as desirable. The lower end of this twig is cut wedge-shaped. A branch of the plant used as stock is cut off, and a vertical cut made in the end. Into this cut the prepared scion is inserted in such position that its cambium layer and that of the stock come together. To prevent drying of the tissues the entire cut surface is covered with a prepared wax. Usually several scions are inserted in a branch of the stock. When union has taken place and the scion started to grow, all but one may be cut off.

Another method is whip grafting, which is used when the stock is too small for successful cleft grafting. In whip grafting, both stock and scion are cut in a long oblique cut. In the cut surface of each a vertical cut is made. They are then fitted together so that the parts of one slide into and against those of the other, with the cambium of one in contact with that of the other. The two parts are then bound firmly together and the whole covered with wax.

In budding a small bit of bark bearing a bud is removed from the selected plant. Usually, little wood is taken with this. In the stem of the stock a T-shaped cut is made in the bark and the flaps so formed loosened. The prepared bud is inserted under the flaps, which are then pressed down over it and bound tightly in place to insure contact between the two cambium layers. Wax is used here also to prevent loss of water.

In modern horticulture, grafting is a very important practice. Many plants, for instance, do not come true when grown from seed. It becomes necessary, therefore, to propagate such desirable plants vegetatively. This may be done in two ways. One is by means of cuttings, pieces of the plant which are rooted and grown into new plants. The other method is grafting, which is now done on an immense scale. Vegetative propagation must be used also in those plants which do not bear seed, as seedless oranges and seedless grapes.

Commonly the stock used in such cases is not a mature plant but a seedling. This is often chosen for its hardiness or its resistance to diseases and pests. The seedlings are allowed to grow until their roots are well established. The graft is then inserted at the base of the stem. As soon as union has taken place and the scion started to grow, the shoot of the stock is cut off, so that all substances absorbed by the root are sent into the scion. Grafting of this sort is used in producing nursery stock for rubber plantations, as well as nearly all common fruit trees.

Successful grafting can only take place between plants of the same kind or closely related. Others fail entirely to develop any union between the two parts. In nearly all cases the nature of the scion is constant after grafting, so that one can be sure of the product which will result. Because of this it is possible to graft several different scions on a single stock. Not infrequently one sees an apple tree bearing many different kinds of apples maturing at different times of the year. Dwarf apple and pear trees are produced by budding, using quince as stock. Grafting also hastens the time of fruiting, grafted plants coming into bearing earlier than those growing from seed.

Bridge grafting is done for a very different reason. Often trees are completely girdled at the surface of the ground by rodents, especially during the winter months. Damage of this sort is fatal to the tree unless quickly corrected. Correction is done by bridge grafting. This is done by trimming the edges of the girdled region and inserting small twigs across the gap in the bark in such a way that the cambium region of the strips is in contact with that of the tree in which it is inserted. Long sloping ends greatly increase the probability of such contact. These "bridges" unite with the damaged tissues and allow movement of materials to occur. Gradually the damaged and new tissues fill in the gap, and the damage is repaired. (R.M.W.)

GRAIN. **Fruit; Wood; Abrasive.**

GRAIN SIZE. The grain or crystal size of metals is determined by microscopic examination of a suitably prepared section. (See **Metallography.**) There are two principal standards of grain size in use in this country. Both are standards of the American Society for Testing Materials.

For most non-ferrous alloys, particularly **brass and bronze** and other alloys having homogeneous grain structures with **twin bands,** a set of ten **photomicrographs** having average grain diameters ranging from 0.010 to 0.200 mm. are used for direct comparison with microstructures at a magnification of 75 times.

The A.S.T.M. standard grain size chart for steels covers about the same range of average grain diameters but the comparison is made at 100 times magnification and the grain size is expressed by numbers from 1 to 8. In general, grain sizes 1 to 3 are considered coarse, 4 to 6 intermediate, and 7 to 8 fine. The grain size of steel can also be judged from a clean fracture if the steel can be fractured without appreciable plastic deformation. This is possible with most heat-treated machine steels and tool steels, but low-carbon steels are often too tough to break with a crystalline fracture. A series of standard fractures is available for direct visual comparison, and the numbering system for these standards coincides with that of the charts used for microscopic determination of grain size.

The grain size of metals is related to many important properties. In general, fine grain size is an indication of relatively high strength, **hardness,** and toughness

while coarse grain indicates softness and **plasticity**. However, the **hardenability of steels** by heat treatment is highest for coarse grain steel. Coarse grain size is usually desirable for **creep** strength at elevated temperatures.

In the case of sheet and strip for drawing or stamping, coarse grain may give a rough surface. On the other hand, metal with too fine a grain size may lack plasticity and crack in the dies, therefore, a compromise must be reached.

The grain size of castings is generally much coarser than that of wrought products such as rod or sheet. In the case of steel castings the original coarse structure may be refined by **heat treatment**. This is not possible in the case of most non-ferrous alloys because they do not undergo a change in type of crystal structure on heating or cooling.

In the case of hot rolled or forged metals the finishing temperature has an important influence on grain size. A high finish-forging temperature, for example, will permit grain growth by recrystallization. In the case of metals finished by cold-working processes the final annealing temperature establishes the grain size. A high annealing temperature results in coarse grain size. (See **Recrystallization.**) (R.H.H.)

GRAININESS OF THE PHOTOGRAPHIC IMAGE. The term graininess is used to describe the mottled or grainy appearance of the image observed frequently in projected prints. It is due to the non-homogeneity of the silver deposit in the negative which is a direct consequence of the clumping of the silver halide grains and the scatter of light within the emulsion. Graininess is a matter of concern wherever a negative image must be greatly enlarged, as in miniature camera work and certain fields of applied photography.

For a given degree of enlargement, the graininess of the *positive* image depends upon:

1. *The Emulsion.* The graininess of an emulsion, other factors being constant, appears to increase with the average grain size and with the range of grain sizes; i.e., the size-frequency. There are other factors, such as the turbidity of the emulsion and the thickness of the coating, but these appear to be of less importance in producing the larger aggregates of silver which give rise to the degree of inhomogeneity associated with graininess. Manufacturers have succeeded in recent years in greatly reducing the graininess of emulsions and modern fine-grain emulsions represent a notable advance in this respect. Despite the great amount of attention given to fine-grain developers and processing, greater progress has been made by the manufacturers in reducing graininess through the improvement of emulsions. The first and most important step, therefore, in making fine-grain negatives is the use of a modern fine-grain film.

2. *The Density of the Image.* For a giv.n emulsion and conditions of development, the graininess increases with the density up to a maximum which varies from 0.3 to 0.5. The graininess varies, therefore, with the tones, or brightness of the image, being more pronounced in the highlights of the positive and in areas of relatively uniform brightness, such as the sky. Factors which keep negative density to the minimum necessary for good printing quality, i.e., avoidance of overexposure and development to a relatively low **gamma**—assist in maintaining a fine-grain image.

3. *The Degree of Development or Gamma.* The graininess of the negative image, other factors being constant, increases with the degree of development or gamma. The increase in graininess with the gamma is more pronounced with emulsions tending towards graininess, than with fine-grain emulsions and is more marked with negative than with positive materials, such as motion picture positive film. For the finest grain, therefore, development should be to the lowest gamma which will produce negatives of good printing quality.

4. *The Composition of the Developer.* The only true fine-grain developing agent is paraphenylenediamine, and possibly orthophenylenediamine. With all other developing agents, the differences are slight if the negative is developed to the same gamma unless a solvent of silver halide is added to the developer. Developers, such as the familiar elon-hydroquinone-borax formula, employing an excess of sodium sulfite as a solvent of silver halide, produce a slight improvment in graininess and are popular where the degree of enlargement is not great. Developers containing more active silver halide solvents, such as potassium thiocyanate, produce images of finer grain but at the expense of emulsion speed. There is no known way of reducing graininess in development which does not necessitate a sacrifice in either emulsion speed, image contrast, or both. While much has been written on the subject of fine-grain developers, the fact remains that the composition of the developer is less important in producing fine-grain images than the emulsion.

5. *Conditions in Projection.* In general, all conditions affecting the contrast of the print have a like effect on its graininess. The use of a direct (non-diffused) light in the enlarger will result in prints of greater contrast and graininess than when a diffused light source is used. Increasing the diffusion of light through the use of ground glass, or opal glass, is effective, however, only up to a certain point. The use of a contrast grade of paper will result in an increase in graininess over the softer grades. Graininess will be reduced also by the use of matt or rough-surfaced paper, by diffusion of the image, or by the use of texture screens. (C.B.N.)

GRAM. A metric unit of mass or of weight, equal to about 1/28.35 of an avoirdupois ounce. Originally the gram was defined as the mass of 1 cc. of pure water at its maximum density (4° C.). But since the actual metric standard of mass is now the **kilogram** at Sèvres, the present gram is one-thousandth of this standard; this exceeds the original value in the approximate ratio 1.000028:1. One unfamiliar with metric weights may find it helpful to remember that a silver dime weighs about 2 grams. The avoirdupois pound is about 453.6 grams. (L.D.W.)

GRAM-MOLECULAR VOLUME. Chemical Composition.

GRAM-CHARLIER SERIES. The Gram-Charlier series consist of two types, Type A and Type B. Like the **Pearson system** of curves it may be derived from the **hypergeometric probability function** and may be regarded as based on **probability.** It may be used either as an empirical **frequency distribution** to explain actual frequency distributions or it may be used as an approximation to theoretical distributions (**probability functions**).

We define Type A (using 3 terms) by

$$P_t = \phi(t) - \frac{\alpha_{3:t}}{3!}\phi^{(3)}(t) + \frac{\alpha_{4:t} - 3}{4!}\phi^{(4)}(t),$$

where P_t are the ordinates of Type A, and

$$\phi(t) = \frac{e^{\frac{-t^2}{2}}}{\sqrt{2\pi}}, \quad t = \frac{x - \bar{X}}{\sigma_x}, \quad \alpha_{3:t} = \alpha_{3:x},$$

the measure of **skewness** of the function being approxi mated by Type A,

$$\alpha_{4:t} = \alpha_{4:x},$$

$$\phi^{(3)}(t) = \frac{d^3\phi(t)}{dt^3} = (-t^3 + 3t)\phi(t),$$

$$\phi^{(4)}(t) = \frac{d^4\phi(t)}{dt^4} = (t^4 - 6t^2 + 3)\phi(t).$$

The Type A series may be continued to more terms if desired.

$$P_t = A_0\phi(t) + A_1\phi^{(1)}(t) + A_2\phi^{(2)}(t) + \cdots + A_n\phi^{(n)}(t),$$

$$\phi^{(n)}(t) = \frac{d^n\phi(t)}{dt^n}.$$

In this case the coefficient of A_n is given by

$$A_n = \frac{(-1)^n}{n!}\int_{-\infty}^{\infty} H_n(t)P_t dt,$$

where $H_n(t)$ are the **Hermite polynomials**, remembering

$$\int_{-\infty}^{\infty} t^n P_t dt = \alpha_n.$$

Tables of $\phi(t)$, and $\phi^{(n)}(t)$, n, 1 to 8 are available. To find the theoretical frequency f_t in the class whose limits are $t = t_1$ and $t = t_2$ in a frequency distribution where $\Sigma f_x = N$ we use

$$f_t = N\int_{t=t_1}^{t=t_2} P_t dt$$

$$= N\left\{\int_{t=t_1}^{t=t_2}\phi(t)dt - \frac{\alpha_3}{3!}\left[\phi^{(2)}(t_2) - \phi^{(2)}(t_1)\right] + \frac{\alpha_4 - 3}{4!}\left[\phi^{(3)}(t_2) - \phi^{(3)}(t_1)\right]\right\}.$$

The Gram-Charlier Type A may be used wherever the Pearson Type IV is indicated or whenever the frequency distribution is not too skewed. The Gram-Charlier Type A is an excellent approximation to the **Bernoulli probability function** when s in the Bernoulli distribution is rather large. The first term of the Gram-Charlier Type A is merely the **normal curve.** The Gram-Charlier distribution has been used by R. A. Fisher to approximate **Fisher's z distribution** when n_1 and n_2 are both more than 24, and in this case it is excellent. It has also been used to approximate **Student's t distribution** and the χ^2 **probability function** when the **degrees of freedom** in these distributions are more than 30.

The Type B series is defined in the case of a **discrete variate** by

$$P_x = c_0\psi(x) + c_1\Delta\psi(x) + c_2\Delta^2\psi(x) + c_3\Delta^3\psi(x) + c_4\Delta^4\psi(x),$$

where $\psi(x) = \dfrac{e^{-m}m^x}{X!}$, $m = \bar{X}$, the mean,

$$\Delta\psi(x) = \psi(x) - \psi(x-1) \text{ for } x = 0, 1, 2, \cdots \infty, \psi(-1) \equiv 0.$$

Then $c_0 = 1$, $c_1 = 0$, $c_2 = \frac{1}{2}(\mu_2 - m)$, $c_3 = -\frac{1}{3!}(\mu_3 - 3\mu_2 + 2m)$, $c_4 = \frac{1}{4!}[\mu_4 - 6\mu_3 + \mu_2(11 - 6m) + 3m(m-2)]$.

It is generally used when the frequency distribution is skewed. It should be noted that the first term of the Type B series is the **Poisson distribution.** (L.A.A.)

GRAMPUS. Mammalia, Odontoceti. A large **dolphin,** *Orcinus orca,* of very vicious habits, also known as the killer. They hunt in groups and attack even large whales. (A.W.L.)

GRANITE. This name is applied to a common and widely occurring group of deep-seated igneous rocks consisting of **orthoclase, plagioclase, quartz, hornblende, biotite, muscovite** and minor accessories such as **magnetite, garnet, zircon** and **apatite.** Rarely a **pyroxene** is present. Ordinary granite always carries a small amount of plagioclase, but when this is absent the rock is then referred to as an alkali-granite. An increasing proportion of plagioclase feldspar causes granite to pass into granodiorite. A rock consisting of equal proportions of orthoclase and plagioclase plus quartz may be considered a quartz **monzonite.** A granite containing both **muscovite** and biotite micas is called a binary granite.

The word granite comes from the Latin *granum,* a grain, in reference to the grained structure of such a crystalline rock.

Granite occurs as **stock-like masses** and as **batholiths** often associated with mountain ranges and frequently of great extent. Granite has been intruded into the crust of the earth during all geologic periods, except perhaps the most recent; much of it is of pre-Cambrian age. Granite is found extensively in Canada, New England, New York, the Appalachian region (especially the Piedmont), Wisconsin, Minnesota, South Dakota, Missouri, Oklahoma, Texas, the Rocky Mountains in general and the Pacific Coast States. There are innumerable foreign localities. (E.S.C.S.)

GRANITOID. A textural term derived from **granite** and signifying the relatively uniform and coarse-grain of **batholithic** rocks, such as granite, **syenite, anorthosite,** etc. In a typical granitoid rock each species of mineral occurs as a single generation; the **silicates** crystallizing first, and any surplus of free silica crystallizes last in the form of **quartz,** or is finally driven off with the surplus water to form quartz veins. (R.M.F.)

GRANODIORITE. Granite.

GRANULE. Cell.

GRANULITE (LEPTITE). This is a general term for a group of rocks that vary considerably in composition but for the most part seem to be derived by **metamorphic** processes from **quartz-feldspar** rocks. The classic locality for granulite is in Saxony, where there occurs a granular **gneiss** of quartz and feldspar plus such accessory minerals as **pyroxene** and **garnet,** with occasionally small quantities of **kyanite, spinel** and similar minerals. The Saxon granulites have a decided banded structure and seem to resemble **injection gneisses.** It appears reasonable to suppose that these and other granulites may have been derived from sedimentary formations severely altered by igneous processes. **Leptite** is a term used in the Scandinavian countries for fine-grained granulites that originally were rhyolitic tuffs and lavas.

Besides the Saxon and Scandinavian granulites these rocks are found in the northern highlands of Scotland, India, West Africa, and Canada. (E.S.C.S.)

GRAPE. *Vitis* sp. Vitaceae. Grapes are climbing plants, many of which have long been cultivated by man for their fruits and the various products obtained therefrom.

Climbing in grapes is made possible by tendrils, modified stems which coil tightly around any suitable support. These tendrils are usually interpreted as terminal portions of the stem which have been pushed to one side by the more rapid growth of an axillary (see **Axil**) bud. The leaves of grapes are simple, palmately lobed and alternate, with small stipules. The stems elongate rapidly and are of a coarse porous nature; the internodes of young stems are frequently hollow, the **nodes** solid. The flowers are borne in compact **panicles.** Each flower is small and inconspicuous. The **calyx** is a mere rim around the tip of the **pedicel;** the **corolla** five-parted and greenish. When the flower opens, the petals, united at their tips but free at the base, are forced away from the base of the flower and drop off. There are five stamens and a single pistil. The fruit is a 2-celled berry.

Commercial grapes are largely derived from three species, *Vitis vinifera,* the wine grape of Europe, a native of Asia, *Vitis Labrusca,* the northern fox grape of eastern North America, and *Vitis rotundifolia,* the south-

ern fox grape. Many varieties and hybrids of these exist, as well as hybrids with other wild species. In commercial vineyards, grapevines are variously pruned to increase yield and improve quality. Pruning cuts are made through the nodes, to prevent the leaving of hollow internodes in which disease might gain entrance to the plant. Propagation of the grape is mainly by means of stem cuttings, a method which has been used in Europe for centuries.

Grapes are grown mainly for raisins and for wine. Both of these products come from the fruit of *Vitis vinifera,* which is much sweeter than other cultivated grapes. For the best raisins, selected ripe fruit is carefully sun-dried, after which the stems are removed, and the product packed. More commonly, grapes for raisin-making are first dipped in weak lye, then rinsed and dried either in the sun or, if necessary, artificially. After drying, the stems and seeds are removed and the product packed, entirely by machinery.

For wine-making the grapes are crushed and the juice allowed to ferment with yeast. If a dry wine is desired, fermentation is continued until all the **sugar** of the grape is changed to **alcohol.** Using both the skins and pulp of grapes with a colored flesh gives a red wine. Using colorless grapes, or those with colorless pulp and removing the skins, gives white wine. In sweet wine-making, fermentation is stopped before all the sugar is changed to alcohol, by adding alcohol, a procedure called fortifying the wine. Distilling wine produces brandy.

In addition to these two main uses, many grapes are eaten fresh. More are crushed to prepare fresh grape-juice, which is bottled without fermenting. Grapes are sometimes grown merely for ornamental purposes. (R.M.W.)

GRAPEFRUIT. **Citrus Fruits.**

GRAPE-LEAF FOLDER. Insecta, Lepidoptera. A **moth,** *Desmia funeralis,* whose larva eats the leaves of grape vines and lives in a fold fastened with silk. It is not an important pest. Arsenical sprays used for other insects destroy it. (A.W.L.)

GRAPE-LEAF SKELETONIZER. Insecta, Lepidoptera. A **moth,** *Harrisina americana,* whose larvae, working in groups, destroy the soft tissues of the grape leaf, leaving the network of veins. Rarely an important pest, and easily destroyed by arsenical sprays. (A.W.L.)

GRAPH OF A FUNCTION. The graph of a function $y = f(x)$ is the **locus of the equation** $y = f(x)$. (L.L.S.)

GRAPHICAL STATICS. The **equilibrium of forces** is often treated graphically in such practical problems

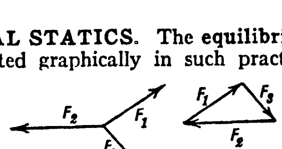


Fig. 1. Three forces in equilibrium.

as the stresses in the members of a framed structure. If three concurrent forces are in equilibrium, the three vectors drawn to a common scale to represent them may be made to form a closed triangle (Fig. 1); or if more than three, a closed polygon (Fig. 2). The principle may be extended and is much used in the calculation of the forces in a truss by means of the so-called stress diagram. A simple example is shown in Fig. 3, which represents a small roof-truss with equal loads resting on it at the joints *A, B, C, D, E,* and supported by the upward reac-

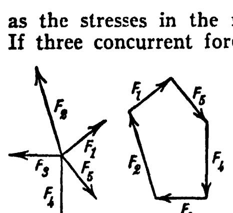

Fig. 2. Five forces in equilibrium.

tions of the walls at *A* and *E.* The several compartments of the figure are numbered, and both the external forces and the forces acting along the members

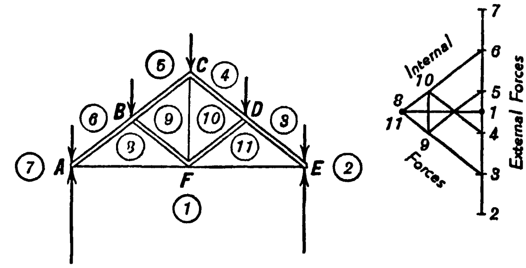

Fig. 3. Elevation of truss with corresponding stress diagram.

between these compartments are represented, both in magnitude and direction, by the lines joining the corresponding numbers in the stress diagram. For example, the compressive force in the strut *BF* is represented by the line 8–9, while the tension in the vertical rod *CF* is given by 9–10. The closed figure 5–4–10–9–5 in the stress diagram indicates the equilibrium of the forces acting at the joint *C.* This method of analysis is attributed to Maxwell (see **Statics** and **Bow's Notation.**)

In the graphical solution of some types of **trusses** it is found on reaching a particular joint that the arrangement of members is such that there are more than two unknowns. It is then necessary to replace the unknowns by a substitute system which reduces the number of unknowns at the joint to two. The substitute system consists of a single member inserted in such a way that the truss remains stable and determinate (see **Determinate Structure**). This member is called a substitute, fictitious or phantom member. When the solution reaches a joint where the stress in the members is unaffected by the substitution, the substitute arrangement is replaced by the original arrangement. The graphic procedure is reversed in direction to find the stress in the original members. (L.D.W., C.W.C.)

GRAPHIC GRANITE. A coarsely crystalline variety of granite or **pegmatite** composed almost entirely of **quartz** and **feldspar** which have intergrown in such a manner as to simulate semitic or cuneiform characters. (R.M.F.)

GRAPHIC REPRESENTATION OF EQUATIONS. An equation in two variables determines a **function** of one variable, and the **graph** of this function gives at the same time the graphic representation of the equation, which will be a **curve.**

An equation in three variables determines a function of two variables, which is represented by a **surface** in space. (L.L.S.)

GRAPHIC REPRESENTATION OF FUNCTIONS. A **function** of one **variable** $y = f(x)$ may be represented graphically by plotting as points in a plane pairs of corresponding values of the variable and the function as **rectangular coordinates** or **polar coordinates,** and drawing a smooth curve through these points. This graph of the function $y = f(x)$ is the same as the **locus of the equation** $y = f(x)$. (L.L.S.)

GRAPHIC SOLUTION OF EQUATIONS. The real **roots** of an **equation** with one unknown are represented graphically by the **abscissas** of the points where the **graph** of the equation or corresponding **function** cuts or touches the X-axis.

Sometimes the roots of an equation with one unknown can be found graphically by arranging the equation as an equality of two properly selected functions, plotting the graphs of these functions on the same diagram and

finding their intersection points. This method can be used to great advantage frequently in **quadratic** and **cubic equations** and certain **transcendental equations.** (L.L.S.)

GRAPHITE (PLUMBAGO). Graphite is an allotropic form of **carbon.** It is produced artificially by heating **coal** or, more commonly, **coke** in the **electric** furnace. Graphite is also found in nature as a mineral. It crystallizes in the **hexagonal** system, often in the form of scales or plates, or in large foliated masses. It has a perfect **basal cleavage**; is soft; hardness 1–2, and feels greasy to the touch; specific gravity 2–2.2; luster metallic; color black to steel gray; **streak** black; opaque. Graphite is a rather widely distributed mineral and is found in a variety of rocks. It occurs in marbles, gneisses or schists; granites and other igneous rocks often carry graphite. It has been noted in pegmatites. It is likely that graphite has been formed by different processes, by magmatic separation of the graphite as an original constituent or as the result of assimilation of carbonaceous rocks, by pneumatolytic action, or by the metamorphism of sedimentary rocks that contained original carbonaceous matter. Well-known localities are in Siberia, on the Island of Ceylon, which is the chief producing district at present; England, Madagascar, Mexico, and Canada. In the United States it is found in the Adirondack region of New York State, in Massachusetts, Rhode Island, Pennsylvania, Alabama, New Mexico, and Montana. Graphite is important as material for crucibles, lubricants, paints, pencil "leads," etc. Graphite has been called black lead, but there is no connection between lead and graphite. The German mineralogist, A. G Werner, devised the name graphite from the Greek meaning *to write,* with reference to its use in pencils.

In the metallurgy of steel and iron, graphite is an important constituent of **pig iron, cast iron,** and **malleable cast iron,** and of certain special die steels.

Graphite contributes to the wear-resistance of irons and steels by its lubricating action. When present in cast iron in excessive amounts or in the form of large interlocking flakes or films it greatly reduces the tensile strength. (E.S.C.S., R.H.H.)

GRAPHS. The graph of an equation is the **locus** (or totality) of all points whose **coordinates** satisfy the equation. The graph of a **function** of one variable is the locus of all points whose coordinates are the values of the variable and of the function. (L.L.S.)

GRAPHS OF TRIGONOMETRIC FUNCTIONS. **Trigonometric Curves.**

GRAPNEL. Broadly speaking, a grapnel is any device used to grapple with an object which is obscured to view, such as a submarine object. Grapnels generally take the form of grapnel hooks, which have several flukes, so that they will be certain to hook into any object with which they may come in contact. (F.T.M.)

GRAPTOLITES. **Invertebrate Paleontology.**

GRASS FAMILY. Gramineae. Of all plant families the Grass Family is the most important economically. Including many thousand species, the family is one of the largest in the plant kingdom. Members of the grass family were probably the first plants to be cultivated by the human race. Grasses are found everywhere plants can grow, from the coldest polar regions to the tropics, from the coasts to the upper limits of vegetation on mountains.

Most grasses are herbaceous plants of low stature. A few, notably the **Bamboos,** become woody plants of great height, and a small number are of clambering or trailing habit. The cereals, and many other grasses, are annuals, completing their growth in a single growing season; others are perennial plants. Some of the former are winter annuals, plants which start growth in one season, remain dormant over winter, and complete growth and fruit in the following season. Winter wheat is an example.

The root system of a grass plant is made up entirely of fine fibrous roots, which enlarge but little, remaining about the same diameter throughout their length. These roots are mainly **adventitious,** arising from the lowermost nodes of the stem. The roots of many grasses penetrate deep into the ground, so reaching supplies of moisture which enable the plant to live in dry regions where surface moisture is rare.

The stems of grasses, frequently called culms, are cylindrical and in most genera hollow except in the region of the nodes, where solid plugs occur. When young the stem is solid, but as growth continues the central portion fails to keep pace with the outer and gradually becomes hollow. Corn is an exception, the stems being permanently solid in that grass. In most grasses the stem grows erect, but frequently falls over during the growing season, due to climatic disturbances or to lack of suitable nutrient sources to give it strength. Such fallen stems do not remain so but gradually become erect through renewed growth in the nodal regions of the stem. The cause of such a growth is not definitely known. The upward bend, negative geotropism, may be produced by **auxin** which accumulates in the lower half of the node and stimulates overgrowth in that region. In many species of grass the lowermost nodes normally give rise to a number of buds which develop into lateral branches which give the plant a tufted appearance. Such basal branches are known as tillers, stools, and the habit of forming them as tillering or stooling. It is a valuable property of many cereals, and undesirable in others, for example, corn, where it causes a considerable reduction in yield. In a few grasses, the basal portion of the stem becomes enlarged by an accumulation of reserve food material, the plant being known as a bulbous grass. Many grasses develop underground stems known as rhizomes, from the nodes of which erect branch stems may develop, as well as numerous adventitious roots. These rhizomes may be short and the erect branches numerous, producing a tufted grass, or they may be long and wide spreading, as in the case of witch grass, *Agropyron repens,* also called quack or witch grass. Due to the readiness with which the joints of the rhizomes of the latter grass strike root and develop to erect stems, it becomes a pestiferous weed. Eradication by chopping up the rhizome with a hoe only serves to increase its numbers, each joint or node producing a new plant. Only by preventing the green tops from forming can the plant be controlled and eliminated, or of course by complete removal of the entire underground rhizome. In some grasses the stem grows out over the surface of the ground, being then known as a stolon. Rhizomes and stolons form an effective way of propagating the plant, and in many species insure considerable dispersal over a limited area.

The leaves of grasses are composed of two parts, a basal sheath which enwraps the stem and a flat elongate blade. The veins of the leaf are all parallel to one another, with few inconspicuous interconnecting veinlets. The blades of grasses grow from the bases, so that the apical portion is older and the cells of the basal portion retain for some time the ability to divide and increase. Because of this property grasses can be mowed by machines or cropped by animals, the upper portions of the blades being removed and the basal portion growing to renew the blade. Each node bears a single leaf, which is often reduced to a small scale, especially in the lowermost nodes, and in modified stems, such as rhizomes. At the junction of the sheath with the blade there occurs in many grasses a distinct structure called the ligule. This appears on the stem side of the leaf, and is a membranous or cartilagous fringe or ring.

The **inflorescence**, in grasses, is composed of large numbers of groups of flowers, called spikelets, attached to the main stem or rachis. These spikelets are variously arranged. If they grow directly from the main stem and the latter is unbranched, the inflorescence is said to be a spike. If the main stem produces many branches, which in turn branch, the resulting inflorescence is a panicle. The nature of the branches, whether long or short, spreading or appressed, determines the nature of the panicle. In other grasses the inflorescence is a raceme, the spikelets being borne on short unbranched lateral branches.

The individual spikelet of a grass is composed of a short axis called a rachilla from which arise a series of opposite overlapping **bracts**. The two lowermost bracts are called glumes; these are empty, that is, have no

A grass, red top (*Agrostis alba*). 1, panicle of flowers, ½ natural size; 2, single flower, consisting of three stamens and one pistil with two branching feathery styles, all enclosed by scales; ×15.

flowers formed in their axils. The next bract above the glumes is the lemma, in the axil of which is borne a flower. In many grasses each spikelet contains several lemmas, each with its associated flower. Opposite the lemma is the palea, which is not borne on the rachilla, but on a short pedicel, or flower-stalk. Opposite the palea and at the base of the **ovary** appear two minute scales, the lodicules. Three **stamens**, each with a long slender filament and a large **anther**, come next, while a single **pistil** grows at the apex of the pedicel. The pistil is composed of a 1-celled, 1-seeded ovary, two **styles** and two feathery stigmas. Many variations from the typical spikelet described occur in different species, the number of parts being increased, or parts being completely absent. In many species of grass, conspicuous prolongations on the glumes or the lemmas are noted—these are the **awns.**

Pollination in grasses is almost entirely by wind, the light dry pollen being scattered from the open anthers, often in conspicuous clouds. Grass pollen is a particularly common cause of hay-fever.

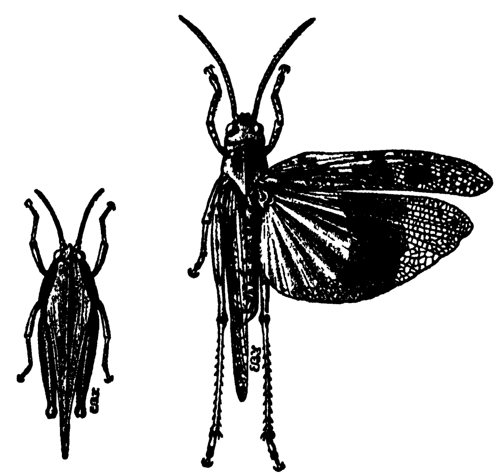
The fruit of grasses is 1-seeded, dry and indehiscent, that is, does not split open at maturity to liberate the seed. The ovary wall, or **pericarp**, is attached to the seedcoat. Within the latter is an abundant starchy **endosperm.** Such a fruit is known as a grain or a karyopsis.

Considerable speculation has been advanced as to the probable origin of grasses, whether they are primitive **monocotyledonous** plants from which others such as lilies may have developed, or whether they are reduced plants. To many the available evidence indicates reduction from lily-like ancestors, a reduction in which two of the three pistil lobes of the ancestral form have been lost, also an entire whorl of stamens, and many of the **perianth parts.** The anatomy of the floral parts lends support to this conception; the vascular bundles suggesting that reduction has occurred. For example, in the pistil there are three vascular bundles, two passing to the styles, and the third bearing the ovule.

The vast importance of grasses to mankind has been previously noted. Grasses supply an important part of the food of the more valuable of man's domestic animals. Many of the forage grasses occur in the wild state, forming extensive ranges on which stock may be pastured. Others are cultivated, and used directly as forage or dried and stored as hay. The search for improved hay grasses has led to the introduction of many valuable species. Notable among them is Timothy, *Phleum pratense,* a grass particularly adapted for cool, moist climates. Another group of forage grasses is that of the millets, lush-growing annual grasses used not only as green forage and cut for hay, but also occasionally grown for their "seeds," used in poultry foods. Millets grow very rapidly and are drought-resistant, and are therefore valuable in regions where the rainfall may be deficient. Another source for bird seed is *Phalaris canariensis,* a grass which is not extensively grown in the United States, but widely in Argentina.

Vast in importance, but few in number, are the grasses grown for their fruit or grain; these are the cereal grasses. These are particularly important in regions of cooler climates, where the grain they produce during the short growing season is a valuable crop which can be stored and used as food during the remainder of the year. The principal cereals are **wheat, corn, oats, rye, barley,** and **rice.** (B.S.M.)

GRASSHOPPER. Insecta, Orthoptera. **Insects** ot moderate to large size, usually with four wings, and with the hind legs long and strongly built for jumping.



Grasshoppers. The figure at the left is a grouse locust, that at the right a common grasshopper.

The mouth parts are formed for biting and the front wings are thickened tegmina which conceal the hind wings when folded. The long-horned grasshoppers include the **katydids** and related species, which have very long many-jointed antennae. Short-horned grasshoppers have short antennae with a moderate number of joints

and are the grasshoppers or **locusts** of common usage. The term locust applies properly to these insects, although it is also used for the cicadas.

The family Tettigoniidae, to which the long-horned grasshoppers belong, contains the katydids, **meadow grasshoppers, cone-headed grasshoppers,** and a number of wingless forms, including the cave or **camel crickets,** the **mormon cricket,** and the **sand cricket,** none of them true crickets.

The family Locustidae includes insects of more uniform appearance. The only members that differ strikingly from the grasshoppers of common experience are the little grouse locusts or **pigmy locusts.** They are less than an inch long and have the dorsal shield of the thorax prolonged over the entire body in an acute point.

In the plains and prairie states grasshoppers are sometimes a serious pest, destroying green crops completely. They are destroyed by the use of poison baits made of bran (25 lbs.), molasses (2 quarts), Paris green or arsenic (1 lb.), and six finely chopped lemons or oranges, mixed with 2–4 gal. of water, according to the prevailing humidity. The mixture should break apart slowly when squeezed into a ball. It is sown broadcast in the fields, preferably late in the day so that it may remain moist as long as possible.

In low crops, such as clover, a hopper trap has been used with great success. It is drawn through the field by horses. The hoppers are shoveled into sacks and when dead are spread out to dry in the sun before they are stored. They are an excellent winter food for poultry, hence this method of control is doubly profitable. (A.W.L.)

GRASSQUIT. Aves, Passeriformes. A Jamaican name for certain of the small birds more commonly called **buntings.** (A.W.L.)

GRATE. Bars which are arranged to support solid **fuel** for **combustion** are grates. The purpose of a grate is not only to support the fuel bed, but also to allow air to pass into it evenly. Service conditions of grates call for considerable structural strength, resistance to temperature and oxidation, and a shape serrated or rough edged, so as to leave air openings between adjacent grate bars. Furthermore, since ashes are generally dumped through the grate bar system, a means for increasing the spacing between bars so as to pass ash between them must be provided in such a way that motion of a shaking crank or lever will clear ash over the entire grate surface. Because of its cheapness and its resistance to oxidation, cast iron has been the material most used for the construction of grates. (F.T.M.)

GRATE EFFICIENCY. The efficiency of a grate is a measure of the effectiveness with which the grate or its equal prevents combustible from reaching the ashpit. Too frequent slicing of the fire-bed, a poorly maintained fuel bed, and a clinkering type of ash, are sources of combustible in the refuse. Analysis of ashpit contents shows that the combustible is practically all carbon, having a heating value of 14,540 B.T.U. per lb. If the ashpit contents analyze $Z\%$ combustible, the fraction of a pound of carbon per pound of coal thus represented is:

$$\frac{Z}{100 - Z} \times \frac{\text{(Per cent ash in the coal)}}{100}.$$

The grate efficiency is found by subtracting from 100% that per cent of the heating value of the coal represented by the combustible in the refuse at the rate of 14,540 B.T.U. per lb. (F.T.M.)

GRATICULE. The pattern of lines representing parallels of **latitude** and meridians of longitude on a map or chart is known as the graticule of the chart. A person familiar with the various types of **map projection** can usually tell by examination of the graticule the type of projection that was used in constructing the sheet. (W.K.G.)

GRATING. Diffraction Grating.

GRAVES' DISEASE. Thyroid Gland.

GRAVITATION AND GRAVITY. The distinction between these two terms is that between a universal property of matter and the special manifestation of that property exhibited in the vicinity of the **earth** or other celestial attracting mass and modified by the **centrifugal force** of planetary rotation.

Newton's conception of gravitation was expressed by his statement, to the effect that every particle of matter attracts every other particle with a force proportional to the product of the masses and to the inverse square of the distance. We are thus left to picture an infinitely complex network of attractions joining every two particles in the universe and tending to pull them together. Newton did not specify what the "particles" were assumed to be, whether atoms or otherwise. Faraday introduced a somewhat different picture in the form of a stressed medium, with its curved lines and tubes of force. The Einstein concept, again, envisages a space so warped by the presence of surrounding masses that a particle, which if projected into an empty space would follow a straight line, actually follows a more or less complicated curve, a geodesic line of this warped space, which represents physically the most direct path between any two points of the space. Furthermore, **Einstein's equivalence principle** makes no distinction between gravitation and centrifugal force.

The Newtonian law may be expressed by the equation $f = Gm_1m_2/r^2$, in which m_1 and m_2 are the masses of two particles, r the distance between them, and G the **gravitation constant.** For practical purposes the "particles" may be homogeneous spheres, r being the distance between their centers. Other bodies of finite size, such as cubes or cylinders, would not do, as they are not "centrobaric"; that is, there is no one point toward which their attraction is directed. The planets and stars being sensibly spherical, they may be treated approximately as particles. It was from the study of the **two-body problem** as applied to such objects that Newton deduced the conclusion expressed in his law.

At any point on the earth's surface, the earth's gravitational attraction is directed approximately toward its center. But since the earth rotates, the "weight" of a body is somewhat less than the earth's attraction for it, because of the centrifugal force, and is, furthermore, not in general directed toward the earth's center. A plumb line 10′ long in the **latitude** of New York departs about ¼″ to the south from a line in the direction of the earth's geometrical center. This same influence accounts for the oblateness of the earth, and these two facts together, for the variation of gravity from equator to poles. Thus at the equator the weight of a gram mass is 977.99 **dynes,** while at the poles it exceeds 983 dynes. These facts are ascertained by observations with such instruments as **Kater's pendulum,** and the Eötvös balance (a kind of **torsion balance** used for gravity measurements), by means of which the acceleration that would be given to a freely falling body is indirectly determined. Various more or less complicated formulas expressing the intensity of gravity as a function of latitude and altitude have been proposed by Clairaut, Helmert, Hayford, and others, but these must always be modified to suit local conditions of topography and density of the crust. For purposes of standardization, the acceleration due to gravity adopted by international agreement is $g = 980.665$ cm./sec.^{2}. (L.D.W.)

GRAVITATION CONSTANT. The constant G in the equation expressing **Newton's** law of **gravitation,** which gives the attraction between two particles of masses m_1, m_2 at distance r as

$$f = G\frac{m_1m_2}{r^2},$$

is called the Newtonian constant or the constant of gravitation. Newton himself was ignorant of its value. Not until 1798 did Cavendish utilize the **torsion balance** in the measurement of this important quantity. The obvious procedure is to place two known masses m_1, m_2 at a known distance r and measure the force of attraction f between them; from which $G = fr^2/m_1m_2$. The constant might be interpreted as numerically equal to the force between unit masses at unit distance. In the actual experiment, large metal balls weighing several pounds each exert a torque on smaller balls mounted at the ends of the torsion balance beam. This torque, and hence the forces producing it, can be measured. The most recent determinations, made by P. R. Heyl at the Bureau of Standards in 1928, gave the value of G as 6.67×10^{-8} dyne cm.^{2}/g^2. The attraction between two small spheres of one gram mass each with their centers 1 cm. apart would thus be 6.67×10^{-8} dynes. The exceedingly small magnitude of the quantity sought accounts for the difficulties in technique and the relatively low precision attained. (L.D.W.)

GRAVITY. Gravitation and Gravity.

GRAVITY FAULT. Fault; Normal Fault.

GRAVURE. Photomechanical Reproduction Processes.

GRAY SCALE. A term used in color photography to denote a series of achromatic tones ranging from black to white. A gray scale may be divided into three or more steps but 10 is a common number of divisions. A gray scale is generally included with the subject when making a color photograph so that measurements of its densities on the separation negatives or tripack will give the density range of that stage in the reproduction. A gray scale is helpful in controlling the processing stages in the analysis and synthesis of a color photograph. (H.C.C.)

GRAYLING. Pices, Teleostei. *Thymallus.* Fishes (**Pisces**) of the northern hemisphere, found in cold lakes and streams. Related to the salmon and trout. Two species in North America. (A.W.L.)

GRAYWACKE or GRAUWACKE. This term is of British origin and is not used extensively outside of western Europe. As originally defined graywacke designates hard, dark-colored, coarse sandstones and grits having an **argillaceous** matrix or cement and occurring among the lower **Paleozoic** formations of Wales, England. Many typical graywackes are similar to **basic arkoses,** the dark color being due to a preponderance of the **femic** minerals and **plagioclase feldspar.** (R.M.F.)

GREASE. A lubricating agent of higher viscosity than oils, consisting essentially of a calcium or sodium soap jelly emulsified with mineral oil. Greases are employed where heavy pressures exist, where oil drip from the bearings is undesirable, and where the motion of the contacting surfaces is discontinuous so that it is difficult to maintain a separating film in the bearing. Grease-lubricated bearings have greater frictional characteristics at the beginning of operation, causing a temperature rise which tends to melt the grease and give the effect of an oil-lubricated bearing. Calcium and sodium base greases are most commonly used; sodium base greases have higher melting point than calcium base greases but are not resistant to the action of water. Graphite, either by itself or mixed with grease, is also employed as a lubricant. Gear greases consist of rosin oil, thickened with lime and mixed with mineral oil, with some percentage of water. (See **Lubrication; Petroleum Products.**) (H.C.H.)

GREAT-CIRCLE CHART. Among navigators the **gnomonic projection** is commonly known as a great-circle chart, because of the fact that on this type of projection, great circles are projected as straight lines. (W.K.G.)

GREAT-CIRCLE COURSE. The shortest distance between any two points on the surface of a sphere is a great circle. For all practical purposes of navigation the earth may be considered as a sphere, and, hence, the shortest course which a vessel may follow between any two ports is a great-circle course.

The great-circle course between two ports is frequently impractical for a ship to follow, because of the fact that it may lead across land or into dangerous waters. For example, the great-circle course between two points in the same **latitude,** but separated by 180° of **longitude,** will lead across the pole of the earth. Before deciding whether or not the great circle is practicable it is necessary to compute the course, computing a sufficient number of points so that the track may be plotted on a chart. Such computation is laborious and, to avoid the necessity of doing the computing, a **great-circle chart** may be used. On such a **chart** any great circle appears as a straight line and all that is necessary for the purpose of studying a great-circle course is to draw a straight line between the two points on the chart and examine it.

Even though the great-circle course does not lead the ship into danger, it is very difficult to follow such a course for it makes a different angle with each successive meridian and would require the helmsman to continually change his course. To avoid this difficulty, as well as to avoid dangers, and still approximate as closely as practicable to the shortest distance between the ports, the **composite course** is the type almost universally followed by vessels. (W.K.G.)

GREBE. Aves, Colybiformes. Swimming birds (**Aves**) with lobed toes, short legs and neck, and a sharp beak, in some species quite long. The grebes are found in temperate regions of both hemispheres and members of the same species may have a very wide range. The pied-billed grebe is also called the **dabchick.** (A.W.L.)

GREENBACK. Pisces, Teleostei. A species of **trout,** *Trutta smaragda,* reported from the headwaters of the Arkansas and South Platte rivers. (A.W.L.)

GREENOCKITE. The mineral greenockite is **cadmium** sulfide and is used as an ore of that metal. It is found rarely in **hexagonal** crystals, sometimes as earthy coatings on other minerals. Its hardness is 3–3.5; specific gravity, 4.9–5.0; luster, adamantine to earthy; color, yellow to yellowish-orange; subtransparent. It is found in Scotland, Bohemia, and France. Also in the United States at Franklin Furnace, New Jersey; and Marion County, Arkansas, where it occurs as a yellow coloring matter in **smithsonite;** and in Mono County, California. It was named for Lord Greenock. (E.S.C.S.)

GREENSAND. Glauconite.

GREENSHANK. Aves, Charadriiformes. A European **sandpiper,** *Tringa nebularia,* related to the **willets** of North America. It migrates into South Africa and Australia. (A.W.L.)

GREEN'S THEOREM IN SPACE. This is one of several mathematical results discovered by Green; it is of very great importance in all parts of mathematical physics. It gives a transformation of a surface integral in space into a triple (volume) integral, or vice versa.

Let $P(x, y, z)$, $Q(x, y, z)$, $R(x, y, z)$ be **continuous** together with their first **partial derivatives**, within and on the closed boundary **surface** S of a region V of space. Then

$$\iint_S \{P(x, y, z)dydz + Q(x, y, z)dzdx + R(x, y, z)dxdy\} = \iiint_V \left(\frac{\partial P}{\partial x} + \frac{\partial Q}{\partial y} + \frac{\partial R}{\partial z}\right) dxdydz.$$

If dS denotes a surface element, and if α, β, γ are the **direction angles** of the outer normal to the surface, the **surface integral** above may be written

$$\iint_S (P\cos\alpha + Q\cos\beta + R\cos\gamma)dS.$$

This theorem is sometimes called Green's theorem in space, sometimes the **divergence** theorem, sometimes Gauss' theorem.

In **vector** language and vector notation, this theorem may be stated thus: The volume integral of the divergence of a vector function **F** of position taken over any region V of space is equal to the surface integral of **F** taken over the closed surface S bounding the region V:

$$\iiint_V \nabla\cdot\mathbf{F}dV = \iint_S \mathbf{F}\cdot\hat{\mathbf{n}}dS.$$

Other important formulae derived from the preceding, and which are often referred to as Green's theorems also, are the following:

$$\text{I.}\quad \iiint_V u\left(\frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2} + \frac{\partial^2 v}{\partial z^2}\right) dV + \iiint_V \left(\frac{\partial u}{\partial x}\frac{\partial v}{\partial x} + \frac{\partial u}{\partial y}\frac{\partial v}{\partial y} + \frac{\partial u}{\partial z}\frac{\partial v}{\partial z}\right) dV = -\iint_S u\frac{\partial v}{\partial n}dS,$$

where u and v are functions of x, y, z, and where $\frac{\partial v}{\partial n}$ is the directional derivative of v along the inner normal to S; in **vector** form, this becomes:

$$\iiint_V u\nabla^2 v dV + \iiint_V \nabla u\cdot\nabla v dV = \iint_S u\nabla v\cdot\hat{\mathbf{n}}dS.$$

$$\text{II.}\quad \iiint_V (u\nabla^2 v - v\nabla^2 u)dV = -\iint_S \left(u\frac{\partial v}{\partial n} - v\frac{\partial u}{\partial n}\right) dS.$$

$$\text{III.}\quad \iiint_V \nabla^2 u dV = -\iint_S \frac{\partial u}{\partial n}dS.$$

$$\text{IV.}\quad \iint_S \frac{\partial u}{\partial n}dS = 0 \quad \text{if } \nabla^2 u = 0,$$

i.e., if u is a solution of **Laplace's equation.**

$$\text{V.}\quad \iiint_V \left[\left(\frac{\partial u}{\partial x}\right)^2 + \left(\frac{\partial u}{\partial y}\right)^2 + \left(\frac{\partial u}{\partial z}\right)^2\right] dV = -\iint_S u\frac{\partial u}{\partial n}dS,$$

if u is a solution of Laplace's equation: $\nabla^2 u = 0$. (L.L.S.)

GREEN'S THEOREM IN THE PLANE. The English mathematician and physicist Green (1793–1841) discovered a number of mathematical results concerning transformations of various types of **integrals** into other useful types. Green's theorem in the plane, which is one of several so-called Green's theorems, expresses a **line integral** in the plane in terms of a **double integral** in the plane, or vice versa.

Let $P(x, y)$ and $Q(x, y)$ be two functions of x and y, which, together with their first **partial derivatives,** are **continuous** within and on the boundary C of a region S, then

$$\int_C (Pdx + Qdy) = -\iint_S \left(\frac{\partial P}{\partial y} - \frac{\partial Q}{\partial x}\right) dS,$$

where the right-hand side is a double integral of a function of x and y over a plane region S.

An immediate consequence of this theorem is: If P and Q are functions satisfying the preceding conditions, and if $\frac{\partial P}{\partial y} = \frac{\partial Q}{\partial x}$, then $\int_C (Pdx + Qdy) = 0$; and conversely, if $\int_C (Pdx + Qdy) = 0$, then $\frac{\partial P}{\partial y} = \frac{\partial Q}{\partial x}$. (L.L.S.)

GREENSTONE. Greenstone is an old field term for more or less altered **basalts** and **dolerites,** which because of the development of **chlorite** or perhaps **hornblende** or **epidote** develops a characteristic green color. Many **diabases** and **epidiorites** have been called greenstones. (R.M.F.)

GREGARINIDA. An order of 1-celled animals, parasitic in various invertebrates. (See **Sporozoa.**) (A.W.L.)

GREGARIOUSNESS. An association of animals of the same species which may be of benefit to the individual but is not essential. The incidental grouping of animals, as in the swarms of maggots in a dead body, is not an association of this type, but the grouping of caterpillars of certain moths, even though the group originates in a like manner by the deposition of eggs in a mass, must be regarded as a gregarious association because the maintenance of the group is due to the behavior of the individuals. They are free to scatter but do not.

Herds of grazing animals cooperate for the common defense and such animals as the killer whale and the wolves are able to attack large animals by hunting in groups, but in all such cases the individual is able to subsist without the assistance of his fellows. (A.W.L.)

GREISEN. An old German **petrological** term originally proposed by Werner for an **igneous** rock of **granitic** or **aplitic** texture composed principally of **quartz, alkali feldspar,** the **fluorine**-rich micas, and sometimes containing **topaz.** Greisens are pneumatolytically altered granites which are closely associated with the development of the tin ore mineral, **cassiterite.** (R.M.F.)

GREYHEN. Aves, Galliformes. The female of the Eurasian black **grouse.** (A.W.L.)

GRIBBLE. Crustacea, Isopoda. A small marine **crustacean,** *Limnoria lignorum,* which bores into submerged timbers. A source of serious damage to docks and piling. (A.W.L.)

GRID. The grid is the control electrode inserted in the path of the electrons in an electron **tube.** Its primary function is to exercise some sort of control on the tube without collecting any more **electrons** itself than necessary. This is distinguished from the operation of the **anode** which, in a triode, is intended to collect all of the electrons. In the usual vacuum tube the control grid is an open mesh or grid-like structure near the **cathode.** Voltages impressed on this grid exert considerable influence upon the passage of electrons across the tube

space. The screen grid is an additional open type element inserted between the control grid and the anode to reduce the **interelectrode capacitance** between them. The suppressor grid is inserted between the screen and anode to reduce secondary emission. Some special-purpose vacuum tubes, e.g., the **mixer** or first detector of a **superheterodyne**, have other grids, each however controlling in some way the electron stream which is eventually collected by the anode. In many gas-filled tubes and in the **cathode ray tube** the grid is a solid cap-like element with a single hole for the passage of the electrons. (L.R.Q.)

GRID-CONTROLLED RECTIFIER. Thyratron.

GRID-GLOW TUBE. Thyratron.

GRID LEAK. This term is frequently applied to the resistance in the grid circuit of a vacuum tube. (L.R.Q.)

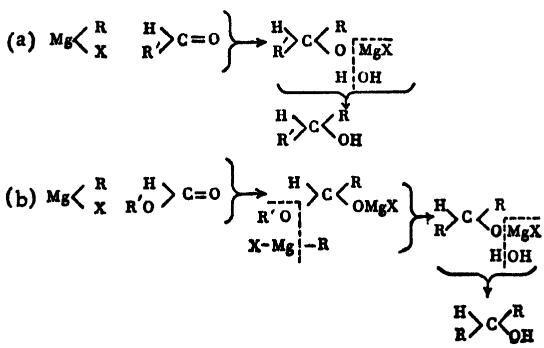
GRIGNARD REACTION. Magnesium metal plus haloid (see **Chlorine, Bromine, Iodine**) hydrocarbon $\left(\mathrm{Mg}<^{R}_{X}\right)$ in anhydrous **ether**, introduced by Grignard, is used as reagent for the preparation of:

1. Secondary alcohols by treatment with **aldehydes** or **formic acid** esters.
2. Tertiary alcohols by treatment with **ketones** or **esters** (not formic acid esters).
3. Primary **alcohols** by treatment with **formaldehyde.**
4. Alcohols by treatment with **oxygen** gas or **hydrogen peroxide.**
5. **Hydrocarbons** by treatment with water, alcohols, **phenols, amines.** With R X as ethyl bromide (C_2H_5Br) the volume of ethane gas (C_2H_6) evolved may be utilized as a measure of hydroxyl (OH—) or amino (NH_2—) radical. One mol of ethane for each equivalent of either.
6. **Carboxylic acids** (group —COOH) by treatment with **carbon dioxide.**
7. Sulfinic acids (group —SOOH) by treatment with **sulfur dioxide.**
8. Organic **phosphines, arsines, mercury** di-, tin tetra-, **lead** tetra- compounds.

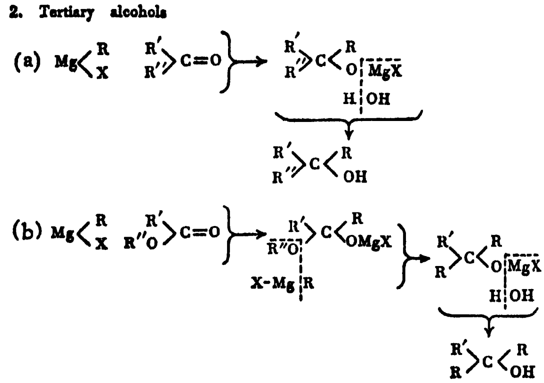
An intermediate compound, identified in numerous cases, but generally not isolated, is formed, and this is decomposed subsequently by addition of water or acid with the formation of magnesium hydroxyhalide (magnesium halide solution when acid is used) plus the main product. The main product is usually extracted with ether followed by recovery upon evaporation of the ether. "Within recent years no single group of compounds has proved of such value in synthetic chemistry as these [Grignard] reagents." (Bernthsen-Sudborough, 1930.)

Illustrative examples follow:

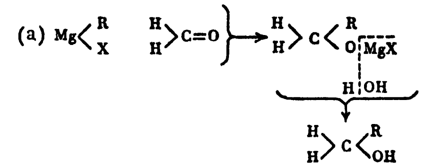
1. Secondary alcohols



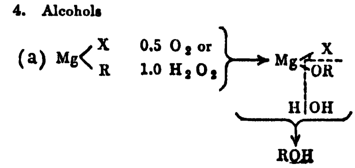
2. Tertiary alcohols



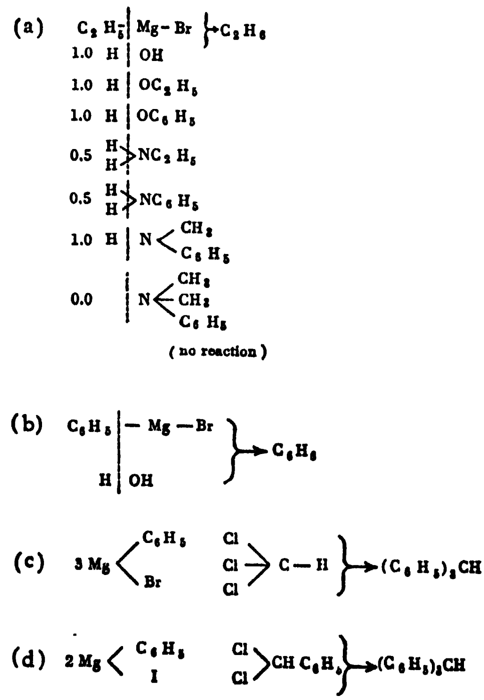
3. Primary alcohols



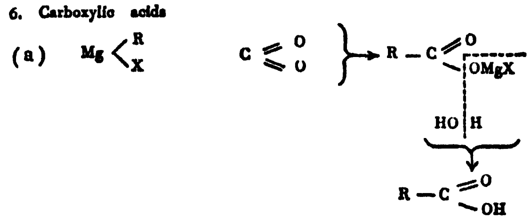
4. Alcohols



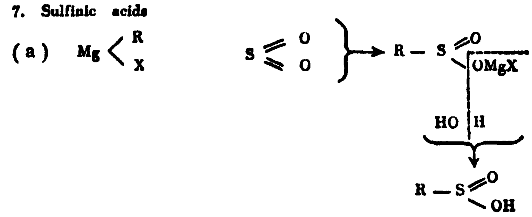
5. Hydrocarbons



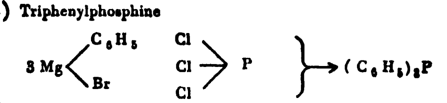
6. Carboxylic acids



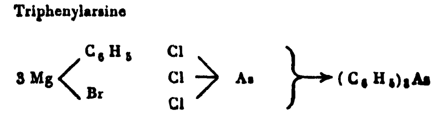
7. Sulfinic acids



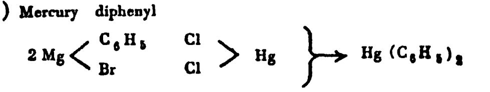
8.(a) Triphenylphosphine



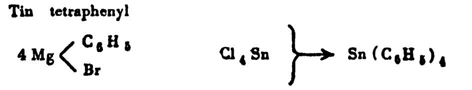
(b) Triphenylarsine



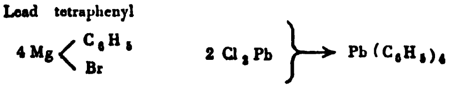
(c) Mercury diphenyl



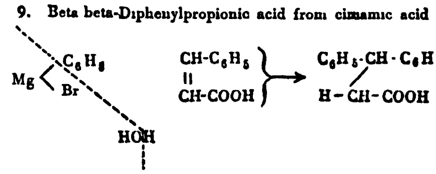
(d) Tin tetraphenyl



(e) Lead tetraphenyl



9. Beta beta-Diphenylpropionic acid from cinnamic acid



The choice of haloid hydrocarbon is in some cases important in determining the yield of the desired substance. (R.K.S.)

GRILLAGE. A grillage is a system of timber or steel beams which is used under **columns** to spread the **loads** over a comparatively large area. Timber grillages, consisting of layers of wooden beams, laid at right angles to each other, are generally used for temporary construction, although there are instances in which they have been inclosed in concrete for permanent construction. If this grillage is used for permanent foundation it should be either entirely submerged or creosoted to withstand deterioration.

The steel grillage consists of one or more layers or tiers of beams which are encased in concrete. If there are two or more tiers the beams in one tier are laid at right angles to those in the next tier. The individual beams in each tier are held in place by rods and pipe separators, cast iron separators or steel diaphragms. Since the concrete-encased steel grillage has more resistance to bending than the ordinary reinforced concrete spread **footing** it can be used to distribute heavy column loads over large areas. (C.W.C.)

GRINDING. The process of removing solid particles by means of solid or sectional abrasive wheels rotating at comparatively high speeds (6000 ft. per min. or greater). Originally employed for sharpening tools, it has beecome a useful and accurate production process for both hardened and unhardened metal parts.

Grinding machines are quite varied in type and function. Bench and floor grinders usually consist of a motor, with a two-wheel spindle replacing the motor shaft, and are used for tool sharpening and general off-hand grinding. Plain and universal grinding machines are essentially similar to engine lathes, with the carriage and tool post replaced by a wheel stand carrying a grinding wheel and spindle, and are used for grinding cylindrical and conical work. Internal grinders are used for finishing cylindrical and conical holes. Surface grinders employ either a rotary or a reciprocatory table for holding parts on which plane surfaces are required. Centerless grinding machines are used for mass production finishing of cylindrical and conical parts. The part to be ground is supported between the grinding wheel, a work rest, and a suitable regulating or feed wheel which imparts axial motion to the part. Internal centerless grinders, for finishing roller bearings races and bushings, are also used. Disk grinders are used for plane surfacing operations, are similar to bench and floor grinders, but are equipped with metal disks to which abrasive disks are cemented. Grinding wheels consist of abrasive grains held together by some bond such as clay, shellac, or rubber. The hardness of the abrasive, the shape and form of the grain fracture, and the tenacity of the bond are each important in grinding operations. The grade of a grinding wheel denotes its hardness, which cannot be accurately determined by the bond mixture or the method of manufacture. Wheel grade is often indicated by letters, running from *E*, soft, to *Z*, extremely hard.

Grinding wheels are dressed or trued by metal "star" wheels or by mounted diamonds, to remove metal particles or dull grains of abrasive, and to restore their original shape and accuracy. (See **Abrasive.**) (H.C.H.)

GRIP. Rivet.

GRISON. Mammalia, Carnivora. *Galictis.* A small South American animal with long slender body and tail and short legs. Related to the weasels. (A.W.L.)

GRIT. An old term for coarse-grained sandstones whose components are angular or "gritty." There is a tendency to use it for any coarse-grained sandstone without regard to the angularity of the fragments. (R.M.F.)

GRIVET. Guenon.

GROSBEAK. Finch.

GROSSULARITE. Garnet.

GROUND. In electrical terminology, a ground is a conductor connected to earth, or a large conductor whose potential is taken as zero (e.g., the steel frame of a car). A ground may be an undesirable, inadvertent, or accidental path taken by an electrical current in its effort to reach ground potential; or it may be the deliberate provision of **conductors** well connected to the ground by means of plates buried therein, or similar device.

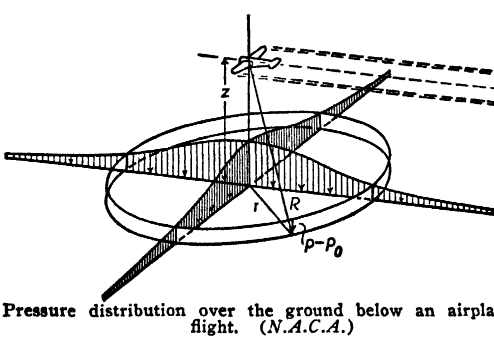
There is always the possibility that, during the life of an insulated conductor, the insulation may be punctured or broken down and a ground occur. Usually, a ground develops rapidly into a low-resistance path through which currents of damaging magnitude may flow. **Insulation** may be damaged in many ways—by the effect of moisture, or chemical vapors, by age, heat, abrasion, breaking, or crushing. Two-wire d-c systems are permanently grounded on one side of the line, three-wire d-c systems permanently grounded on the neutral wire. The same applies to two- or three-wire single-phase a-c systems. The common grounding point of station three-phase lines is the generator neutral.

The grounding system of the a-c generating station fulfills two distinct functions. The first is the grounding of non-current-carrying parts, the second is the furnishing of a ground connection for generator or transformer neutral to provide for the operation of a ground protection system. A common ground **bus** is employed, to which are connected the frames of all electric machines, the cases of instruments, transformers, circuit breakers, the secondaries of current and potential transformers, the switchboard ground bus, conduits, insulator bases, building structural steel, etc. Thus, if the grounding system is effective, a zero, or earth, potential will be established on all metal parts which might otherwise be dangerous in case a ground developed. To the common ground bus is also connected the fault bus, when used.

Grounds shou'd be detected as soon as possible after they occur and the defective section immediately taken out of service. If the ground persists, in a short time an otherwise small repair job may become a large one. Lamp types ground detectors are used to a considerable extent on low-voltage circuits because they are reliable and cheap. It is important that the low-voltage control circuits be kept as free of grounds as the main circuits. They may be applied to high-voltage lines through the interposition, between lamps and line, of potential transformers. Also the vacuum tube type and the electrostatic type of ground detector are available for direct connection to the high-voltage lines.

In the terminology of building construction, a ground is a strip of wood about 2″ wide and as thick as the plaster, which is applied to the framing when nailing room is needed. Grounds are used around windows and doors, at baseboards, cornice, etc. (F.T.M.)

GROUND EFFECT. Persons of an inquisitive turn of mind may occasionally have wondered what action replaces the concentrated reaction of the wheels of an airplane against the ground after the airplane is airborne. The answer is that there is a slight increase of atmospheric pressure upon the surface of the earth, which is maximum directly below the airplane but which dwindles to zero only at an infinite distance. However, nearly all the airplane weight is accounted for by the pressure increase over a circular area of a diameter of 20 times



Pressure distribution over the ground below an airplane in flight. (*N.A.C.A.*)

the height of the airplane over it. The figure shows the calculated distribution of pressure from an airplane flying at altitude z over the earth's surface. By use of the circulation theory and replacing the wing by a simple vortex, an equation for the increase of atmospheric pressure $p - p_0$ due to the support of the airplane at radius r may be derived.

When this is multiplied by the area on which it presses, i.e., $2\pi r dr$ and integrated to infinity, the result is no more or less than the weight of the airplane. Of course the pressures are ordinarily very small, since the area carrying the weight is so large. For example, the increase of pressure under an airplane of 4000 lbs. weight flying at 100′ directly overhead is only about .0005 lb. per sq. in.

However, there is one flight condition where this increase of atmospheric pressure and density is of real moment. It is when an airplane is flying just a few feet off the surface of the ground, especially a low-wing monoplane, where only 4 or 5′ may separate ground and wing. Here the strength of the bound vortex is sufficient to build up a substantial change in atmospheric properties, with effects on airplane flying qualities usually called *ground effect*. Induced drag is reduced and the stall occurs at a smaller apparent angle of attack. The airplane may seem, to the pilot attempting a landing, to "float" instead of immediately stalling to a normal landing. While, in general, this is not hazardous to landings once the pilot becomes familiar with an airplane's floating tendencies, it does offer a peculiar and distinct hazard at the take-off of overloaded airplanes, since the ground effect might aid the airplane to become airborne, but would practically disappear as soon as a climb to altitude was started. (F.T.M.)

GROUND ICE. Ice will occasionally form in stream beds, especially in the lee of rocks or other obstructions which tend to reduce the velocity of the water and allow freezing to take place. Such ice formations are known as ground ice or anchor ice. (R.M.F.)

GROUND LOOP. An uncontrollable violent turn of an airplane while taxiing, or during the landing or take-off run. (F.T.M.)

GROUND MORAINE. When a valley glacier melts completely away the debris carried on or within it is dropped upon the valley floor, forming a deposit called ground moraine. The ground moraine from the melting of the great **Pleistocene** ice sheets is usually spoken of as **till.** (R.M.F.)

GROUND PEARL. Insecta, Homoptera. The iridescent covering secreted by some of the scale insects which live on the roots of plants. Used as ornaments. (A.W.L.)

GROUND ROD. Earthwork.

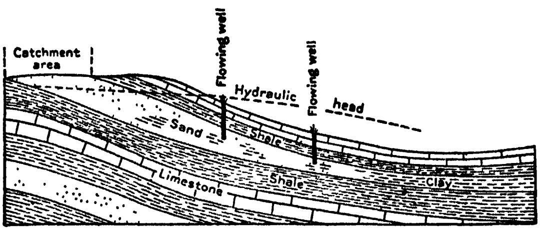
GROUND WATER. At varying depths below the surface of the earth, depending upon wet or dry seasons, underground structures, and other natural and unnatural factors, is a zone which is saturated with water most of which comes from rain which has penetrated the ground. The upper surface of this saturated zone is called the water table, and the water itself, the ground water or the sub-surface water. The region above the upper surface of the water table is called the zone of aeration or vadose zone.

There is a lower limit to the saturated zone as well as an upper limit. Little ground water exists at depths below 2000 or 3000′. Deep down in the earth's crust the pressure must be so great that all pores in the rocks are completely closed; thus at depths of several miles below the surface there could exist no zone of saturation.

The ground water moves through the rocks and unconsolidated materials of the earth near the surface, constantly seeping into streams and lakes to maintain these bodies of water between rains. If this seepage is suffi-

ciently strong on hillsides or elsewhere springs may result. A well is simply an opening dug deep enough to encounter the zone of saturation.

In certain cases the ground water will flow through porous tilted beds called aquifers from higher to lower localities, establishing a "head" which is sometimes suf-



Structure section illustrating flowing artesian wells in a monocline. (*After U. S. Geological Survey.*)

ficiently great to cause the water to flow out under pressure and rise above the surface of the ground, when the aquifer is penetrated by a drill. Such a source of water is called an artesian well from Artois, France, a classic locality for such waters. Artesian conditions exist along much of the Atlantic Coastal Plain of the United States and in North and South Dakota, Nebraska, Kansas, Illinois, Indiana, Missouri and Arkansas. Since the supply of underground water is largely dependent upon structure, the geology of water supply is one of the most important economic phases of the earth sciences. From the point of view of their origin, ground waters are classified as juvenile, connate and meteoric. Juvenile waters are of volcanic or magmatic origin, hence original. Connate waters are those in which the sediments were originally deposited. Meteoric waters are those of atmospheric origin.

All pure water, and most of all of the underground waters are of meteoric or surface-water origin. (R.M.F.)

GROUND WAVE. The energy which reaches the radio receiving **antenna** from the **transmitter** by travel along the surface of the earth rather than by reflection from the **ionosphere** is called the ground wave. The ground wave is unaffected by seasonal or diurnal variations and is consequently very reliable for communication. However, it is attenuated by absorption of the earth and gradually becomes too weak to furnish a reliable signal. This attenuation depends in a complicated way upon the frequency, the soil conductivity and dielectric constant, but increases markedly with frequency. Thus, while it is suitable for communication over several thousand miles at the lower radio frequencies, over a hundred or two in the broadcast band, it becomes almost useless at the high frequencies. See **fading** for its effect on the total received signal. (L.R.Q.)

GROUNDHOG. Woodchuck.

GROUP. For the significance of this term in Geology, see **Era.**

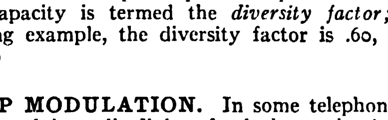
GROUP DRIVE. There is some controversy as to the respective merits of individual and group drives. Individual motor drives are used on many modern machine tools, are very convenient, and are extremely efficient when the power capacity of a machine is definitely known and when it is generally operated at full capacity. In many machine tools operated at high rates of production, two or more motors are often used on the same machine for more efficient operation of its separate elements.

Group drive by means of a number of countershafts and a lineshaft driven by a large motor is less expensive in initial cost than individual motor drives. Individual motor-driven machines must each have motors that will, on occasion, deliver the full power requirement of that machine even though the machine may usually be operated at half its power capacity. A large group drive motor of a capacity equal to the aggregate capacity of the individual motors is not only less expensive than the small separate units, but it is frequently possible to use a group drive motor with a capacity of three-fourths or one-half that of the individual aggregate. To illustrate: suppose a shop has ten lathes, each of which has a maximum power capacity of 5 hp.; individual drives for these machines will aggregate 50 hp. even though the machines may operate at half-capacity most of the time. For a group drive, however, a 30 hp. motor would probably furnish sufficient power capacity to drive all the machines, even if several were to operate at full load at one time. The ratio of total anticipated power required to total machine capacity is termed the *diversity factor;* in the foregoing example, the diversity factor is .60, or 60%. (H.C.H.)

GROUP MODULATION. In some telephone carrier circuits and in radio links of telephone circuits several carrier **channels** are treated as a single group and the whole modulated upon a new **carrier.** This is known as group modulation. In the reception of such a system, of course, the received signal must first be demodulated into the various channels and then in another step each channel must be demodulated to obtain the original voice currents. (L.R.Q.)

GROUP VELOCITY. The velocity of propagation of an **interference** pattern between two or more wave trains traveling in the same direction with different speeds. It may be quite different from the velocity of any one of the component wave trains. If there are more than two components, the character (wave form) of the resultant wave changes as the "group" progresses, so that the group velocity becomes ambiguous. For two components the analysis is fairly simple.

To illustrate, first suppose for the moment that the wave train A of shorter wavelength λ is standing still, and the other, B, of wavelength $\lambda + \Delta\lambda$ is moving past it in the positive direction (see figure). For example,



Two sets of waves traveling with different velocities. Resultant maximum is at X.

let $\lambda = 1$ cm. and $\lambda + \Delta\lambda = 1.1$ cm., and let the velocity Δv of the train B relative to the (stationary) train A be $+3$ cm. per sec. As often as B moves forward 0.1 cm., the coincidence or **beat** maximum X moves backward 1 cm.; consequently X moves with respect to A with the velocity -30 cm. per sec., which is -10 times, or in general $\frac{\lambda}{\Delta\lambda}$ times, the velocity Δv with which B moves. (The analogy to a **vernier** should be quite apparent.) Now suppose that an additional velocity v is imposed upon both wave trains, so that now A moves with velocity v and B with velocity $v + \Delta v$. If $v = +100$ cm. per sec., A moves with this velocity, B moves 103 cm. per sec., but X moves only $100 - 30 = 70$ cm. per sec. That is, the velocity of the interference maximum X is $u = v - \lambda \cdot \Delta v/\Delta\lambda$. This is the group velocity; usually written

$$u = v - \lambda \frac{dv}{d\lambda}.$$

In the case of media in which there is **dispersion,** v is a function of λ; where there is no dispersion, $u = v$, since $\frac{dv}{d\lambda}$ is then zero.

Take the case of sodium light traveling through carbon bisulfide. This light has two close components with respective wavelengths 5890 angstroms and 5896 angstroms (in air). The **refractive index** for the 5890-angstrom component being about 1.64, the velocity v of this component in CS_2 is about 1.83×10^{10} cm. per sec. Now the dispersion of CS_2 in this part of the spectrum is such that $\frac{dv}{d\lambda}$ is readily computed to be 3.81×10^{18} cm. per sec. per cm., while the wavelength λ in CS_2 is 3590 angstroms or 3.59×10^{-8} cm. Hence the group velocity u is 1.83×10^{10} cm. per sec. $- 3.59 \times 10^{-8}$ cm. $\times 3.81 \times 10^{18}$ cm. per sec. per cm. $= 1.69 \times 10^{10}$ cm. per sec.

Michelson, using the same revolving-mirror method as for the **electromagnetic constant**, actually obtained this velocity in carbon bisulfide, showing that it is the group velocity which this method really measures. (L.D.W.)

GROUPER. Pisces, Teleostei. A marine game fish (**Pisces**) of the West Indies and the Atlantic Coast. Related to the sea bass. (A.W.L.)

GROUPS. A set of elements G is said to form a group when they satisfy the following conditions:

1. There is an operation by which to each ordered pair of elements A and B of G there is associated an element C of G, denoted by $C = AB$.
2. For this operation the associative law holds: $(AB)C = A(BC) = ABC$ for any three elements A, B, C of G.
3. There exists: (a) a unit-element E in G such that $EA = A$ for each element A of G, and (b) to each element A of G there exists a reciprocal (or inverse) element A^{-1} of G such that $A^{-1}A = E$.

If the commutative law $AB = BA$ holds for any elements A and B of G, the group G is called an Abelian group. (L.L.S.)

GROUSE. Aves, Galliformes. Game birds with compact rounded bodies and legs feathered to the feet. The closely related ptarmigans have both legs and feet feathered.

Grouse are birds of the northern hemisphere. The ptarmigans, including the red grouse of the British Isles and the willow grouse, are found at high altitudes and in the north. Most of these birds have white plumage in the winter. Grouse vary in habits, some frequenting woodlands and others open ground.

Among the best known North American species are the ruffed grouse, *Bonasa umbellus*, the prairie chicken, *Tympanuchus*, and the sage grouse, *Centrocercus urophasianus*. The heath hen, *Tympanuchus cupido*, an eastern species resembling the prairie chicken, has recently become extinct. Two western species, the Franklin grouse, *Canachites franklini*, and dusky grouse, *Dendagapus obscurus*, are locally called the fool hen. (A.W.L.)

GROUSE LOCUST. **Grasshopper.**

GROUT. Grout is a mixture of **cement** and water or cement, sand and water of such consistency that it will flow, or may be forced by pressure, into small confined spaces.

It is widely used at present to seal geological faults, cracks, crevices, or other cavities in the rock **foundations** of dams. Grout is also excellent for use in connection with **column footings** and machine foundations which require level bearing surfaces. Since a column footing can never be poured to an exact elevation it is usually built up to within about an inch of its final elevation. Steel shims (fillers) are placed on the top of the footing so as to provide the correct elevation for the bottom of the base plate of the column. The column base which is an integral part of the column is then set on the shims. After the anchor bolts, which are used to fasten the column to the footing, have been tightened, the space between the top of the footing and the bottom of the base plate is filled with grout. (C.W.C., E.W.S.)

GROWTH. Increase in size. Growth of living structures depends upon increase in the number of cells or in the bulk of cells and intercellular material. It is based on the process of intussusception through which materials received as food become an integral part of the structures already present. Accretional growth is of very limited occurrence in living things and is not independent of intussusception.

Most animals exhibit determinate growth; that is, they increase in size until they approximate a limit characteristic of their kind. A few mature within rather wide limits according to the amount of food available. In the adult body the capacity of various tissues to continue their growth varies, but in all cases tissues which are worn away in the course of normal life have the power of renewal and some, such as the bone-producing cells of vertebrates, are capable of becoming active for the restoration of damaged structures. These aspects of growth are closely associated with **regeneration.**

The rate of growth in different parts of the body also varies, as also does the rate of total growth at different periods of life. Most mammals increase in size rapidly during early life and gradually slow down as maturity is approached, while man grows rapidly during infancy, slowly during childhood, rapidly again during youth, and more slowly toward the completion of his size. In his body the nervous system most rapidly approaches its maximum size and the reproductive system lags until the onset of maturity. Some of the glandular tissues increase rapidly before maturity and then decrease in bulk. The balance of all of these processes when normal food is available results in the gradual process of general growth, and the attainment of stability in adult life is a result of their correlation with external factors. Although no one factor is wholly responsible for growth, **hormones** of the pituitary and thyroid glands are of great importance in its regulation in vertebrates. Deficiency of either gland may result in dwarfing, and pituitary excess sometimes causes human beings to attain unusual height. Persons taller than 7′ are probably due in all cases to such abnormality.

Plant growth is indeterminate. In the higher plants primary growth is confined to the tips of stems and roots, secondary growth to **cambium** layers which produce wood and bark. The cambiums and the undifferentiated tissues at the tips of stems and roots are called meristems. Meristem cells divide rapidly and some of them finally become the mature cells of the plant. Each cell starts to grow, like an animal cell, by adding more protoplasm but finally increases tremendously in size by taking up a quantity of water to form a large central vacuole. Tissues are differentiated by the accumulation of excess food (cellulose, lignin, suberin) on the outside of each cell in the form of a cell wall. Certain columns of cells thicken their side walls, digest their end walls, and then die, leaving long tubes (vessels) which conduct water. Other cells die from an excess accumulation of impervious wall material and become **fibers** or **cork** cells. Others remain alive for a season or two and manufacture, transport, or store food, much more food than the plant can ever use. Some few cells become concerned with the isolation of meristems in reproductive organs (ovules, seeds). These isolated meristems produce the cells of new plants. The life of a plant need never terminate. There is no adult stage as in animals. **Propagation** may serve to keep a single set of meristems in action continuously. Stem tips and annual plants die, but only because the terminal meristems are captured in the developing

ovary of the flower. (See also **Cambium**, **Roots**, **Stem**, and **Wood**.) (A.W.L., P.A.W.)

GROWTH SUBSTANCE. Auxins.

GRUB. The soft white larvae of certain beetles. They have few legs, limited to the anterior part of the body. Other animals of similar appearance are also called grubs. (A.W.L.)

GRUIFORMES. The **rails**, **coots**, **cranes** and related species. An order of wading and swimming birds (**Aves**) of varied form with lobed toes or with neither lobes nor webs. Feet never fully webbed. (A.W.L.)

GRUNERITE. Cummingtonite.

GRUNT. Pisces, Teleostei. A term applied to food fishes (**Pisces**) of several marine species on the Atlantic Coast. (A.W.L.)

GUACHARO. A native name for the oil **bird**. (A.W.L.)

GUAN. Aves, Galliformes. Game birds (**Aves**) of Central and South America, related to the curassows. One species, the chachalaca, *Ortalis vetula*, enters southern Texas. (A.W.L.)

GUANACO, HUANACO. Mammalia, Artiodactyla. A wild representative, *Lama huanacos*, of the group commonly called **llamas**, the New World representatives of the camel family. The guanaco ranges from high altitudes in Ecuador to Tierra del Fuego and is larger than the vicuna, the one other wild species. (A.W.L.)

GUANIDINES. Amines and Amides.

GUANINE. Alkaloids.

GUARD CELLS. Stoma.

GUARD RAIL. Railway Track.

GUARD STAKE. Station.

GUAVA. *Psidium Guajava*, and other species. Myrtaceae. Guava, a shrub or small tree indigenous to tropical America, has oblong, short-petioled leaves and white flowers. The fruits have a curious penetrating odor and vary greatly in appearance. Their slightly acid, seedy pulp is principally used in making guava jelly. The plant has been widely introduced into tropical countries throughout the world; in the United States it is grown in Florida and southern California. (R.M.W.)

GUAYULE. *Parthenium argentatum*. Compositae. A perennial shrubby plant native to the semi-desert regions of north central Mexico and southwestern Texas which has long been a minor commercial source of **rubber**. The plants are seldom more than 2′ high, and bear leaves with a gray, silvery appearance. Formerly wild plants were harvested on a considerable scale for rubber but most guayule rubber at the present time comes from cultivated plants. Guayule is grown as a crop plant principally in the vicinity of Salinas, California. The plants are grown from seed which must, however, be subjected to a special washing treatment followed by treatment with sodium hypochlorite before a good percentage of germination can be obtained. In practice the seeds are usually sown in the late winter or early spring and the plants transplanted from the nursery beds the following January. The plants are usually not harvested until they are 5 years old. The harvested plants are cut into small pieces and the rubber separated by mechanical maceration of these pieces in a pebble mill. In the best selected strains of guayule about 20% of the dry weight of the plant is rubber at the end of 5 years. The yield per acre is about 1600 lbs. of rubber for 5-year-old plants and 2200 lbs. per acre for 6-year-old plants. The rubber obtained from guayule is of good quality, but contains a considerable percentage of resins which must be extracted before it can be used for many purposes. (B.S.M.)

GUDGEON. Pisces, Teleostei. *Gobio*. Small fresh-water fishes (**Pisces**) of Europe. (A.W.L.)

GUEMAL. Deer.

GUENON. Mammalia, Primates. A group of African **monkeys** of the genus *Cercopithecus*. All species are slender and of moderate or small size. The genus includes the vervet, grivet, mona monkeys, patas, nisnas, ludio, hocheur, and several other species named as monkeys. (A.W.L.)

GUEREZA. Mammalia, Primates. An African thumbless **monkey** of the genus *Colobus*. (A.W.L.)

GUILLEMOT. Aves, Charadriiformes. *Uria*. Birds (**Aves**) with short legs, webbed feet, and upright posture, related to the auks. The several species are found chiefly about the northern oceans. (A.W.L.)

GUINEA FOWL. Aves, Galliformes. African birds (**Aves**) of several species, related to the pheasants. All have some dark plumage with light spots, and brightly colored bare skin about the head and neck. The common Guinea fowl, *Numida meleagris*, is among the common domesticated species. (A.W.L.)

GUINEA PIG. Cavy. These little rodents are widely kept as pets and are useful to medical science as laboratory animals. Because of their high rate of reproduction they have also been bred for the study of heredity. (A.W.L.)

GUINEA WORM. Nemathelminthes, Nematoda. A large roundworm, *Filaria medinensis*, parasitic in man. It sometimes reaches a length of more than a yard. The worm lives in the superficial tissues, forming an abscess open to the surface, and can be removed by gradual traction on the end of the body exposed in this opening. The eggs are dropped in the water and the young develop in the bodies of water fleas. The species occurs in tropical Asia and Africa. (A.W.L.)

GULDINUS. Theorems of Pappus and Guldinus. (See **Pappus' Theorems**.)

GULL. Aves, Charadriiformes. Water birds (**Aves**) with webbed feet and long narrow wings. Their flight is powerful and easy, and they are more often seen in the air than on the water. They are common along the seashore and on larger bodies of fresh water, but Franklin gulls are often seen far from water, even following the plow to pick up insects. With the exception of the sabine gull they may be distinguished from the closely related terns by the square end of the tail. The kittiwake is a related species of the North Pacific and Bering Sea. (A.W.L.)

GUM-BICHROMATE PROCESS. A process of photographic printing once quite popular among salon exhibitors in France, where it originated, and in America but now practically obsolete. It is based upon the fact that a colloid such as gelatin, gum arabic, etc., is rendered insoluble upon exposure to light in the presence of a bichromate such as ammonium or potassium

bichromate. An outline of the process follows: Heavy drawing paper is first coated with a mixture of gum arabic, potassium bichromate and a ground pigment of the color desired. When dry, the paper is exposed in contact with the negative to daylight, or a strong source of artificial light. No image is visible as a result of this exposure, but on placing the paper in water, the portions not exposed to light, i.e., the highlights of the image, dissolve slowly leaving an image consisting of pigment in the hardened gum. As the scale of tones is short, it is generally necessary to resort to multiple printing. Usually, at least three printings are necessary; one for the shadows, one for the half-tones and a third for the highlights. The second and third printings are made by coating the paper a second and third time with coating mixtures of different consistencies, exposing and washing out the unattached pigment as with the first coating. Obviously, registration marks on the paper and the negative are necessary in order to superimpose the three printings.

The gum bichromate process produces prints with deep, rich shadows and affords considerable control over local tone values. (C.B.N.)

GUMBO. Till.

GUMMA. A soft spongy inflammatory **tumor** which occurs in late untreated **syphilis.** The common sites for gummata are the skin, liver, brain, and lung. Treatment with anti-syphilitic drugs causes them to disappear. (D.M.H.)

GUMS. These are **carbohydrates** of complex structures which are formed as decomposition products in many plants. They are particularly common in plants growing in very dry regions. They have neither taste nor odor and are insoluble in alcohol and ether. Many gums are soluble in water, while others unite readily with water to form a mucilaginous product, or swell greatly in water.

Gums are employed in making adhesives, in calico-printing, in sizing fabrics, both silk and cotton, and in confectionery. Medicinally they are widely used because of their soothing properties, and as a vehicle for insoluble substances.

While a great many plants form gums, only a few of these are of any importance to man. One of these, gum arabic, is a product of an **acacia** tree of tropical Africa. This tree, *Acacia Senegal,* grows in very dry regions. It has bipinnately compound leaves which have a gray color, and small yellow flowers borne in axillary racemes. The gum exudes from cracks which are formed in the bark of the stem and branches at the beginning of the dry season when very rapid drying of the plant occurs. Gum arabic is entirely soluble in water. Another gum is obtained from a small shrub growing in desert regions of southwestern Asia. This shrub, *Astragalus gummifera,* a **legume**, has pinnate (see **Pinna**) leaves. The leaflets fall off, leaving the leaf axis as a stiff thorn. The plant has small yellow flowers and small 1-seeded pods. The gum, known as gum tragacanth, is only partially soluble in water. In America several small shrubs of the dry plains yield a gum called mesquite. One of these shrubs is *Prosopis glandulosa.* Many species of *Prunus,* including the common cherries and plum trees, yield a dark-colored gum which is entirely insoluble in water. (R.M.W.)

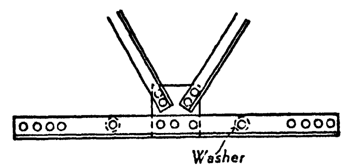
GUN COTTON. Explosives.

GUNDI. Mammalia, Rodentia. A nocturnal burrowing animal living in rocky country near the Sahara desert. (A.W.L.)

GUPPY. Pisces, Teleostei. *Lebistes.* A small species of the **killifish** family, popular for tropical aquaria. The males are brightly colored and variable, the females larger and duller. They bear living young and are easily reared if protected from the cannibalistic parents. (A.W.L.)

GURNARD. Pisces, Teleostei. *Trigla.* Marine fishes (**Pisces**) with high angular heads and finger-like appendages on the pectoral fins. These processes are tactile and also aid in supporting the fish on the bottom. Some are called the sea robins and one British species is known as the piper. The flying gurnards and beaked gurnards belong to a related family. They are widely distributed marine fishes whose bodies are strangely formed and armored with bony plates. (A.W.L.)

GUSSET PLATE. A gusset plate is a flat plate connecting two or more structural members where they meet at a **joint.** **Stress** is transferred between the members through the gusset plate by riveted, bolted, or welded connections. A gusset plate should be of a shape giving a minimum waste of material, which can



be fabricated in the shop with minimum amount of labor. For this reason it should be cut with straight edges. The thickness of a gusset plate should be sufficient to give *bearing* value, so that the material or the rivet will not be crushed. Minimum thicknesses of gusset plates are usually $\frac{1}{4}''$ for inside protected structures and $\frac{3}{8}''$ for outside exposed structures. The area between rivet holes should be great enough to transmit the stress from one member to another. Examples of gusset plates are to be found in all types of welded and riveted steel structures, and in gussets which strengthen and make the joints in the rib structure of an airplane wing. (F.T.M.)

GUSTS. Transient but rapid fluctuations of wind velocity. Gusts are the result of turbulent air flow. Gusty winds usually vary radically in direction. (P.E.K.)

GUTTA PERCHA. *Palaquium Gutta,* and related species. Sapotaceae. Gutta percha is prepared from the **latex** found in the stem and leaves of certain trees native in Malaysia and various South Sea Islands. To obtain the latex, which does not flow readily from living trees, the tree may be felled and a series of rings cut in the bark. From these the latex oozes and may be gathered. Such a method is naturally very destructive to continued production. A more desirable method is practiced in plantations of today. Fresh leaves are gathered and chopped up and crushed. The crushed mass is then boiled in water and the gum removed and pressed into blocks.

In South America a related tree, *Mimusops Balata* (Sapotaceae) yields a similar gum of somewhat inferior quality. This tree is usually tapped by cutting a row of zigzag gashes which connect one with another. Down these the latex flows, to be gathered in a cup at the bottom, and later coagulated in trays.

Gutta percha is a yellowish or brownish somewhat leathery solid containing up to 90% of a **hydrocarbon,** gutta. On heating, it becomes plastic and is very resistant to water. It is therefore much used as insulation for marine cable and electrical equipment, as well as in the manufacture of golf balls and in dentistry. The cheaper balata is also used in the manufacture of beltings. (R.M.W.)

GUTTATION. The loss of liquid water from intact plants is called guttation. This process should not be confused with **transpiration** which is the loss of water vapor. Guttation occurs most commonly from the leaves, the exuded drops of water appearing at the tips or margins of the leaves. The water is not pure but contains traces of sugars and other solutes. Guttation occurs through distinctive structures called hydathodes or water stomates. In external structure a hydathode resembles an enlarged **stomate.** In temperate regions guttation can most often be observed on cool, late spring mornings following a warm day. Exuded drops of water can be observed at the margins or tips of many, but by no means all, kinds of herbaceous plants at this season. The exudation of water is believed to result from a root pressure (see **Ascent of Sap**) which is imposed on the sap in the xylem ducts. The drops of water exuded in this process are often erroneously considered to be dew. The quantities of water lost by most species of plants in guttation are negligible compared with the quantities lost in transpiration. (B.S.M.)

GWYNIAD. Pisces, Teleostei. *Coregonus.* A whitefish (**Pisces**) of the English lakes. (A.W.L.)

GYMNOLAEMATA. **Bryozoa.**

GYMNOPHIONA. A class of **amphibians** made up of legless burrowing species which resemble worms or small snakes. They live in the tropics of South America and the Old World. About 40 species are known. (A W.L.)

GYMNOSPERMS. The Gymnosperms form one of the two main divisions of the seed plants or **Spermatophytes.** The characteristic feature of the Gymnosperms is the occurrence of the **ovule** on the surface of the scale which bears it, and not surrounded by the **ovary** wall. In most Gymnosperms the reproductive bodies are borne in cones. The overlapping scales of the ovulate cones protect the developing **embryo** and cover the seed until it is mature.

The Gymnosperms are the most primitive of seed plants. Arising early in geological time, these plants became abundant and widespread in the **Carboniferous** period. From that period to the present gymnosperms have decreased in numbers, many groups becoming entirely extinct. Today there are about 500 species of Gymnosperms, occurring in nearly all sections of the world, but attaining their greatest development in the temperate zones. There they often form a dominant forest tree, with a comparatively small number of species, but many individuals. Other species occur in small isolated groups of few individuals occupying a very limited area.

Gymnosperms are woody plants. The majority of them are trees, which often attain immense size, being among the largest known plants. A few are low shrubby plants, and a very small number of vine-like species exist. Nearly all Gymnosperms are plants of xerophytic habit, that is, fitted to survive in regions in which water is not abundant. Some, like *Welwitschia* of the arid deserts of southwestern Africa, live in regions where the annual rainfall is but a fraction of an inch.

The living orders of Gymnosperms are the **Cycads,** Ginkgo, the **Conifers,** and the Gnetales. The last order, composed of three genera of widely different habit, has no single distinguishing feature, except the presence of vessels in the secondary wood. The three genera are: 1. ***Gnetum,*** a genus of tropical Africa, most of whose species are lianas, growing over other plants. A few are trees or shrubs. 2. ***Welwitschia mirabilis,*** a most striking odd plant growing in deserts of southwestern Africa. The plant has a large turnip-shaped stem which tapers into a long slender taproot which goes deep into the ground to reach the water table. It has two thick leathery leaves which last throughout the life of the plant, growing at the base as they wear away at the tip. 3. ***Ephedra,*** comprising low much-branched shrubs found in desert regions of Africa and America. ***Ephedra*** yields the drug ephedrine, a crystalline alkaloid which is used to give relief to sufferers from asthma and hay fever. (See also **Paleobotany.**) (R.M.W.)

GYMNOSPORE. Asexual reproductive cells which are capable of active locomotion by amoeboid movement or by **cilia or flagella.** (A.W.L.)

GYMNURA. Mammalia, Insectivora. Small animals of Burma, the Malay Peninsula, and adjacent islands. They resemble the shrews in appearance, with a sharp nose, long tail like that of a rat, and short legs. The name is that of a genus but is also used as a common name. (A.W.L.)

GYNANDROMORPH. An abnormal individual whose body shows the characteristics of the two sexes in different parts. Not synonymous with **hermaphrodite** although this term is sometimes applied to these abnormalities.

Gynandromorphs are fairly common among the insects, where they are often of the bilateral type. Such individuals have one side of the body male and the other female, with a sharp boundary in the median line. Mosaic gynandromorphs present an irregular distribution of the sexual characters. (A.W.L.)

GYNECOLOGY. That branch of medicine and surgery which covers diseases of women related to the genital organs and associated structures. (R.S.M.)

GYPSUM. The mineral gypsum is hydrous **calcium** sulfate, $CaSO_4 \cdot 2H_2O$. It occurs as flattened **monoclinic** crystals, often twinned, transparent cleavable masses, called selenite, or silky and fibrous, called satin spar; it may also be granular or quite compact. It is a soft mineral, hardness 1 5–2; has two good cleavages which yield rhombic plates whose angles are 66° and 114°. Its specific gravity is 2.31–2.33; luster vitreous to silky or pearly; color, colorless to white and gray, may be tinted red, yellow, blue, brown, etc, by impurities; transparent to opaque. A very fine-grained white or lightly tinted variety of gypsum is called alabaster, and prized for ornamental work of various sorts. Gypsum is a very common mineral, thick and extensive beds of which are associated with **sedimentary rocks.** The largest deposits known occur in strata of **Permian** age. Besides being a result of deposition in sea and lake waters, gypsum has been deposited by hot springs, from volcanic vapors, and by sulfate solutions in veins. Notable foreign localities for gypsum are in Greece, Czechoslovakia, Austria, Saxony, Bavaria, Italy, France, Spain, England and Mexico. In the United States well known localities are at Lockport, New York; the Mammoth Cave, Kentucky; Ellsworth, Ohio; Grand Rapids, Michigan; Hermosa, South Dakota; Wayne County, Utah; and San Bernardino County, California. In Canada the Provinces of New Brunswick and Nova Scotia have large gypsum deposits. The word gypsum is derived from the Greek meaning to cook, in reference to the burnt or calcined mineral. Because the gypsum from the quarries of the Montmartre district of Paris has long furnished burnt gypsum used for various purposes this material has been called plaster of Paris. (E.S.C.S.)

GYPSY MOTH. Insecta, Lepidoptera. A **moth,** *Porthetria dispar,* introduced from Europe and now a serious pest in the northeastern United States. The caterpillars are able to defoliate shade and forest trees and also attack apple and sometimes the conifers. The

damage and control are the same as in the case of the **brown-tail moth.** (A.W.L.)

GYRO COMPASS. **Compass.**

GYRO PILOT. **Compass.**

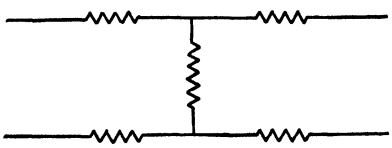
GYROCOTYLIDEA. **Cestoda.**

GYROSCOPE. A gyroscope is a heavy wheel or disk which may be set into rapid rotation and, because of the conservation of its angular **momentum,** serves to illustrate in various ways the tendency of rotating bodies to maintain a fixed axis of rotation or to exhibit **precession.** In its usual form the "gyro," or rotating disk, is mounted in a ring so that it can be handled while spinning; and this is frequently hung in a second ring or frame to form gimbals. In this case the outer ring or frame may be moved or turned in any manner, without bringing to bear a torque tending to change the direction of the axis of rotation.

The complete theory of the gyroscope is far too complex to be included in a work of this character and reference must be made to advanced texts on mechanics. (See **Instruments, Aircraft.**) (L.D.W., W.K.G.)

H

H SECTION. In many circuits, particularly in the telephone field, it is necessary to have both sides of a circuit balanced to **ground** to reduce the effect of interfering influences (see **Inductive Interference**). This is accomplished by dividing any series impedance into two equal parts and inserting one in each line, rather than putting the total amount in one line. (See figure.) (L.R.Q.)



HABIT. As used by the mineralogist, this term denotes the sum of the external characteristics of a mineral. It is also, but more rarely, applied to rocks. (R.M.F.)

HACHURE. A short line drawn parallel to the slope as a means of illustrating topography on a map. (R.M.F.)

HACKLY. Used by mineralogists to describe a jagged **fracture.** (R.M.F.)

HACKSAW. Saw.

HADDOCK. Pisces, Teleostei. An important marine food fish, *Gadus aeglefinus,* taken on both sides of the Atlantic. It is closely related to the cod. Usually dried and smoked for the market. (A.W L.)

HADE. Fault.

HAEMATOXYLIN or **LOGWOOD.** *Haematoxylon campechianum.* Leguminosae. Logwood is obtained from a small tree which is native in Central America, but has been extensively planted in the West Indies and South America. The tree, seldom more than 25′ tall, has **pinnately** compound leaves with smooth obovate leaflets, and fragrant yellow flowers in terminal **racemes.** The fruit is a dry 2-seeded pod.

The wood is very hard and yellow; on exposure to air it turns red. It has a rather pleasant odor. To obtain the dye the sapwood is cut away and the heart wood cut up into chips. From these chips the dyestuff is extracted. Logwood dye is used to color cottons, woolens, silks and leathers. To make the dye **mordants** must be added, in this case the salt of some metal, usually iron. Haematoxylin is also used in the making of **inks,** and as a histological stain in the preparation of organic tissues for microscopic examination. Following ferric ammonium sulfate, as a mordant, it is an excellent dye for chromosomes. Small quantities are used medicinally, in the form of extracts of the wood, in cases of chronic diarrhea. It is also a mild astringent. The active principle in this case is tannin, not the dye. (R.M.W., B.S.M.)

HAEMOCOELE. A cavity in which blood or haemolymph circulates. Well developed in the **arthropods** and **mollusks** where it superficially resembles a true body cavity. It is associated with some tubular blood vessels whose contractions propel the blood in it, and these movements are supplemented by the shifting of its contents as a result of body movements. (A.W.L.)

HAEMOCYANIN. A **protein** containing copper which combines readily but unstably with oxygen and serves as a respiratory medium. It occurs in the blood of **arthropods** and **mollusks.** When oxidized it is bluish in color. (A.W.L.)

HAEMOGLOBIN. Hemoglobin.

HAEMOLYMPH. The **blood** of higher **invertebrates,** consisting of a clear plasma and white cells but without red cells. Respiratory pigments are dissolved in the plasma. It contains a lower percentage of water than the blood of more primitive forms. (A.W.L.)

HAEMOSPORIDIA. Sporozoa.

HAFNIUM. Symbol: Hf. Atomic number: 72. Atomic weight: 178.6. Melting point: 1700° C. (**Isotopes:** page 290.)

Hafnium is similar in chemical properties to zirconium, but separable from the latter by repeated fractional crystallization of the double **potassium** fluoride (K_2HfF_4), which collects in the mother liquor, from potassium zirconium fluoride which collects in the crystals. Discovered by Coster and Hevesy in 1922 in the mineral **zircon** of Norway by the Moseley **x-ray** spectrographic method of analysis, and later found to be present in almost all **zirconium** minerals and chemicals (most of these containing about 5% Hf in the zirconium).

The use of hafnium metal in lamp filaments and radio tubes has been proposed.

Oxide: Hafnium oxide (HfO_2), white. (R.K.S.)

HAGFISH. Cyclostoma.

HAIL. A precipitation is often called hail if it is in the form of lumps or pellets of ice. Strictly, the term should be applied only to the globose or sometimes irregular masses which fall at the beginning of a thunderstorm in hot weather. The most typical hailstones are somewhat oblately spheroidal and of the size of a hazelnut, though very rarely they attain a diameter of 2 or 3″ or larger. When broken, they reveal a structure of concentric alternate layers of clear and opaque white ice.

The fact that true hail never occurs except during a violent thunderstorm indicates that wind plays an essential rôle in its formation. It seems probable that hailstones have their origin in those vortices or whirlwinds in whose interior masses of cloud-laden air rush upward with great speed and then circle downward outside, only to be drawn inward and upward again, like a gigantic smoke-ring. The lower part of such a thundercloud may be composed of raindrops and the upper part of snow crystals. A raindrop, blown upward into the colder region, freezes and collects a layer of snow, then descends to have more water frozen upon it, then upward for more snow, and so on, until it finally becomes too heavy to circulate further, and falls. Often several hailstones freeze together into a shapeless, nodular mass. Large hailstones, naturally, are somewhat dangerous and often very destructive. (See **Hydrometeors.**) (L.D.W.)

HAIRSTREAK. Insecta, Lepidoptera. Small **butterflies,** those of the temperate zone dull-colored and those of the tropics often brilliant. The hind wings of

most species bear hair-like tails. With the coppers and blues they make up the family Lycaenidae. (A.W.L.)

HAIR-TAIL. Pisces, Teleostei. Predacious fishes, (**Pisces**), chiefly tropical, whose bodies taper at the posterior end to a slender point. They are long, slender, scaleless, and have the fins reduced excepting a long dorsal and the pectorals. (A.W.L.)

HAIRWORM. Nemathelminthes, Nematoda. Long slender roundworms of small size which live as parasites in the bodies of **invertebrates,** chiefly insects. (A.W.L.)

HAKE. Pisces, Teleostei. Inferior marine food fishes (**Pisces**) related to the cod. Both sides of the Atlantic and colder waters of southern hemisphere. The squirrel hake and white hake are also called codling and the silver hake, *Merluccius bilinearis,* is known as the whiting or stockfish. (A.W.L.)

HALATION. The halo which is sometimes observed in photographic images of bright objects, or sources of light, is known as halation when due to light reflected back into the emulsion from the rear of the support. Ordinarily, the halo produced by halation is indistinguishable from that due to the spreading of light within the emulsion which is known as irradiation. The size and density of the halo, when due to halation, increase with the exposure and the degree of development and decrease with an increase in the turbidity and thickness of the emulsion.

Halation can be almost entirely prevented by placing a light-absorbing layer either on the back of the support or between the emulsion and the support. Light-absorbing layers of this type are termed *backings.* Dyes which are decolorized by the sulfite in the developer have replaced the old mixtures of lamp black and similar materials which had to be removed by washing in water and discolored the developer so that it could no longer be used.

The tendency of negative materials to show halation may be lessened by incorporating a gray dye in the film support, or by double coating, first with a slow- and then with the regular high-speed emulsion. The first of these methods is used for certain motion-picture negative materials and the latter, in conjunction with a backing, for professional sheet film. (C.B.N.)

HALF-VALVE PERIOD. **Decay Coefficient.**

HALF-WAVE. **Rectifier Circuits.**

HALIBUT. Pisces, Teleostei. A large **flatfish,** *Hippoglossus,* reaching a length of 6′ and a weight of 400 lbs. Found in all of the northern seas.

The flesh of the halibut is inferior to that of some of the smaller flatfishes but the species is valuable as a source of vitamins. Halibut-liver oil is reported to be about 10–30 times as rich in vitamin D and 80 to 200 times as rich in vitamin A as cod-liver oil. (A.W.L.)

HALITE. **Rock Salt.** The mineral halite is naturally occurring **sodium** chloride, NaCl, common salt. It is isometric with cubic habit and cleavage. It is brittle; hardness, 2.5; specific gravity, 2.4–2.6; luster, vitreous; colorless when pure, but usually white, yellow, red or blue. It is soluble. Halite occurs interbedded with sedimentary rocks in all parts of the world and in all but the very oldest rocks. It frequently occurs in association with **anhydrite** and **gypsum.** In the United States this type of "salt beds" have been exploited in Michigan, New York, Ohio and Pennsylvania. Louisiana produces salt from great sub-surface dome-shaped masses often 2000–4000′ thick. The salt domes of the Gulf Coastal Plain are particularly important as subsurface structures on the flanks of which are apt to occur large and important pools of **petroleum.** Poland, Saxony, Austria and France possess well known deposits of salt as well as Russia, England, Algeria, India and China. Salt is chiefly used in cooking and as a preservative; in the manufacture of soda ash for the glass industry, and as a source of many **sodium** compounds. It derives its name from the halogen group of elements to which **chlorine** belongs. (R.M.F.)

HALL EFFECT. In 1879 Hall, at Johns Hopkins University, discovered that if a strip of gold-leaf, carrying an **electric current** longitudinally was placed in a **magnetic field** with the plane of the strip perpendicular to the direction of the field, points directly opposite each other on the edges of the strip acquired a difference of electric potential, and that if such points were joined through a sensitive galvanometer a feeble current would be indicated. In other words the equipotential lines, ordinarily running across at right angles to the edges, were skewed into an oblique position, and the electric lines of flow in the plate were deflected to one side.

If one looks along the strip in the direction of the current, with the magnetic field directed downward, then with strips of antimony, cobalt, zinc, or iron the electric potential drop is toward the right and the effect is said to be positive; while with gold, silver, platinum, nickel, bismuth, copper, and aluminum, it is toward the left and the effect is called negative. The transverse electric potential gradient per unit magnetic field intensity per unit current density is called the "Hall coefficient" for the metal in question. A special case known as the "Corbino effect" occurs when a circular disk carrying a current radially is placed at right angles to a magnetic field; the result being a current component around the disk.

The Hall effect as first observed, in gold, agrees in direction with the lateral thrust on current-carrying armature conductors in a motor, and suggests the identity of these phenomena. But this explanation is upset by the reverse action in some metals, and is further complicated by many other experimental facts. At present the Hall effect cannot be said to be fully understood. (See **Ettingshausen, Nernst,** and **Righi-Leduc Effects.**) (L.D.W.)

HÄLLEFLINTA. A Swedish term for hard, dense **metamorphic** rocks composed chiefly of microscopic crystals of quartz and feldspar with occasional **phenocrysts.** Accessory minerals may be **hornblende, chlorite, hematite** or **magnetite.** The texture and composition of hälleflinta suggests that it is the metamorphosed equivalent of **acid** lava flows or **tuffs.** (R.M.F.)

HALLER'S ORGAN. Sense organs of uncertain function borne on the anterior legs of some **ticks.** (A.W.L.)

HALLEY'S COMET. This is probably the most famous of all the **comets** and is deserving of special mention. The general subject of comets is discussed elsewhere, and this article, therefore, will confine itself to Halley's comet alone.

Halley's comet is of special interest because of the fact that it was the first comet whose return was predicted. When Halley computed the **orbit** of the great comet observed in 1682, he found the elements to be almost identical with those of prominent comets observed and studied by Kepler in 1607 and by Apian in 1531. He noticed that the interval between 1531 and 1607 was not exactly equal to the interval between 1607 and 1682, but suspected that the difference might

be due to attractions by other planets. He was unable to predict just what effects the attractions of Jupiter might produce on the next return, but suspected that they would retard it and predicted the return for the early part of 1759. In the meantime, mathematical astronomy had developed to such a point that April, 1759, was predicted by Clairaut. The comet actually came to **perihelion** on March 13th of that year. At the next return in 1835, the predicted date of perihelion differed from the observed date by only 2 days, and for the return in 1910 the agreement was practically perfect.

Extensive calculations made by Crommelin and Cowell after the observations in 1910 carried the dates of perihelion passages back through the centuries. Examination of ancient records prove that the comet was observed and recorded at every perihelion passage back to 87 B.C. In some cases, the descriptions are complete enough to prove, both that the comet has always been a striking object and also that the ancient records were surprisingly accurate as to position of the comet.

Due to **perturbations** of the planets the periods between successive perihelion passages have varied considerably. The average is about 77 years. Historians have, at times, attempted to use observations of comets as a means for fixing dates, employing the hypothesis that any bright comet appearing at about the correct date was Halley's. This is a very dangerous practice for there have been many others of as equally striking appearance as Halley's and their appearances were always noted.

At the return in 1910 the comet was first picked up by Wolf at Heidelberg on September 11, 1909, when it was 310,000,000 miles from the sun, and it was followed photographically until July 1, 1911, when it was 520,000,000 miles from the sun. When close to perihelion it was a magnificent object, particularly during the early part of May, when it was observed in the morning sky. On May 19th, about a month after perihelion passage, the comet passed directly between the earth and the sun, but no change in the brightness of the sun could be observed even with the most delicate instruments. At one time the tail of the comet extended across the sky for a distance of nearly 120°, appearing as a broad bright band much like the milky way. On May 21st the earth certainly grazed the tail of the comet and probably passed through it.

In 1949 the comet will reach its greatest distance from the sun, being at that time more distant than the planet **Neptune.** It should return to perihelion on April 29, 1986. (W.K.G.)

HALLUCINATION. A mental state in which sensory impressions are not based on reality. The sensory impressions may be of sight, hearing or smell. Hallucinations are most frequently seen in some forms of acute **alcoholism, opium,** and **cocaine** habituation, delirium from high fever and in certain forms of insanity.

An hallucination should not be confused with (1) a delusion, which differs in being a false belief, not correctable by reasoning or evidence of the senses, or (2), an illusion—a false interpretation of a sensory image. (R.S.M.)

HALO. This term applies to a class of phenomena observed in the sky in connection with the **sun** (or sometimes the **moon**) and due to particles of frost suspended in the air. The minute spicules of ice, in falling, take some definite attitude determined by their shape. Some are needle-like and assume a horizontal position, some are flat disks or stars and fall with their planes horizontal, while others, made up of both disks and rods, behave like a parachute. The sunlight is refracted by each type in a characteristic manner and dispersed into colors; it is also reflected from their external surfaces without dispersion. The most commonly observed effects are: the colored parhelia (commonly called "sun dogs") on a level with the sun and 22° each side of it; a 22° halo passing through the parhelia; a 46° halo, usually faint; and certain other appended arcs or partial halos due to refraction and reflection by the variously oriented crystals.

In addition to these phenomena may be mentioned the colored rings, called coronae, often surrounding the sun or moon. These are due to **diffraction** by particles of fog or mist. The diameter of the **corona** is greater, the smaller the fog particles. (L D.W.)

HALOGENS. The chemical elements **fluorine, chlorine, bromine,** and **iodine.** (R.K.S.)

HALTERE. The vestigial hind wing of a 2-winged fly (**Insecta, Diptera**). In this order the 2-winged condition is due to the loss of the hind wings as organs of flight. They persist, however, as small knobbed organs, in some species large enough to be seen with the naked eye just behind the bases of the functional wings. They contain sense organs, and both static and chordotonal functions have been attributed to them. The evidence seems inconclusive. (A.W.L.)

HALYS. Reptilia, Sauria. Asiatic vipers of several species, related to the copperhead and water moccasin of North America. One small species of Ceylon and India is called the carawila. (A.W.L.)

HAMADRYAD. Cobra.

HAMMER. Sheet Metal Processes; Forging; Press Working.

HAMMERHEAD. Pisces, Plagiostomi. *Sphyrna.* Large **sharks** of the tropical seas. The head is greatly widened to form lateral projections bearing the eyes. (A.W.L.)

HAMSTER. Mammalia, Rodentia. Burrowing animals of Europe and Asia. The common hamster, *Cricetus,* attains a length of 1′. It is sometimes extremely numerous and is then a serious pest to the farmer. It damages crops of all kinds. The flesh is eaten and the fur is useful, although not of high quality. (A.W.L.)

HAND. The terminal portion of the pectoral appendage of **mammals,** developed for grasping and in some species largely freed from locomotor uses. True hands appear only in the **primates.**

The skeletal structure of the hand includes the series of five bones, the metacarpals, which attach it to the wrist, and the five divergent series of phalanges located in the digits. Of the digits, one, the thumb, is placed and articulated so that it can be opposed to the other four, which are fingers. As a result the appendage can be used for grasping like a forceps and also as a prehensile organ by folding the fingers back against the palm. In some of the monkeys the prehensile method of grasping is more important in moving through the trees and the thumb has shifted and become smaller so that it can no longer be opposed.

The human hand is the most versatile grasping organ in the animal kingdom and has been of primary importance in the manufacture of tools and machines, and distinguishes man from all other living things. (A.W.L.)

HAND SET. This is the part of the modern telephone which contains the transmitter and receiver, i.e., the part which the user holds when talking. While this placing of transmitter and receiver on the same handle seems

a rather insignificant accomplishment, the necessity of avoiding **feedback** from the receiver into the **transmitter** makes very careful acoustical design necessary. In addition the electrical and mechanical construction of the transmitter must be such that it can be operated in almost any position as the user will hold the instrument in innumerable positions. (L.R.Q.)

HANGER. **Bearings.**

HANGING VALLEY. Under normal conditions a tributary stream enters the main stream at grade, that is, at the same level. Under certain circumstances the tributary valley may be at a greater elevation than the main valley into which the tributary stream will plunge, forming a waterfall. In such cases the tributary valley is called a hanging valley, and the stream in it is said to be out of adjustment with the main stream.

Hanging valleys originate in the following ways: by glacial action, the main glacier cutting down its valley faster than a tributary glacier; by river action, the main stream eroding its bed faster than the tributary stream; by **faulting**, the tributary stream flowing off the upthrown block. A fourth type of hanging valley, much less common, may result from a stream plunging over wave-cut cliffs or other escarpments into a lake or ocean basin. (R.M.F.)

HANGING WALL. The use of this term in geology is discussed in the article on **Fault.** (R.M.F.)

HANGNEST. Aves, Passeriformes. A group of birds (**Aves**) whose nests are woven of vegetable fiber, grass, and hair, and are suspended from small branches. The Baltimore **oriole** is a common North American species. Others occur from the southwestern states to Brazil. (A.W.L.)

HANUMAN. **Langur.**

HAPALOPS. **Miocene.**

HAPLOSPORIDIA. **Sporozoa.**

HARD COAL. **Coal.**

HARD FACING. Deposition of a hard wear resistant alloy on a metal surface. The material to be deposited is generally in the form of a welding rod and may be applied by gas or arc **welding.** Such surfaces are usually finished by grinding.

While hard facing or hard surfacing is usually a maintenance operation, it is also used in new production. The surfacing material may be **cemented carbides,** nonferrous Stellite-type alloys, or iron-base alloys with alloying additions such as chromium, tungsten, manganese, silicon, nickel, and carbon. While hard facing is most often applied to **steel, cast iron** and some of the non-ferrous alloys such as **Monel metal** can also be coated. Typical applications are metal-working dies, oil well drilling tools, excavating equipment, shafting, and rolling mill rolls. (R.H.H.)

HARDENABILITY OF STEEL. The hardenability of **steel** refers to the ease with which it can be hardened rather than the maximum **hardness** value attainable. For example, a 1-in. diameter bar of a certain 0.20% carbon alloy steel can be hardened to 50 Rockwell "C" in the center by **quenching in oil.** A similar bar of plain carbon steel requires a drastic quench in brine to attain the same hardness, and therefore, has a lower **hardenability.** Neither bar can be quenched to a greater **hardness** because 50 Rockwell "C" is the maximum attainable for a 0.20% carbon steel. A 0.40% carbon steel can be hardened to a maximum of about 60 Rockwell "C" and the maximum for high-carbon steel is about 65 Rockwell "C."

Of the several methods for determining the relative hardenability of steels, the Jominy test is the most widely used. A cylindrical specimen 1" in diameter and about 3" long is heated to the hardening temperature and quenched in a special fixture which holds the specimen in a vertical position and directs a stream of water on the bottom surface. The stream takes an "umbrella" shape and does not wet the sides. Cooling occurs progressively from the bottom to the top of the cylinder and the cooling rate at any distance from the bottom is known and reproducible from one sample to another. The hardness along the length of a quenched Jominy bar decreases from bottom to top. The distance from the bottom, expressed in sixteenths of an inch, to the point where the hardness is 50 Rockwell "C" is one method of reporting the hardenability.

One of the principal functions of alloying elements in steel, such as manganese, chromium, nickel, molybdenum, etc., is to increase the hardenability. Whereas prodigious amounts of expensive alloys were formerly used to insure full hardening, especially in medium and heavy sections, wartime shortages have focused attention on the use of as little alloy as possible within the hardenability requirements. A large number of National Emergency Steels have been developed containing relatively small additions of a number of elements, thus utilizing the residual alloy contents normally present in much of the steel scrap now available. (R.H.H.)

HARDENING OF METALS. There are three principal methods of hardening metals and alloys, **cold working** by plastic deformation, **precipitation hardening,** and **heat treating** as applied to steel. The last two methods involve heating and cooling operations. Alloying itself is a hardening process since an alloy addition generally hardens a pure metal. (R.H.H.)

HARDENING OF THE ARTERIES. **Arteriosclerosis.**

HARDIE. **Forging.**

HARDNESS. The significance of this term as applied to solids has various interpretations. Commonly, it refers to the resistance of the substance to surface abrasion, so that of two solids, the one that will scratch the other, as diamond scratches glass, is the harder. Again, it may denote rigidity, or lack of plasticity, or even strength; in some cases a combination of several such properties. The Mohs' Scale of Hardness, used by mineralogists, is as follows: 1. Talc (softest). 2. Gypsum. 3. Calcite. 4. Fluorite. 5. Apatite. 6. Orthoclase. 7. Quartz. 8. Topaz. 9. Corundum. 10. Diamond (hardest). Example: If a mineral can be scratched by orthoclase and will not scratch apatite its hardness is between 5 and 6.

In metallurgy and engineering hardness is determined by methods based on resistance to penetration by an indenter of greater hardness than the material being tested. Aluminum, copper, lead, magnesium, tin, and their alloys as well as plastics are generally indented by hardened steel balls ranging in size in the various tests from 1/16" to 10 mm. in diameter. The same methods may be used for soft steels and irons, but for heat-treated steels and all other alloys which develop high hardness special diamond indenters, or in some cases sintered tungsten carbide balls, are used. In all of the technological tests the indenters are impressed into the test material under carefully regulated loads; thus the relative size of the resulting indentation becomes a measure of hardness. The operating principles of the instruments most widely used in this country follow:

Brinell. The indenter is a 10-mm. diameter hardened steel ball. A sintered tungsten-carbide ball is also coming into use, especially for testing hard metals. The load applied is generally 500 kg. for soft metals and 3000 kg. for steels and hard metals. Brinell hardness is equal to the load (kg.) divided by the surface area (sq. mm.) of the impression made in the test material. Tables are available for direct conversion to hardness from the diameter of the indentation as measured with a calibrated magnifier after removal of the piece from the testing machine.

Rockwell. Indenter is 1/16"-, 1/8"-, or 1/4"-diameter steel ball or a conical diamond having an apex angle of 120° and a slightly rounded point. The various scales used are designated by letters. Rockwell "B," for example, indicates a 100-kg. load on a 1/16"-diameter ball. Rockwell "C" indicates a 150-kg. load on the diamond indenter. Rockwell "30T" designates a load of 30 kg. on a 1/16"-diameter ball. (An instrument of higher sensitivity known as the Rockwell Superficial Tester is used for loads of 15, 30, and 45 kg.) The size of the indentation is measured by a **dial gauge** as the final depth minus a small preliminary penetration produced by a minor preload of 10 kg. The Rockwell hardness values are arbitrary numbers having an inverse relationship to the depth of the indentation.

Vickers. Also known as Diamond Pyramid Hardness. Indenter is a square-based diamond pyramid with included angle between faces of 136°. Loads may vary from 1 to 120 kg. with 10, 30, and 50 kg. in common use. Hardness is equal to load (kg.) divided by surface area (sq. mm.) of the permanent indentation. It is determined directly from optical measurements of the diagonals of the indentation which appears square at the surface of the metal.

Tukon. A recently developed instrument for determining hardness under very light loads down to 25 grams. The small indentations are measured at high magnifications up to 1000 times. The indenter is a diamond pyramid that makes an elongated impression, one diagonal being 7 times the other in length.

Eberbach. Also used for very light loads. Consists of a spring-loaded, Vickers-type diamond pyramid indenter arranged for use on a metallurgical microscope.

Scleroscope. Depends on the height of rebound of a diamond-tipped body falling under the force of gravity from a fixed height. The instrument is relatively small and is portable. One type reads directly on a graduated dial.

While there is overlapping in the field of useful application of the various hardness tests, each has certain special qualifications. The Brinell test makes a large indentation, giving an average hardness value for several grains even in rather coarse-grained metals; however, it cannot be used on small or thin specimens. The various Rockwell tests are widely used, especially for rapid production inspection of parts. The Vickers test, which originated in England, is less rapid than the Rockwell but has the advantage of a single scale covering the hardness of all metals from lead to the hardest tool materials. The Tukon test makes it possible to determine the hardness of very thin sheets and of thin metallic coatings such as chromium plate, or zinc on galvanized steel. The Scleroscope test is used principally on heavy forgings or castings which cannot be placed in an indentation-type instrument, or for field tests where a portable instrument is required. It is less accurate than the indentation-type instruments. An instrument known as the King Brinell, employing the standard Brinell principle, is also available in portable form for shop or field tests.

It is often desirable to be able to convert from one hardness scale to another. Unfortunately, no single set of conversions is accurate for all materials.

TYPICAL HARDNESS VALUES

Material	Brinell 500 kg.	Brinell 3000 kg.	Rockwell	Vickers 50 kg.
Aluminum, annealed	23		H 45	25
Magnesium alloy	63		B 21	63
Armco iron	66	73	B 31	71
Yellow brass, annealed	72	82	B 40	77
Copper, cold rolled	99	83	B 55	110
Mild steel, annealed	107	117	B 70	123
Aluminum alloy, 24st	130	144	B 78	146
Stainless steel, annealed	121	145	B 80	153
Yellow brass, cold rolled	174	178	B 91	189
Ni-Moly steel, quenched in water, tempered at 1200° F.		241	C 23	255
Same, 1000° F.		293	C 31	310
Same, 800° F.		363	C 38	380
High speed tool steel		684	C 62	740

(L.D.W., R.M.F., R.H.H.)

HARD-PAN. The term which prospectors and miners give to the sub-surface or basal layers of placer deposits in which the gold-bearing gravels have been cemented and hardened. The same term is also used to designate till or boulder clay which has been cemented by **limonite.** (R.M.F.)

HARE. Mammalia, Rodentia. Rodents (**Rodentia**) with long ears, large hind legs and small front legs, and a very short tail. Adapted for speed and for jumping. The Old World species burrow and those of the New World often occupy holes in the ground although they do not burrow. The rabbits and hares belong to the same genus and the two names are not sharply distinct. The North American species are more commonly called rabbits but the white or snowshoe rabbit of the north is also called the varying hare, and the white-tailed jack rabbit is known as the prairie hare. Hares are indigenous to all continents except Australia.

Among the domesticated species of hares and rabbits many breeds have been developed. These animals are kept for pets and as a source of meat. They are also valuable laboratory animals in medical science and have been used in the study of heredity. The fur is fine and soft but the pelts are relatively weak. They are valuable for linings and when sheared and dyed are used in inexpensive garments. Rabbit fur is also used in making felt. (A.W.L.)

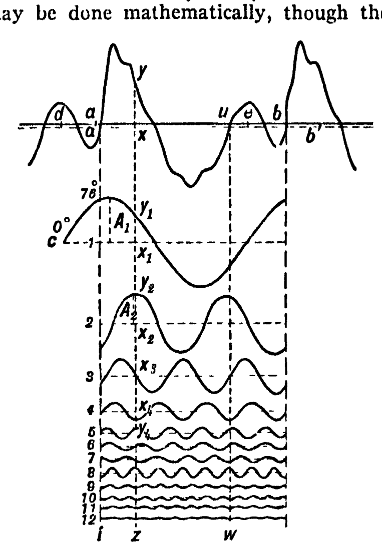
HARELIP. A congenital deformity in which there is a failure of fusion of the maxillary and globular processes resulting in a cleft in the upper or lower lip. It is more common in the upper lip and may be associated with a cleft palate. It may be double, in which case there is a division on either side of the mid line of the lip. The treatment is surgical. (D.M.H.)

HARMONIC ANALYSIS. Not only is it possible to combine two or more simple **harmonic motions** of different period, amplitude, and phase to form a complex motion, but there are also means of analyzing the resultant motion, when the latter is given, to find its component harmonics. For example, if the wave form of such a complex tone as that produced by a bell or a saxophone is accurately graphed by means of a phonodeik (see **Vibrations and Waves**, and **Musical Sounds**), the equation of the vibratory motion can be deduced in such form as to show the separate components. Fourier showed that the same analysis is possible for any periodic motion, however complicated. The equation, called **Fourier's series,** may be written

$$y = a \sin 2\pi nt + b \cos 2\pi nt + c \sin 4\pi nt + d \cos 4\pi nt + e \sin 6\pi nt + f \cos 6\pi nt + \cdots,$$

in which y is the displacement of the vibrating particle and t is the time. The fundamental frequency n and the constants a, b, c, d, etc., must be calculated from the given wave form or the data from which it is plotted.

There is a type of instrument, called a "harmonic analyzer," which automatically computes the coefficients; or it may be done mathematically, though the process



Records of a complex sound and twelve of its components. (*D. C. Miller.*)

is very laborious. The accompanying figure shows the wave form and the twelve components of a complex tone, analyzed by Professor D. C. Miller. (L.D.W.)

HARMONIC CURVE. By a harmonic curve is usually meant a curve whose equation is of the form $y = a \sin nx$ or $y = a \cos nx$. (L.L.S.)

HARMONIC DIVISION OF A LINE-SEGMENT. A line-segment is said to be divided harmonically by two points if these two points divide the segment internally and externally in the same ratio. The two points of division are called harmonic conjugates. (L.L.S.)

HARMONIC FUNCTIONS. A harmonic function is any real **function** u which satisfies **Laplace's equation** $\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2} = 0$, and which, together with its first and second **partial derivatives,** is **continuous** and single-valued throughout a certain region. (See also **Laplace's Equation.**) (L.L.S.)

HARMONIC LAW. **Keplerian Laws.**

HARMONIC MEAN. Given the N positive **variates** $x_1, x_2, x_3, \cdots, x_N$, the harmonic mean, H, is defined as the reciprocal of the **arithmetic mean** of the reciprocals,

$$\frac{1}{H} = \frac{\frac{1}{x_1} + \frac{1}{x_2} + \cdots + \frac{1}{x_N}}{N}.$$

The arithmetic mean of N unequal positive variates is greater than the **geometric mean** which in turn is greater than the harmonic mean. The harmonic mean is used in time and rate problems. (L.A.A.)

HARMONIC MOTION. A distinct type of periodic motion, or vibration, characteristic of elastic bodies; illustrated by a bird-cage bobbing up and down at the end of a spiral spring, or (approximately) by the piston of a steam engine. It may be either simple, with only one **frequency** and amplitude, or made up of two or more simple components and consequently of more complex character. The essential feature of simple harmonic motion is that, with its range extending to equal distances on both sides of an equilibrium position or origin, the **acceleration** is always toward the origin and directly proportional to the distance from it. With elastic vibrations this is easily seen to follow from Hooke's law, since the force tending to restore the deformed body to equilibrium is proportional to the deformation. (See **Elasticity.**) The motion is called "harmonic" undoubtedly because the vibrations of bodies emitting musical sounds are of this character. Any simple harmonic motion may be represented by the equation

$$y = a \cos (2\pi nt + \varphi),$$

in which y is the distance at time t, a is the amplitude, n is the frequency or number of vibrations per unit time, and φ is the phase constant, such that when $t = 0$, $y = a \cos \varphi$.

It is interesting to note the relationship between harmonic and circular motion. If a peg is inserted in the face of a circular disk or wheel and the latter uniformly rotated, the motion of the peg, as viewed with the wheel seen edgewise, is simple harmonic. In fact, uniform circular motion is made up of two simple harmonic components of the same period and amplitude at right angles, one being a quarter-period ahead of the other in phase. If the two harmonic components have a phase difference other than a quarter-period, the resultant in general is motion in an ellipse; while if they have unequal periods, the path is one of a class of more or less complicated loci called "Lissajous' curves." (L.D.W.)

HARMONIC PROGRESSION. A harmonic progression is a succession of numbers whose **reciprocals** form an **arithmetic progression.**

The harmonic mean between two numbers is the middle term of an harmonic progression whose first and last terms are the given numbers. The harmonic mean between a and b is given by

$$H = \frac{2ab}{a + b}.$$

If A, G and H are respectively the arithmetic, geometric and harmonic mean of two numbers, then $G^2 = A \cdot H$. (L.L.S.)

HARMONIC RINGING. This is a system of individual ringing used on party telephone lines. The bell or ringer armature is tuned mechanically to a certain frequency. Then if the coils are excited by currents of this same frequency the armature response is great due to the resonant effect while at other frequencies where the resonant gain is not present the response is too small to give any sound. When the bells of the several phones on the party line are each tuned to a different frequency selective ringing (i.e., the ringing of only the called party) is accomplished by using the proper frequency ringing current. Such a system is not needed on a two-party line but is increasing in use on multi-party lines. (L.R.Q.)

HARMONIC SERIES. The infinite series $\sum_{1}^{\infty} \frac{1}{n}$ is called the harmonic series. It is **divergent.** (L.L.S.)

HARMONICS, ELECTRIC. In a great many types of a-c generators there are present various overtones or multiple frequencies, all related by integral multipliers to the fundamental **frequency.** These higher frequencies are called harmonics of the lower or fundamental frequency. In power systems the only harmonics present are normally the lower odd-numbered ones, i.e., third, fifth, etc. Of these the third is by far the most common and hence the cause of the most trouble. Because of the non-linear relation between flux and mag-

netomotive force in iron most **transformers** draw third harmonic currents which in turn produce third harmonic voltage drops and losses. In a three-phase circuit these currents can flow out over the line wires and return over the neutral. If there is no neutral there can be no third harmonic current in the line wires and unless the transformer banks are connected with at least one set of windings in delta the induced voltages will not be sinusoidal, but will contain third harmonics. There are usually some harmonics present in the output of alternators because of non-sinusoidal flux distribution, tooth and slot effects, etc. Much of this can be reduced by proper coil layout and connection. These higher harmonics also cause appreciable telephone interference unless precautions are taken (see **Transposition**). Unless properly tuned many radio circuits will generate harmonics. In **frequency doublers**, etc., this characteristic is utilized to advantage, but normally these harmonics must be suppressed. In any event, it is undesirable to radiate any harmonic of the carrier from the **antenna.** Various circuit devices are used to suppress these unwanted frequencies but even then there is often some harmonic radiation which accounts for the reception of stations at double, triple, etc, their normal frequency. (L.R.Q.)

HARMOTOME. The mineral harmotome is a **zeolite,** composition approximately $(K_2Ba)Al_2Si_6O_{14}\cdot 5H_2O$; it is monoclinic but often forms double twins giving the effect of a square prism. It is a brittle mineral; hardness 4.5; specific gravity 2.44–2.50; luster vitreous; color, white to gray or perhaps yellow, red or brown; white streak; translucent. Harmotome like other zeolites is found in cavities in basalts and similar rocks, sometimes in **trachytes** or in **gneisses,** occasionally as a gangue mineral in veins of metallic minerals. Some well-known localities are in Bavaria, in the Harz Mts, Norway and Scotland. Harmotome occurs in the United States with stilbite, near Port Arthur, Lake Superior. The name harmotome comes from the Greek meaning joint and to cut, referring to the division of the pyramid formed by the prismatic faces of the mineral when in the twinned position. (E.S.C.S.)

HARPY. Aves, Falconiformes. *Thrasaëtus.* Large crested **eagles** related to the true buzzards. The several species range from Mexico to Patagonia. (A.W.L.)

HARRIER. Aves, Falconiformes. Moderately large **eagles** of several species, and a group of **hawks.** The harrier eagles are mostly limited to Africa but one species extends to Asia and Europe. The hawks are found in all continents They are slender birds with long wings, and in general are useful as destroyers of reptiles and rodents. The marsh hawk, *Circus hudsonius,* is a North American harrier. (A.W.L.)

HARTEBEEST. Mammalia, Artiodactyla. *Bubalis.* An African **antelope** with large ringed horns, irregularly spiraled with the tips pointing back. There are several species. (A.W.L.)

HARVESTMAN. Arachnida, Phalangida. Spider-like animals, most species with small oval bodies and extremely long slender legs. Those with shorter legs are more easily confused with the true spiders but all may be recognized by the segmented abdomen. Daddy longlegs. (A.W.L.)

HASHISH. Hemp.

HAUSEN. Pisces, Chondrostei. The giant **sturgeon,** *Acipenser nuso*, of the Mediterranean and the large rivers and inland seas of Europe and western Asia, also found on both sides of the Atlantic. Specimens weighing over 3000 lbs. are said to have been taken in the Volga River, although half that weight is large for the species. (A.W.L.)

HAÜY'S LAW. Crystallography.

HAWK. Aves, Falconiformes. Birds (**Aves**) of prey with hooked beaks and large curved claws, closely related to the eagles, falcons, harriers, and others and

Cooper's Hawk. (*American Museum of Natural History.*)

not sharply distinguished as a group Hawks are found on all continents. North America has many species, including **buzzards, harriers, goshawks** and other forms. Most of them are beneficial as destroyers of vermin but the sharp-shinned (*Accipiter velox*), and Cooper (*A. cooperi*) hawks destroy too many birds, including poultry, to be regarded as friends. (A.W.L.)

HAWK MOTH. Insecta, Lepidoptera. Large **moths** composing the family Sphingidae, one of the largest of the order. These moths have a long, rather stout body projecting beyond the narrow wings. The front wings are much longer than the hinder pair, and because of their limited surface they are vibrated rapidly in flight The moths have long tongues and visit deep-throated flowers. From their habit of hovering as they probe the flower for nectar they are also called hummingbird moths. Another common name is sphinx moth (A.W.L.)

HAWKSBILL. Turtle.

HAWTHORN. Rose Family.

HAY. Grass Family.

HAY FEVER. (Allergic Coryza.) This condition is one manifestation **allergy** seen in subjects who are hypersensitive to **pollens,** other airborne substances, and certain **foods.** It is characterized by an intense irritation of the membranes of the upper respiratory tract and the eyes. It is seen in two forms (1) the seasonal type which is due to pollens (2) the non-seasonal type which occurs in attacks throughout the year and is due to animal emanations, vegetable or seed powders, or ingested substances.

A common form of hay fever is seasonal hay fever, sometimes known as Rose Cold. Any pollen may cause it in a sensitive individual. The spring type lasts from March to the beginning of June and is due usually to pollens of trees—elm, birch, maple, oak, and hickory. The summer type occurring through June and part of July is due to pollen of **grasses** such as red-top, timothy, June and orchard grass, sweet vernal, and plantain. The fall type begins in August and lasts until frost, and is usually due to the pollens of the ragweeds Over 50% of hay fever subjects are sensitive to more than one pollen. Those that are sensitive to only one pollen are relieved of the hay fever as soon as pollenization of the particular plant stops. During the following years attacks begin at the same time of year.

The symptoms of hay fever are local and consist of attacks of severe itching, congestion, and weeping of the

eyes. Sneezing is apt to be violent due to the irritative reaction within the nose. Swelling of the nose may cause obstruction to nasal breathing. An irritating discharge from the nose is usually present. The entire attack closely resembles a severe head cold.

The most frequent complication of hay fever is **sinusitis** and this occurs in a large percentage of cases. **Asthma** is present in 15–20% of hay fever cases.

Non-seasonal hay fever (perennial hay fever, vasomotor rhinitis) may be continuous or occur in paroxysmal attacks throughout the year. The substances causing this form may be inhaled or ingested. They are animal dust and vegetable or seed powders. House dust is one of the most common exciting agents. The specific substance in house dust has not been identified. The dust of hay and straw causing hay fever is not related to the pollens of these substances that cause the seasonal type.

The determination of the specific offending substances is accomplished by means of skin tests, scratch tests, or the intracutaneous injection of dilutions of various test substances. A positive test is said to occur when a wheal of irregular outline, surrounded by a zone of irritation, is produced. The wheal may vary from ¼ to several inches in diameter. Marked itching may be present at the site. Sensitivity tests may also be carried out by instilling dilutions of test substances into the conjunctival sac of the eye.

The treatment of the acute attack of hay fever consists of the local application to the nose of ephedrine-like drugs—"privine," "neosynephrin," etc., which shrink the mucous membrane, diminish the discharge, and control the itching. Similar drugs taken orally ("propadrine") achieve the same result.

Prophylactic treatment against hay fever is successful in many cases, especially those of the seasonal type. Subcutaneous injections of a solution of the offending substance are begun 10 weeks in advance of the expected attack. The dose injected is very dilute at first—the strength being gradually increased. The effects of the treatment are not permanent and the desensitization must be repeated each year. Results are quite satisfactory even in those cases where **asthma** complicates the picture.

Some forms of hay fever, especially of the non-seasonal type, can only be prevented by avoidance of the exciting agent. (R.S.M., D.M.H.)

HAZE. Very small particles of salt and dust in the air reduce visibility and cause the atmosphere to appear off-color. Against a dark background the veil appears bluish, and against a bright background it seems yellowish or orange. This is known as dry haze. Very small water droplets cause a haze more grayish than dry haze known as damp haze or mist. (P.E.K.)

HEAD. In zoology, the head is the region of a bilaterally symmetrical animal body lying at the front end in relation to the ordinary direction of locomotion, or, in bipedal vertebrates like man and some of the birds, at the highest level.

The development of a head is indicated in animals which are without sharply separated body regions, such as the flatworms. This process of cephalization is closely correlated with bilateral symmetry. The portion of a bilateral animal which goes first inevitably is the first to encounter new sources of stimuli, and shows some concentration of sense organs. Usually the chief nerve center, a cerebral ganglion or brain, also develops here. The concentration of sense organs and nervous control in the head remains characteristic of the region throughout the animal kingdom and in most groups is accompanied by the location of the mouth in the head, together with associated structures for securing food. (See **Hydrostatic Pressure.**) (A.W.L.)

HEADACHE. Headache is not a disease but one of the most common symptoms met in medical practice. It may be the first symptom of a number of grave organic diseases. Before treating persistent headache lightly, the cause should be determined. The explanation of the mechanism of headache is difficult. The pain is often a pressure phenomenon within the skull. This may be due to increased or decreased pressure within the blood vessels of the brain or in the brain substance itself. The causes of these pressure disturbance are exceedingly numerous.

Headache varies in location, character, and severity of pain and time of occurrence. Often pain in the face and outside the skull is indistinguishable from headache; such pain may accompany toothache, **sinusitis**, eyestrain, and neuralgia of facial nerves.

The causes of headache fall into three classifications:

1. *Organic causes.* These include injury to the brain, either from simple compression or fracture of the skull, **syphilis, abscess** and **tumor** of the brain or its coverings, cerebral accidents (stroke, hemorrhage, or **embolism) meningitis, arteriosclerosis,** middle-ear disease, diseases and disorders of the eye, high or low blood pressure, etc.

2. *Toxic Causes.* The inhalation of poisonous gases, especially **carbon monoxide,** and over-indulgence in alcohol, tobacco, etc. Headaches accompanying any severe infection or illness, kidney disease (**nephritis**), **constipation, digestive** disorders, **allergic** diseases, and **menstrual** disorders are sometimes loosely termed "toxic," although the mechanism of their production is obscure.

3. *Functional Causes.* These include mental or emotional strain, fatigue, and the emotional maladjustments of the *psychoneuroses.* **Migraine** is discussed separately. (D.M.H.)

HEADER. Any pipe, **conduit**, duct, or channel, which acts as a central point of distribution of a fluid flow to several branch lines, is a header. An example is the steam header, which is usually a large steam pipe well anchored, to which several **boilers** supply steam through boiler lead pipes, and from which steam is taken for such uses as the individual case presents. Header ducts are used where a fan is to supply air to several sources. Cases often arise, also, where a liquid, such as water, oil, etc., is to be distributed from a header for several uses. (F.T.M.)

HEADING. The **direction** of the forward end of the keel of a ship (either air or seaborne) is known as the heading of the ship. Unless a qualifying adjective is used with the term, heading is the direction referred to true **north. Compass** heading, or magnetic heading, may be converted to heading by applying the **compass corrections.** (W.K.G.)

HEADSTOCK. Lathe, Milling.

HEART. Circulatory System.

HEART FAILURE. Heart failure is a loose term which covers several types of disordered heart function. Congestive heart failure denotes passive engorgement of the vascular system, due to weakness of the heart so that it cannot pump forth the blood which fills its chambers in **diastole.** Back pressure, high venous pressure and stasis result. The patient has **dyspnoea,** congested swollen organs, and often **edema** of the dependent portions. **Digitalis** is the most important drug in the treatment of congestive failure. Hypertension, arteriosclerosis, rheumatic fever, and syphilis are the common causes ot heart disease resulting in congestive failure.

The heart failure which results from sudden severe damage to the heart, such as occurs in **coronary occlusion,** usually produces acute circulatory failure, and "collapse" or "shock." Weakness, feeble, rapid pulse, and

decrease in blood pressure are the characteristic features. These phenomena are the results of diminished output of blood by the heart, occurring suddenly. (D.M.H.)

HEARTBURN. A burning sensation in the esophagus and stomach caused either by some irritating substance which has been eaten, or by increased acid production in the stomach. It occurs frequently in peptic ulcer with hyperacidity of the gastric juice. (R.S.M.)

HEARTWOOD. **Wood.**

HEAT. That heat is a form of **kinetic energy** has been known only since the work of Rumford and Davy in the first decade of the nineteenth century. They succeeded in boiling water and melting ice by heat generated mechanically. Prior to their work, heat had been believed to be a substance, a sort of gas called "caloric." This was no doubt suggested by the shimmering appearance in the air surrounding a hot object. No one appears, at that time, to have tested the question as to whether a heated body weighs more than a cold one, or to have attempted the isolation and analysis of the supposed caloric as it escaped from the body on cooling. This well illustrates the very imperfect state of scientific thought a century ago.

The chaotic agitation of **molecules** which we now associate with heat, and the violence of which determines the temperature, is strikingly exhibited, though on a much altered scale, by the **Brownian movement.** When a substance is heated, its molecules receive impulses which result in the acceleration of their motions of translation, of rotation, and sometimes of internal vibration. With most gases composed of diatomic molecules, a simple calculation based upon the known **specific heat** and upon the **kinetic theory** shows that 60% of the energy, at ordinary temperatures, goes into the translational molecular motion and the other 40% to rotational motion; the internal vibrations apparently do not begin until higher temperatures are reached. This apportionment is in accord with the principle of **equipartition of energy** and the **quantum theory.**

Although we now recognize that heat is energy, it is still customary to express quantity of heat in the old water-temperature measure, by means of **British thermal units** or of **calories**; and whenever heat quantities so expressed are used in thermodynamic calculations, it is necessary to use the **mechanical equivalent of heat** as a conversion factor between these and the ordinary dynamic units of energy (foot-pounds or **ergs**). (See **Temperature, Calorimetry, Thermal Convection, Thermal Conduction, Thermal Radiation, Thermodynamics,** etc.) (L.D.W.)

HEAT BALANCE. A **heat** balance is a method of accounting for all heat units in a process or change during which heat is transferred. Examples of cases where heat balances might be undertaken are: 1. Determining the nature and the magnitude of the various losses which occur when coal is burned in a steam boiler **furnace.** 2. Accounting for all heat units during the operation of a prime mover such as a **Diesel** engine or a **steam turbine.** 3. Determining the distribution of heat in a static heating device such as a water heater supplied with steam.

Heat balance work is based upon the first law of **thermodynamics,** a statement of which is: Energy may not be created or destroyed, but may be converted from one form to another. The significance of this law applied to the heat balance is that the total energy may be accounted for by straight addition, hence striking a heat balance resembles bookkeeping, with heat supplied on the credit side of the ledger, and various heats usefully employed on the debit side. One way of showing a heat balance is a tabular form, another shows the heat as a stream, properly branched and subdivided to indicate the distribution of heat. Briefly, a heat balance might be said to be the bookkeeping by which heat supplied is shown to be equal to the sum of heat utilized and lost. (F.T.M.)

HEAT BALANCE IN THE ATMOSPHERE. Heat received from the sun is the primary source of energy for the earth. Some slight amount of heat is received from the earth's interior by virtue of radioactive rocks but this need not be considered in view of its comparable smallness. Total heat received from the sun, directly below the sun, at the outer limits of the atmosphere (the amount that would be received at the earth's surface if passage were unaffected by the atmosphere and clouds) is very nearly 1.94 gram-calories per sq. cm. per min. This great quantity of heat is distributed in such a way that the maximum is received directly below the sun with a decreasing amount received as the distance from the heat equator increases. Tropical areas, for this reason, are warm and polar regions cold.

Not all the sun's radiation is received at the earth's surface. Clouds and snow reflect about 75% of solar radiation falling upon them; land surfaces reflect an average of 10–30% of that falling on them; water reflects varying percentages of solar radiation from 70% when the sun is only 5° high to less than 2% when the sun is over 50° above the horizon. Some solar radiation is absorbed by the atmospheric gases and some by water vapor in the air. Another part is lost to the earth by scattering in the atmosphere. Altogether solar radiation is distributed as follows:

1. Approximately 42% is sent back into space by reflection.
2. 15% is absorbed by the atmosphere and its impurities and cloud particles.
3. 43% is received and absorbed by the earth's surface.

Clouded days prevent considerably more solar radiation from reaching the earth than is received on a clear day. Loss on a clear day is approximately 17% of the total amount, but on a clouded day the loss is about 78%. Average cloudiness is about 52%. Deserts are conspicuously clear and therefore receive a much larger percentage of the incoming solar heat than do continental west coasts which have considerable cloud cover. Snow-covered regions lose a large percentage of their incoming solar heat when compared with forest and vegetation-covered lands. Water surfaces, averaged the world over, do not reflect a large percentage but water is capable of absorbing large quantities of heat with only a small temperature change. Influence of local terrain on solar radiation plays a considerable role in determining the daily and seasonal temperatures of that area.

The earth receives its heat from a number of direct sources.

1. About 17% is direct solar radiation.
2. 10% is sky radiation (from scattered solar radiation).
3. 70% is long-wave radiation received from the atmosphere which surrounds the earth.
4. 3% is received by contact with warm surface air currents.

It should be realized, however, that all this energy regardless of its immediate source, was received initially from the sun.

There is no accumulation of heat on the earth which indicates a radiative heat balance. Radiation received by the earth goes into several categories.

1. 7% goes to space by radiation through transparent bands in the atmosphere (transparent to radiation from a black body at 300° abs.).
2. 78% goes to the atmosphere by radiation where it is absorbed and redistributed.
3. 15% is used for evaporation and is carried to the atmosphere where it adds to the store of atmospheric heat. Water vapor is the principal absorber of earth

radiation as it passes through the atmosphere. Carbon dioxide and ozone also have some strong absorption bands. (P.E.K.)

HEAT COIL. This is a device used in a telephone circuit to serve somewhat the same function as a **fuse.** However, instead of opening the circuit, it grounds it. The heat coil consists of a coil through which the current flows and a plunger held back by a fusable link and tending to be displaced by a spring. The normal current through the coil produces no effect but a sufficiently high current generates enough heat to melt the holding link and release the plunger which grounds the circuit. (L.R.Q.)

HEAT CONTENT. Heat may be absorbed by a substance in several ways. It may be absorbed in the form of external work done when the heated substance expands against a pressure. It may be absorbed by increasing internal energy associated with the motion of the molecules (commonly measured by temperature). Again, heat may be absorbed by change of state of the substance (see **Heat of Fusion,** and **Heat of Vaporization**), examples of which are the vaporizing of a liquid, the melting of a solid, etc. The total thermal energy possessed by a substance includes that present in these various forms. Heat content at the absolute zero temperature (minus 460° F., or minus 273° C.) is zero. However, an arbitrarily taken datum for heat content often proves more valuable than with the absolute heat content; thus, for example, steam tables which display the heat content of steam do so upon the assumed basis of zero heat content at 32° F. (See **Enthalpy.**) (F.T.M.)

HEAT OF COMBUSTION. Fuels; Thermochemistry; Fuel Calorimeter.

HEAT OF FORMATION. Thermochemistry.

HEAT OF FUSION. Very simple experiments show that the **fusion** of a given mass of any crystalline substance requires a definite quantity of **heat.** The quantity required per unit mass, without any change of temperature, is called the heat of fusion of the substance. It may be measured by means of a **calorimeter.** The fused substance is introduced into the calorimeter at a temperature somewhat above its melting point and allowed to cool, the heat evolved being measured. At the melting point it ceases to cool for a time, but continues to give out heat as it solidifies; and when all congealed, it begins to cool again. At this stage the process is terminated; and the total heat evolved, with corrections for the cooling before and after solidification calculated from the known specific heats, gives the heat of fusion. For ice the value is about 79.71 calories per gram.

The freezing of 10 lbs. of water gives out 1440 B.T.U., which is equivalent to the burning of 0.1 lb. of coal or about 2 cu. in. of kerosene, or which would raise the temperature of 1 gal'on of water 171° F. This fact is sometimes utilized to prevent vegetables from freezing in unheated basements, by setting tubs of water near them; or likewise to protect the battery and radiator of a car on very cold nights. (L.D.W.)

HEAT OF REACTION. Thermochemistry.

HEAT OF SUBLIMATION. Sublimation.

HEAT OF VAPORIZATION. The **evaporation** of a given mass of any liquid requires a definite quantity of **heat,** dependent upon the liquid and upon the temperature at which it evaporates. The quantity required per **unit mass** at a fixed temperature is called the heat of vaporization of the substance at that temperature. It may be measured by allowing the vapor to condense in a suitable **calorimeter,** the heat thus evolved, corrected for fall of temperature before and after condensation, being observed. (The heat evolved in condensing is equal to that absorbed when the liquid evaporates.) The result is often surprising. For example, the evaporation of water at the boiling point requires about 540 calories per gram, or more than five times the heat required to raise its temperature from freezing to boiling. The explanation is the large amount of energy necessary to separate the molecules against their cohesion, and the much smaller amount (about 7.4% of the whole) which is used in expanding the vapor against atmospheric pressure. At lower temperatures the value is still greater, because the cohesion is then more effective; with water, for each degree below the normal boiling point about 0.6 calorie per gram must be added to the heat of vaporization. Trouton found that the heat of vaporization per mole for different liquids bears a nearly constant ratio to the absolute temperature of the boiling point. (L.D.W.)

HEAT TRANSFER. Heat can be transferred by three different methods. by conduction, where the heat must diffuse through solid materials or through stagnant fluids; by convection, where the heat is carried from one point to another by actual movement of the hot material (common in fluids); and by radiation, where heat is transferred by means of radiant wave energy.

The amount of heat transferred by conduction can be determined by using Fourier's law:

$$Q = \frac{KA\Delta T}{L}$$

where Q = Heat transferred per unit time.
A = Area perpendicular to the heat flow through which it is passing.
L = Thickness of the body of matter through which the heat is passing.
K = A conductivity constant dependent on the nature of the material and its temperature.
ΔT = The temperature difference between the hot and cold sides of the substance through which the heat is being transferred.

This law of conduction may also be stated

$$Q = UA\Delta T$$

in which U is the *conductance.* The reciprocal of conductance is resistance. It is the resistance that is additive when several conducting layers lie between the hot and cool regions In a multiple layer partition having an overall conductance, U, and layer conductances U_1, U_2, etc.,

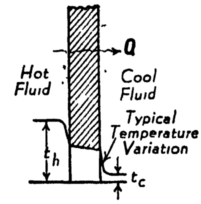
$$\frac{1}{U} = \frac{1}{U_1} + \frac{1}{U_2} + \frac{1}{U_3} \cdots \text{etc.}$$

Thus, when dealing with several different materials in layers, such as might be found in a furnace wall, the form:

$$Q = \frac{A\Delta T}{\frac{L_1}{K_1} + \frac{L_2}{K_2} + \frac{L_3}{K_3} \cdots \text{etc.}}$$

may be used, although this must be modified if the walls are curved. The subscripts 1, 2, 3, etc. refer to the various layers.

When a solid partition is conducting heat from one fluid to another, as in the accompanying figure, a thin layer of fluid remains stagnant against each face of the partition and becomes, in effect, another conducting layer outside of which the free stream fluid temperature exists. Although this film is extremely thin, its relative resistance to heat flow may be high compared to the solid partition. This is especially true in heat exchangers where the solid wall material is metal of good conducting properties. Although **film conductance** is difficult to study or evaluate, being under the control of



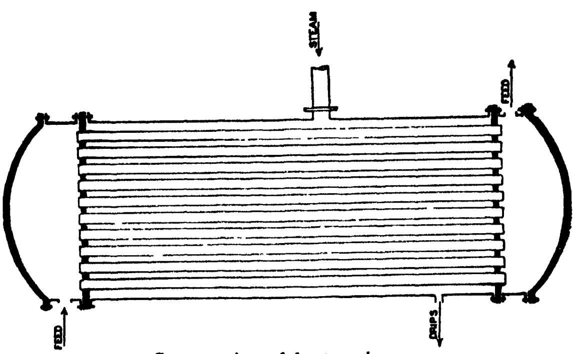
Section of Partition Bathed with Hot and Cool Fluids

several variables (i.e., fluid velocity, viscosity, density, turbulence), its importance to conductive heat transfer is considerable.

Typical conductivities of some common materials are cited in the following table.

Material	Temperature °F.	Conductivity B.T.U. per hr. per sq ft per deg. per ft. thickness
Air	50	.014
Aluminum	100	122
Asbestos, loose	400	105
Brick, fire	2000	.9
Brick, red	100	.27
Concrete, stone	60	.6
Copper	100	220
Corkboard	80	.025
Insulating wallboard	60	.03
Magnesia, powdered	400	.06
Rock wool	90	.023
Rubber, soft	60	.10
Steel	100	25
Water	100	.35
Wood, pine	60	.07

Transfer of heat by *convection* implies a carrying medium traveling from hot to cool region. While this might be a solid (conveying, each trip, heat in the amount of weight × specific heat × ΔT), the important cases of convection arise in connection with fluids in steady motion as the carrying media. Dependent on whether the fluid is under forced, controlled motion or is moved by natural density differences caused by the heat-



Cross-section of heat exchanger.

ing itself, the convective process is termed "forced" or "free." Heat transfer in forced convection is more readily analyzed and predicted than in free convection, although the latter is important in the liberation of heat from steam radiators, hot walls, pipe lines, and other static hot surfaces about which circulate "free" fluid currents. For transfer of heat by convection, use is made of the concept of the *heat transfer coefficient "h"* which is defined as: h = heat transferred per unit time per unit area per unit temperature difference.

The coefficient h for forced convection in conduits can be studied experimentally by using the theoretical relationship:

$$\frac{hD}{k} = K\left(\frac{Du\rho}{\mu}\right)^a\left(\frac{C\mu}{k}\right)^b$$

where $\frac{hD}{k}$ = *Nusselt group* = heat ransfer coefficient × diameter of flowing stream ÷ conductivity of fluid.

K = An experimentally determined constant.

$\frac{Du\rho}{\mu}$ = *Reynolds group* = Diameter of flowing stream × velocity of stream × density of fluid ÷ viscosity of fluid.

a, b = Constants experimentally determined.

$\frac{C\mu}{k}$ = *Prandtl group* = specific heat of fluid × viscosity of fluid ÷ conductivity of fluid.

After K, a, and b have been determined for one system, h can be evaluated for any other geometrically similar system.

Other theoretical equations can be used for other situations, such as flow outside of pipes, condensing vapors (steam), and natural convection in tanks. Many cases have been studied so that information is available for almost every practical problem.

When h has been determined it is put into the equation $Q = hA\Delta T$, where Q is the heat transferred per unit time, A is the area through which it is being transferred and ΔT is the temperature difference across the material through which the heat is flowing. For design purposes, the known facts are usually "Q" and the properties of the fluid, both dynamic and physical. By proper manipulation of the known facts, together with the various formulae, the term "A" (the area) can be determined and from it the equipment size needed can be calculated.

The amount of heat transferred by radiation can be determined by use of the *Stefan-Boltzmann law:*

$$Q = bA(T_1^4 - T_2^4)$$

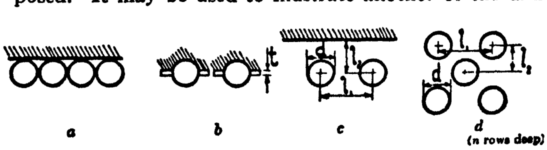
where Q is the amount of heat transferred per unit time, b is a constant, A is the area of the radiating surface, T_1 is the absolute temperature of the radiating body and T_2 is the absolute temperature of the receiving body. Various correction factors are introduced into the formula to account for the shape of the bodies, their thermal radiation characteristics and the properties of the media through which the radiant rays must pass while traveling from radiator to absorber. The thermal radiation characteristics are its emissivity, a measure of its ability to radiate at a given temperature, its absorptivity, a measure of its ability to absorb heat and its reflectivity, which measures its ability to reflect without absorbing.

Radiant energy travels in a straight line. Therefore to transmit it to an object out of sight of the radiator requires a reflector, such as a furnace wall, to deflect the rays to their objective.

It is possible to set up controlled laboratory radiation between simple plane surfaces and determine therefrom accurate coefficients to incorporate into radiation equations. However, the radiation of heat from furnace gases, consisting of non-luminous gases, luminous carbon particles in flame, ash globules, etc., to the walls and tubes of a steam generator in commercial operation at variable load, is another matter. Here, empirical data which are gathered and interpreted from field tests on similar equipment, must still be resorted to however great the designer's urge to go back to basic laws of heat transfer.

Radiant heat transfer in furnaces is roughly proportioned to the difference in the fourth power of the absolute temperatures of the radiating and receiving surfaces. The water wall surface is approximately at boiler saturation temperature, while the superheater surface varies from this to somewhat above the temperature of the steam at the superheater outlet. However, the mean radiating temperature of the furnace gases is usually over 2200° F. The fourth power of the receiving surface temperature is thus seen to be small compared to the fourth power of the transmitting surface temperature; consequently the latter controls the transmittance, and boiler tube temperature does not need to be considered a variable to be accounted for.

The accompanying figure shows some of the arrangements in which radiant heat-absorbing surface is disposed. It may be used to illustrate another of the diffi-



(*Morse's Power Plant Engineering and Design.*)

culties which beset the designer in following a rational or semi-rational form of radiation analysis. Projected radiant surface is one thing; actual radiant energy receiving surface may be quite a different area. For example, suppose the tubes of case (a) to be separated and spaced l_1 inches on centers. The *projected* areas of cases (a) and (c) would then be the same, but it seems obvious that re-radiation from the wall causes more of a (c) tube to receive radiant energy than is the case with an (a) tube. Also, if δ is a factor correcting projected area to *equivalent* absorbing surface, what value should be assigned to it in the case of a bank of tubes which may receive by re-radiation some radiant energy deep in the tube bank? Here δ has a minimum value of 1, but some investigators have derived expressions which indicate that δ may have a magnitude of 3 or more.

Some of the more common cases of industrial heat transfer are:

1. Radiation from fuel beds and luminous gases to absorptive surfaces such as boilers, cylinder walls, etc.
2. Radiation from heat generators such as drying lamps.
3. Convection of heat out of combustion regions.
4. Convection of heat from hot surfaces under either free or forced convection.
5. Conduction of heat through the tubes of boilers, heaters, heat exchangers, condensers, etc.
6. Conduction in walls, pipe covering, and other so-called "heat insulators." (D.E.M., F.T.M.)

HEAT TRANSFER COEFFICIENT. **Heat Transfer.**

HEAT TREATING. Heating and cooling of metals to effect changes in properties. **Annealing** and normalizing are generally for the purpose of softening or improving the grain structure. Patenting is also a softening process in which cold drawn carbon-steel wire is heated above its critical temperature range followed by cooling to below this range in a molten lead or molten salt bath, with subsequent cooling to room temperature.

While heat treating includes the softening treatments, it most often implies hardening and strengthening. In the case of steels this requires heating to above the critical temperature range followed by rapid cooling (**quenching**) in oil, water, or brine, except in the case of special grades which harden on cooling in air. This is followed by **tempering,** a low-temperature reheating treatment which reduces the internal stresses caused by the hardening treatment. Tempering may be carried to a high enough temperature to reduce somewhat the extreme hardness of the as-quenched steel and increase the toughness and ductility, depending on the requirements of the part. (See **Steel.**)

Another important form of heat treatment for hardening is **precipitation hardening.** (See also **Carburizing, Case Hardening, and nitriding.**) (R.H.H.)

HEATER. **Cathode; Tube, Electronic.**

HEATH FAMILY. Ericaceae. This is a small family composed mainly of woody plants. Nearly all plants of this family grow in acid peaty soil, often covering extensive areas. Most of the heaths have a pronounced **xerophytic** habit. The leaves are usually entire, leathery and have a thick cutinized upper surface. Many are evergreen. The flowers may be solitary, but are more frequently in **racemes.** Usually they are regular. There are generally four or five **sepals** and four or five **petals,** more or less united; eight or ten **stamens** and a single inferior **ovary** composed of four or five **carpels.** The **pollen** grains, formed in fours, are discharged from the **anthers** through apical pores. The fruit may be a **capsule,** a **drupe** or a **berry.** Pollination is mainly by **bees.**

Many plants of this family are used by man. Rhododendrons and Azaleas are frequently cultivated because of their beautiful bright-colored flowers, and many hybrids have been formed. There are over 200 species. Eastern Asia is especially rich in plants of this genus. *Epigaea repens,* the trailing arbutus or mayflower of eastern North America, is another plant much sought for its delicately fragrant flowers. It is not easily grown in cultivation. Species of *Gaultheria,* including the red-berried *G. procumbens,* called checkerberry, or wintergreen, contain an oil which is sometimes distilled from the plant. The fruits of blueberries, huckleberries and cranberries, members of this family, are widely used. In recent years considerable attention has been given to the blueberries and several new varieties having very large berries have been developed. Species of *Erica* cover vast areas of moor in England. One species, *Erica arborea,* grows in southern Europe and northern Africa. It is a stout bush several feet high, with a yellow hard close-grained wood. From the rootstocks of this plant briarwood is obtained. This is used in making briarwood pipes. (R.M.W.)

HEATH HEN. Aves, Galliformes. A **grouse** of the eastern United States, resembling the prairie chicken of the central states. The last of these birds were rigidly protected on Martha's Vineyard and increased to a large number by 1916. Later, disease introduced with domestic turkeys affected the birds, and other destructive agents further reduced their numbers until the last individual disappeared in 1931. (A.W.L.)

HEATING, BUILDING. Portions of buildings where persons work or live are heated when the outside temperature falls below that considered necessary for health and comfort. The heat that must be supplied equals the heat which is dissipated from the building. The amount needed varies with the difference in temperature between that maintained on the inside and that determined by the state of the weather. But other things also have a determining influence upon building heating; namely, the area and type of the exposed walls, the roof, the windows, and the leakage through cracks, ventilators, etc. Heat is lost from a building by **conduction** through walls, and by **convection** and **radiation** from outside surfaces such as windows, walls, roof. Heat is also dissipated by air leaking from a building, or by air intentionally discharged by a ventilating system. Research and accumulated statistics have provided the data from which the amount of heat lost through walls, windows, roof, etc., can be determined, given the composition of the walls.

The heat transfer coefficient is stated as the number of **B.T.U.'s** lost per sq. ft. of surface area per hour per degree difference of temperature. By multiplying the coefficient by the exposed surface and the difference between outside and inside temperature, part of the heat loss is determined. This, however, does not take care of heat loss by leakage or infiltration. To allow for that a certain number of air changes per hour are included in the needed heating. For the ordinary room having windows, it is assumed that to allow for leakage, the heating system must supply heat to take care of a complete change of air each hour. (Halls, stores, factories, may need two or three times this allowance.) By computing the heat needed for each heated room, and totalling these for the building, the required heat output of a heating system may be determined.

A person gives off some 400–600 B.T.U. per hour. It will be necessary to reckon with this source of heat in any heating analysis of a public building, where large numbers of people may gather in one room. The building heating system and ventilation are jointly considered in a large building, especially a public one. With any attempt to ensure adequate heating, the modern building owner usually will find it economical to spend money

for heat insulation, since by proper coordination of investment in heat insulation, heating system, and fuel, a minimum annual heating cost can be secured.

Heat insulation is available commercially in a number of forms. The air space between studding, if blocked at the top floor levels, becomes a dead air space, and is effective in insulating against heat loss. Plaster and brick are fairly good conductors; wood, building paper, fiber wall board, are heat insulators. Rock wool, either granular, fluffed, or in bats, is widely used where the maximum of heat insulation is attempted.

Central heating means the supply of heating service to a group of surrounding buildings from a central heating plant. The heat-carrying medium is sometimes steam, sometimes hot water. District heating is similar to central heating, but a distinction can be drawn as follows: A central system can be thought of as that which supplies a group of buildings which are under common building superintendence, or having common aim, as, for example, buildings of an educational institution, or a manufacturing plant. District heating, on the other hand, is a public utility service and applies to the heating of buildings in densely occupied city sections, from a public utility heating plant which sells heating service.

The instances where electric heating is of use are almost numberless in this day, since one may add to the large assortment of domestic electric devices, such as irons, corn poppers, percolators, etc., an equally great variety of commercial devices, like annealing furnaces, bakers' ovens, glue pots, vulcanizers, etc. However, the use of electricity for building heating, though apparently successful in some experimental installations, is at a great disadvantage because of the high cost of electric heat compared to that obtained directly from the fuel. (F.T.M.)

HEATING SYSTEMS. While the words "heating system" generally convey the idea of one of the indirect systems employed at the present time to heat homes or buildings, direct radiation is, itself, a system of heating. A stove located in the room which it is heating proves to be a very efficient means of getting heat from a fuel into the air of the room. As a system, it suffers from the following disadvantages:

1. Unsightliness.
2. Multiplicity of heating units required for a building containing a number of rooms.
3. Unequal distribution of heating.
4. Fire hazard.

While most of the heat supplied by a stove is black body radiation, there is some considerable amount of convection resulting from air currents sweeping up over the heated portions.

A fireplace delivers no heat by convection; rather, it withdraws heat from a room by leakage up the flue. The heating effect of a fireplace comes entirely from radiation. As a heating system, a fireplace is inefficient and wasteful of fuel. The adequate heating of buildings seems to be obtained best by the use of indirect heating, that is, generation of the heat at a central point, as a **furnace**, then loading that heat onto the medium which conveys it to the various rooms in the required amount. The different heating systems in use today can be classified on the basis of the heat-conveying medium, i.e., warm air, hot water, steam. Each of these systems is briefly described below.

In a warm-air heating system the furnace is enclosed by a casing, leaving an air space between casing and furnace. From the casing ducts lead out to the different rooms. Air is supplied to the casing, either directly from the furnace room, from outside the building, or from return ducts which withdraw the air from the rooms. The air in the casing being in contact with the heated furnace, expands, becomes lighter than normal, and rises in the ducts until it is discharged in heated condition into the rooms through registers located in the floor or side wall. The older warm-air systems had a circulation that was maintained entirely by the levity of the heated air leaving the furnace, but had certain disadvantages. For example, the effect of wind blowing against one side of the building caused infiltration which opposed duct air pressure in the windward rooms, an action which tended to give unequal distribution of heat, leaving the rooms on the windward side underheated, and those on the leeward side, overheated. Also, the furnace had to be centrally located, the basement was encumbered with large numbers of ducts, and homes which were not roughly cubical in shape were not well adapted to this style of heating.

Recent developments in the field of warm-air heating have led to the employment of forced circulation of the hot air by a motor-driven blower. Having this, it is not necessary to be so careful about friction losses, and smaller ducts, trunk-line systems, and filters are possible. Since the available pressure is of much higher order than that obtained from gravity alone, there is no difficulty about forcing air equally into all rooms. This system of heating, furthermore, is admirably adapted to **air-conditioning** requirements. The operation of a forced circulation warm-air heating system is controlled by a thermostat located in a representative room. The **thermostat** is connected electrically to a small draft-regulating motor, and in effect becomes a switch for that motor. A certain differential of a few degrees is allowed in a room. When the temperature sinks to a predetermined point, the thermostat operates the draft-controlling motor, which in turn closes the check damper and opens the draft so that the rate of combustion is increased. The temperature of the air in the bonnet of the casing rises until a thermostatically operated switch located there starts the blower. The warm air is then circulated in the rooms until the temperature rises to a predetermined limit, upon which the room thermostat regulates the draft. Soon the slower rate of combustion results in a cooler furnace bonnet, and the blower is thermostatically stopped. This cycle is repeated as frequently as needed, but the room and bonnet thermostatic switching do not necessarily stay in synchronism.

Hot-water heating systems have been very popular in recent years. When the reason for this is sought, it will be found that hot water, as compared to steam or gravity-circulated warm air, offers a more uniform and steady heat. It is free from the unequal heat distribution and bulky duct work of the warm-air system, and from the condensate troubles of the steam or vapor system. Like the steam system, it has no summertime usefulness, and offers no possibility of air conditioning. The radiators and piping, furthermore, are larger than those for an equivalent steam system. In a hot-water system the water is heated in a heater similar to a boiler except that it is completely filled with water, and no boiling takes place. Most hot-water systems operate at atmospheric pressure, which limits the temperature to which the water may be raised to slightly over 200° F. However, for heating homes, this temperature is entirely adequate for the coldest weather. Over much of the heating season, temperatures of 140–180° F. are sufficient. From the heater the water passes to the radiators located in the rooms, where the heat is transferred to the air. Delivery of heat to the air cools the water which, as a result, becomes more dense than that in the supply mains, and it sinks to the heater; thus circulation is maintained by gravity and is due to the difference in density between the columns of hot and cool water between the radiator and the heater. Central hot-water heating systems, and occasionally domestic systems, work on forced circulation created by a motor-driven circulating pump. This gives more flexibility to the system and permits the use of smaller pipes. The control of a hot-water heating sys-

tem is vested in a thermostat which operates the check damper and draft. The expansion elements of the thermostat are immersed in, or are subjected to the temperature of, the hot water in the heater. (The thermostat tends to maintain uniform water temperature by adjusting the rate of combustion.) The temperature of the rooms is controlled by altering the temperature of the water leaving the heater through opposing the action of the thermostat with adjustable weights or springs provided for that purpose, or by a variable rate of by-pass of the water around, instead of through, the heater.

Steam heating, although lacking flexibility, and sometimes having difficulties of clearing condensate from the system, is, nevertheless, a convenient medium for indirect heating because a considerable heating effect is obtained from a relatively small volume of the circulating fluid. Because the heat is released by condensing, latent heat of evaporation is made available, whereas in hot-water systems, only a portion of the heat of the liquid is available. Since latent heat is several times the amount of heat of the liquid, the size of a steam heating system compares favorably with any other of equivalent heating capacity. It is widely employed for large buildings, and to a more limited extent, for residences. As the circulation depends on the difference in density between steam and water instead of between hot water and cool water, it is quite positive. In laying out a steam heating system, it is very important to pitch the return pipes so that condensate will drain properly. In some cases the return and supply pipes are the same, that is, the condensate flows against the steam, but this is suitable only for small inexpensive installations. Two-pipe heating systems are found in many different arrangements involving differences of points of admission of steam to radiators, methods of expelling air, and returning of condensate to the boiler.

Although experimental at present, the "heat pump cycle" may possibly, in the future, receive favorable attention as a building heating system. The heat pump is a reversed refrigeration process. In the normal refrigeration system the refrigerant is compressed, the resulting heat is removed by the radiation of the condenser and then the refrigerant is allowed to expand to cool the stored material, i.e., it absorbs heat from this material. The heat pump uses this same principle, but utilizes a different part of the system for its useful function. It draws air or water from some outside source and cools it by having the refrigerant (if we may still call it this) absorb its heat. This refrigerant is then compressed and the heat removed at the condenser and utilized for heating purposes. This system has the advantage that by proper utilization of the apparatus it may be used for summertime cooling and the disadvantage of requiring a large motor for driving the compressor. (F.T.M.)

HEATING VALUE. The heating, or calorific, value of a **fuel** is the quantity of heat produced by the combustion, under specified conditions, of unit weight or volume of the fuel. The heating value of a fuel may be calculated by formula which may be derived for any fuel by multiplying the percentage of each chemical element present by its heating value per unit weight, and adding the products for all combustible elements in the fuel. Thus for coal, whose combustible elements consist of carbon, hydrogen, and sulfur, the heating value is:

$$14{,}540C + 62{,}000H + 4000S \text{ (B.T.U. per lb. of coal).}$$

The numbers in the above formula are the heating values per lb. respectively, of carbon, hydrogen, and sulfur. In the use of this formula, it is essential that only that portion of the element that is actually free to burn be employed. For example, all coal contains some moisture. Now the hydrogen present in this water is not free to burn (i.e., it is already combined with oxygen). Therefore the figure used for H in the foregoing formula should not include the hydrogen present as water.

Heating value by formula will not necessarily be the same as that obtained experimentally with the fuel calorimeter. The difference lies not in the accuracy of the experiment, nor of the calculation, but in the possible endothermic or exothermic reactions which take place when a compound fuel, such as a hydrocarbon, is burned. The volatile matter of coal must be broken down into the elements of carbon and hydrogen by heat-absorbing action before they may reunite with the oxygen during combustion. For this reason, experimentally determined heating values are less than those which are computed by formula, which make no reference to endothermic or exothermic reactions. Approximate heating values of some of the common fuels are: coal, 13,000 B.T.U. per lb.; natural gas, 1000 B.T.U. per cu. ft.; artificial gas, 300 B.T.U. per cu. ft.; gasoline, 19,000 B.T.U. per lb.; wood, 5000 B.T.U. per lb.

Many thermodynamic analyses require the use of a "lower heating value" which may be obtained from the above values by subtracting an allowance for the latent heat of evaporation of the steam found in the products of combustion. Lower heating value might be thought of as "sensible heating value." (F.T.M.)

HEAVE. **Fault.**

HEAVISIDE LAYER. **Ionosphere.**

HEAVY MINERALS. **Sedimentary Minerals.**

HECTOCOTYLUS ARM. One of the arms or tentacles of the male of certain species of **cephalopod** mollusks, specialized for the insemination of the female. It may serve as an intromittent organ, introducing **spermatophores** into the mantle cavity of the female, and in the paper nautilus, *Argonauta,* it breaks away from the body and enters the mantle cavity of the female, remaining inside for some time. (A.W.L.)

HEDGEHOG. Mammalia, Insectivora. Small compact animals with short legs and tail and a sharp nose. The entire upper surface is covered with sharp spines which protect the entire body when it is curled up. The numerous species live in Africa, Europe, India, and the remainder of Asia north of the Himalayas. They are nocturnal animals. The European hedgehog, *Erinaceus europaeus,* is also called the urchin. (A.W.L.)

HEEL. The prominence at the posterior end of the foot. It is based on the projection of one bone, the calcaneum, behind the articulation of the bones of the lower leg. In the long-footed mammals, both the hoofed species and the clawed forms which walk on the toes, the heel is well above the ground at the apex of the angular joint known as the hock or hough. In plantigrade species it rests on the ground. (A.W.L.)

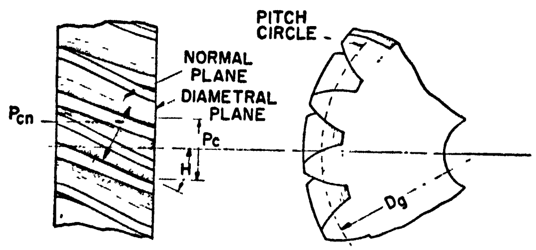
HEIGHT OF INSTRUMENT. **Earthwork.**

HELIATHIN. **Dyes.**

HELICAL GEARING. For high pitch-line velocities and heavy loads, some form of "twisted tooth" gear is generally used. Two important types are helical gears and double-helical or herringbone gears. Both helical and herringbone gears are essentially spur gears with teeth twisted across the face in the form of a helix about the axis of rotation.

When spur gear teeth engage, the contact extends across the entire tooth on a line parallel to the axis of rotation, and may result in noise and shock at high speeds. In helical gear engagement, contact begins at one end of the entering tooth and gradually extends

along a diagonal line across the tooth face as the gears rotate. The nature of the contact is such that with sufficient face width, two or more teeth are in contact



and are carrying the load at all times. Helical gears are therefore used for transmission ratios as high as 10:1, and at pitch-line velocities up to 2000 ft. per min. for commercially-cut units. Herringbone gear sets of special design have been successfully operated at pitch-line speeds of 12,000 ft per min.

Tooth elements of helical gears are similar to those of spur gears. The ***helix angle*** *H* of the tooth is measured between the line tangent to the tooth helix at the pitch circle and the shaft axis. In any pair, the gears have teeth with mating right-hand and left-hand helices. The usual method of tooth measurement is by diametral pitch P_d, which corresponds to circular pitch P_c in the diametral plane, perpendicular to the axis of rotation. By using standard pitches, the pitch diameters (and therefore the center distance of helical gear sets) can be given in commonly used fractions or integers; consequently, a spur gear set of a certain size can be replaced directly by a similar helical gear set. Actual tooth thickness depends upon the pitch and the size of the helix angle; if the circular pitch P_c be held constant, the actual tooth thickness measured perpendicular to its elements will decrease as the helix angle *H* is increased. A different cutter is required for every change in helix angle, although the pitch may remain constant. To eliminate an extensive variety of cutters, commercially available helical gears are made in several standard helix angles, among which are 7° 30′, 15°, and 23°.

By using a standard pitch in a plane normal to the tooth helix, the pitch diameter of a helical gear can be varied to suit a particular center distance by changing the helix angle. In this method of tooth measurement, the normal diameter pitch P_n corresponds to a normal circular pitch P_{cn} in the normal plane. Helical gear teeth designed with normal diametral pitches may be cut with standard spur gear cutters or hobs.

The pitch diameter D_g of a helical gear, based upon normal pitch P_n, is given by

$$D_g = N_g/P_n \cos H$$

where N_g is the number of teeth in the gear. The power transmitting capacity of helical and herringbone gears may be found by methods analogous to those used for spur gearing.

End thrust inherent in single helical gears can be eliminated by the use of herringbone gears that consist virtually of two integral single helical gears of opposite hand, which absorb the axial thrust within the gear. Herringbone gears are extensively used for hoisting and mining machinery, rolling mills, sugar mill and lumber machinery, turbine and compressor drives—in fact for nearly all heavy duty, high transmission ratio applications. (See **Spiral Gearing.**) (H.C.H.)

HELICOPTER. The conception of the helicopter appears first in the Chinese top with two airscrews made of feathers turning in opposite directions. The origin of the Chinese top is lost in antiquity and it even antedates the sketches made in the 16th century by Leonardo da Vinci. It is not certain that the Italian artist-inventor actually flew any helicopter models, but his writings showed good understanding of the lifting screw, and he made use of the Greek word ***helix*** meaning spiral or twist in connection with the idea of flight. Much later, a combination of ***helix*** with the word ***pteron,*** meaning wing, led to the term helicopter whose correct pronunciation is hĕl′ĭ-kŏp′tẽr. Centuries intervened, however, between understanding and realization and there was no truly successful helicopter until the Focke-Wulf FW-61 appeared in Germany in 1936, and Igor Sikorsky built and flew the VS-300 in 1937.

Contrast with the airplane and the autogiro serves to define the helicopter. In the airplane a fixed wing provides lift or sustention; in the autogiro the blades revolving freely like those of a windmill have the same function. In both airplane and autogiro forward thrust or propulsion is given by a propeller which absorbs the whole power of the engine. But in the helicopter the power of the engine is used to drive the blades of the rotor which provides both sustention, at all times, and propulsion (when its axis of rotation is tilted forward)

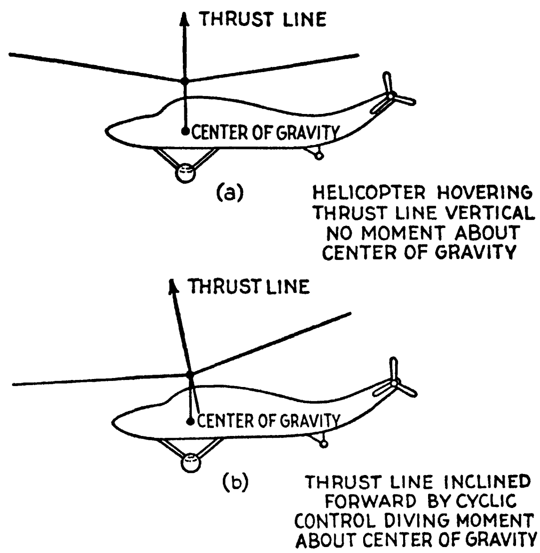


Fig. 1. The process of securing control with a rotor of the flapping-blade type.

(Fig. 1). It is because of this dual function of its rotor that the helicopter is superior in efficiency to the autogiro.

The **autogiro**, invented by the Spaniard, Juan de la Cierva, and first flown successfully in 1921, has been superseded by the helicopter for a reason other than superior performance. The helicopter affords the true vertical flight of which the autogiro is incapable. The helicopter can hover in the air, rise vertically and come down vertically and thus carries man a step further in his conquest of the air. Early inventors thought that to secure direct lift or vertical flight was the sole requirement of a practical aircraft. They were wrong; other objectives must be attained:

1. *Ability of the Blades to Turn or Autorotate in Case of Power Failure.* Thus the helicopter rotor is effectively converted into an autogiro rotor and can come down without power, safely on an inclined path, and somewhat hazardously in vertical descent. Autorotation after engine failure is readily secured by decrease of the blade pitch or setting. The helicopter is then transformed into an autogiro.

2. *Ability to Take up the Torque or Turning Moment of the Lifting Rotor.* To secure a thrust or lift of at least 10 lbs. per hp, the rotor must have a much greater diameter for a given horsepower than the conventional airplane propeller. It also revolves more slowly and

the engine is frequently geared down, 10 to 1 or even more. But gearing down the engine 10 to 1 also means that the torque or turning moment in the shaft is increased in the same ratio. The torque of the rotor ceases to be the subsidiary factor that it is in the airplane propeller and counteracting this torque becomes a prime element in the design of the helicopter. Fig. 1

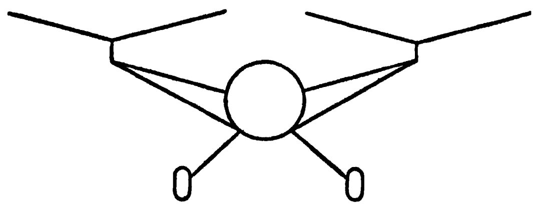

Fig. 2. Two rotors at either side of the fuselage.

shows the arrangement which has become almost conventional; the thrust of an auxiliary tail rotor, also driven by the engine, counteracts the torque of the main lifting rotor. This configuration is used in such well-known aircraft as the Sikorsky and Bell-Young helicopter. Fig. 2 shows the rotors disposed on either

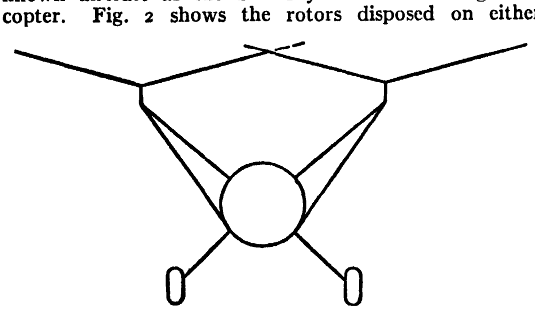

Fig. 3. Two overlapping rotors at either side of the fuselage.

side of the fuselage and rotating in opposite directions. Focke-Wulf in Germany, and Platt-LePage Aircraft in the United States have employed this arrangement. To reduce the over-all width of the helicopter and the air drag of the supporting trusses, Kellett Aircraft have employed the system of Fig. 3, where the rotor disks

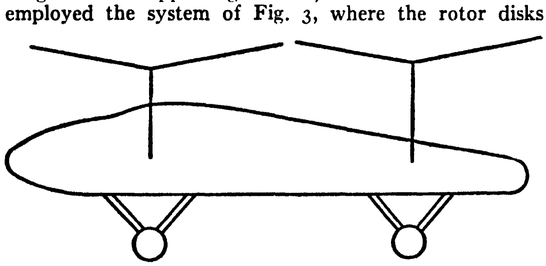

Fig. 4. Two rotors in tandem.

overlap to some extent. The arrangement of Fig. 4 is utilized in the PV Engineering Forum and Rotorcraft machines, and has the advantage of a large central space for the passenger. Bendix and Hiller among others have resorted to coaxial, contrary turning rotors, placed one above the other (Fig. 5). Such coaxial

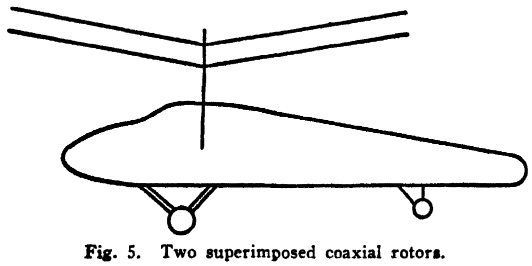

Fig. 5. Two superimposed coaxial rotors.

machines eliminate the loss of power, the complication of a long transmission, and the hazard to the public of the tail rotor. They are also compact, but are complex and have drawbacks. The application of jet propulsion to the helicopter rotor, with the tempting possibility that the mechanical transmission may be eliminated, is being tried on two or three experimental machines. There are advantages and disadvantages for each of the types listed; none has yet proved supreme, and all avenues of approach deserve trial.

3. *Equalization of the Lift on the Advancing and Retreating Blade.* As can be seen from Fig. 6 the

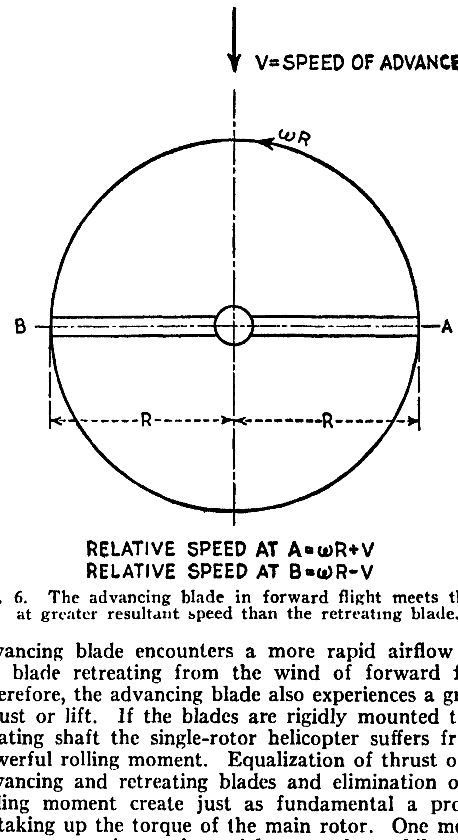

Fig. 6. The advancing blade in forward flight meets the air at greater resultant speed than the retreating blade.

advancing blade encounters a more rapid airflow than the blade retreating from the wind of forward flight. Therefore, the advancing blade also experiences a greater thrust or lift. If the blades are rigidly mounted to the rotating shaft the single-rotor helicopter suffers from a powerful rolling moment. Equalization of thrust on the advancing and retreating blades and elimination of the rolling moment create just as fundamental a problem as taking up the torque of the main rotor. One method is to use superimposed coaxial rotors, but while rolling moments are thus avoided there is no true equalization of lift, so that vibration effects are present. The most generally adopted method is that of the flapping hinge, one of the valuable conceptions of the de la Cierva type which is shown diagrammatically in Fig. 7.

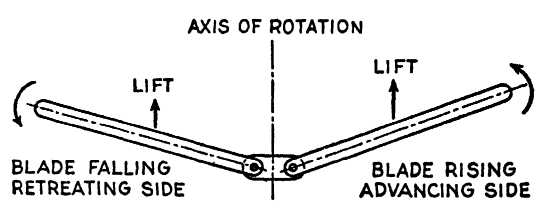

Fig. 7. Flapping to equalize lift in forward flight.

With the free-flapping hinge, no moments can be transmitted to the remainder of the helicopter. The blade on the advancing side rises and receives an additional flow from above. In so doing it decreases its angle of attack and loses lift so that substantial, although not complete, equalization of lift is secured. The flapping motion of the blades is such that it describes the surface of a shallow cone. Flapping introduces difficulties, such

as varying loads in the plane of rotation which have to be met by the introduction of a vertical or lag hinge as shown in Fig. 8. Instead of the flapping, other de-

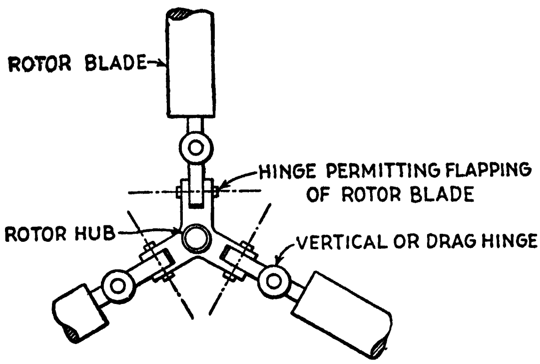

Fig. 8.

signers have sought equalization of lift by using two blades continuous across the axis of rotation and oscillating together about a "see-saw" hinge. Still others have advocated feathering or change in the angle of attack with the angle on the advancing side decreasing. Feathering and flapping are aerodynamically equivalent, since both tend to equalize lift on the advancing and retreating sides.

4. *Control.* In hovering flight, stabilizing surfaces such as are used in the airplane become ineffective, and the helicopter is unstable. Fortunately the time required for its unstable oscillation is long, so that good control by the pilot can make up for lack of stability. The control of the rotor is achieved by cyclical variation of the blade angle or pitch of the blade. In the airplane, control is secured in direct fashion by displacing a control surface such as the elevator and thereby producing a pitching moment, either up or down. In the rotor with flapping blade, the application of cyclic feathering cannot directly produce a pitching or rolling moment since the blade is freely pivoted at its root. Cyclic feathering displaces the tip path plane or the plane in which move the tips of the blade. The direction of the thrust is changed correspondingly as illustrated in Fig. 1. It is only when the direction of the thrust line is altered that a moment about the center of gravity of the aircraft is created. Thus, helicopter control is indirect, and while it is powerful at all speeds, it is accompanied by a certain lag to which airplane pilots must accustom themselves. The mechanism of the control, leading from the pilot's cockpit to the blade, is also more complex than in the airplane since there must be transmission of motion to revolving blades. Tilting plates or swash plates become necessary, with a stationary outer part connected to the cockpit, and an inner revolving part, with a ball race between the stationary and the revolving components of the swash plate. Another difficulty besides hovering stability lies in the fact that air-stream conditions for the blades vary as they revolve, and these variations of force and moment can produce "shaking" or continual motion of the control stick, to the discomfort and fatigue of the pilot.

5. *General Requirements.* The foregoing requirements are those which are special to the helicopter. There are others which are similar to those an airplane has to meet. In the early development stages of the helicopter, the mere ability to achieve vertical flight was so astounding that other requirements were neglected. As the art progresses, greater speed is called for, with a top speed of more than 100 m.p.h. Climb on an inclined path of over 1000′ per min. is deemed necessary. While vertical climb is an essential element of the helicopter, it should be noted that both climb and ceiling are far greater when the helicopter flies on an inclined path. More useful load, a weak spot of the helicopter, is also demanded. Perfect vision forward and down unimpeded by the instrument board, freedom from mechanical difficulties, passenger accommodation and comfort are also sought. The evolution from mere flight to comfortable transportation proceeds rapidly.

Piloting Problems. No discussion of the helicopter is complete without reference to piloting. From some points of view piloting a helicopter is easier than flying an airplane because in landing or in selecting a landing spot the factor of haste is removed. The pilot can hover carefully and, provided the power of his engine holds out, alight safely in the most difficult and restricted terrain. Also, it has been shown again and again that helicopters can operate in snow and fog which ground all other aircraft. In other respects the helicopter is more difficult to fly than the airplane. Because of its instability it has to be "flown" all the time, so that the pilot enjoys neither physical nor mental relaxation. A flight of a couple of hours becomes fatiguing. Excessive vision forward through a hemispherical expanse of transparent plastic may produce vertigo. On the whole, it is easy to learn how to fly a helicopter, perhaps easier for a man who has never flown at all, than for the experienced airplane pilot who mistakenly believes that he can "check out" on a helicopter on a first attempt, without specific instruction. There are many differences in piloting a rotary and a fixed-wing aircraft. One of these differences is the effect produced when the control stick is pulled back sharply. In the airplane this results in increasing the angle of attack and lifting capacity of the airfoil, so that the speed of flight is decreased. Pulling back the stick in the airplane is thus a natural prelude to landing. In the helicopter pulling back sharply on the stick can produce rearward flight which may be quite disconcerting to the airplane pilot. As stated previously, helicopter control is achieved by changing the direction of the thrust line in indirect fashion. Thus, if a helicopter pilot moves his stick to the right, the helicopter first of all moves to the right and only later does it roll to the right. The indirectness of the process may annoy the airplane pilot. Rudder control in the cockpit is as in the airplane, a matter of foot pedals. In a single-rotor helicopter, rudder control is obtained by changing the blade pitch of the tail rotor and hence its thrust. The unbalanced thrust has to be compensated for by a rolling inclination of the helicopter, which is troublesome. In the case of two coaxial rotors, the blade pitches of the two rotors are changed differentially—one rotor receiving an increase in pitch and the other a decrease. The torques of the two rotors are then no longer equal, so that the fuselage receives a net turning moment.

Another difficulty in piloting the helicopter arises from the fact that to the four classical controls of the airplane—rudder, ailerons, elevator, and throttle—there is added a fifth, namely pitch control; and pitch and throttle must be carefully coordinated to give altitude control. Imagine the helicopter on the ground. The pilot selects a low pitch while revving up the rotor. Then, when he wishes to leave the ground, he must increase pitch and throttle simultaneously in the correct proportions. When the helicopter has climbed high enough to have cleared trees or other local obstructions, the pilot may decide to fly horizontally. He pushes his stick forward and flies forward. But because a helicopter is basically more efficient in forward flight than in vertical flight, he now needs less pitch and throttle than in the vertical climb. Therefore, both pitch and throttle must be decreased in the correct proportions, otherwise the helicopter will climb sharply on an inclined path. This problem of an additional control and correlation of pitch and throttle are being met by a synchronization of pitch and throttle by the use of a constant speed governor acting automatically to give

either correct pitch or correct throttle setting. The technique of making a dead-stick landing and flaring out at the end of the glide requires skill. We conclude that learning to fly a helicopter is not difficult, but the art has to be given attention even by an experienced airplane pilot.

Mechanism. In comparing the cost of a helicopter with the cost of an airplane, we have to remember that the helicopter needs all the mechanism of the airplane and much more besides. The full power of the engine cannot suddenly be applied to the rotor without shock to the blades, so that a clutch must be interposed between the engine and the transmission box. This clutch should preferably be automatic and controlled by centrifugal force. The transmission box has to give a speed reduction of 10 to 1, yet be a compact and light device. Long shafting revolving at slow speed and carrying high torque has to be provided. To secure autorotation in case of engine failure, the pitch of the rotor blades must be decreased and simultaneously the rotor must be completely disengaged from the engine. Hence a free-wheeling or over-running device must be interposed between the rotor and the transmission box. The mechanism for changing blade pitch either differentially or simultaneously is also likely to be complex. A brake for the rotor has to be provided when the helicopter is on the ground.

Maintenance. Just as the mechanism of the helicopter is more complex than the mechanism of the airplane, so its maintenance presents additional tasks. Blades must be carefully balanced, and the pitch of all blades kept to exactly the same value, if vibrations are to be avoided. Fabric-covered rotor blades have proved particularly troublesome and are being replaced by plywood or metal covering.

Safety. If a blade of a helicopter should suddenly let go, the ensuing vibration might be so violent as to prevent the pilot from jumping. Engine failure would be most serious if it occurred 50′ or so from the ground so that forward flight with autorotation could not be established in time. But these two hazards aside, the consensus is that the helicopter, by virtue of its hovering characteristics, is safer than the airplane, and capable of operating under weather conditions which ground other types of aircraft.

Immediate Possibilities. Sikorsky helicopters gave the most useful military and naval service in several theaters of war in rescue work at sea; in ambulance work; in landing supplies to men stranded in the jungle; in detailed reconnaissance; in observation work from the decks of small merchant ships. The helicopter is also likely to be useful to the armed forces in acting as a flying crane, and in close artillery observation. Its military future is thus completely secure. In civil use, because of high initial cost, the need of careful maintenance, and the lack of stability, the helicopter is not likely to serve as a personal aircraft for several years to come. On the other hand, it has immediate and assured applications in industry. These applications are numerous and include: surveying; oil pipe laying; delivery of drugs and first aid in cases of disasters; coast patrol and coastal rescue work; forest patrol and fire fighting, etc.

Two Commercially Licensed Helicopters. On March 8, 1946, Bell Aircraft Corporation received the first commercial license ever granted by the Civil Aeronautics Administration on its Basic Model 47 with the designation NC-1 H. Fig. 9 shows one of the Model 47 to be put into service as a flying relief ship by United-Rexall Drug Company. This Model 47 is a 2-place helicopter with side-by-side seating and good vision, equipped with a Franklin Air-cooled 6-cylinder engine of 175 hp. The 2-bladed rotor is controlled by a gyroscopic device mounted under the main rotor and helping to keep the aircraft on an even keel. The gross weight is 2100 lbs. of which 607 lbs. is useful load. It has a top speed of over 100 m.p.h., an operating speed of 80 m.p.h., and a range of approximately 250 m.p.h.

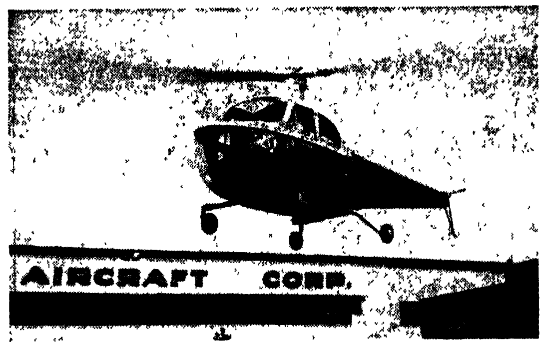

Fig. 9. The Bell Aircraft Model 47 illustrates many of the features of the modern helicopter. Vision forward is secured over almost the entire hemisphere by liberal use of Plexiglas, yet the occupants have a definite point of horizon reference and a sense of protection from enclosures at the sides. In addition to the two main wheels, two nose wheels are provided which are completely swiveling. The scarcely visible blades of the tail rotor are protected by a long skid projecting from the rear end of the fuselage. Engine and transmission are placed in back of the cabin. The vertical shaft on which the two blades are mounted is placed back of the cabin and passes through the center of gravity of the whole helicopter. The rotor is disposed at some distance above the top of the fuselage.

The other helicopter for which CAA license has also been received is the Sikorsky S-51 (Fig. 10) which is a comfortable 4-place model with three passengers seated side by side, just aft of the pilot. The S-51 has a heating and ventilating system, cabin air control and defrosting of the pilot's windows, indicative of the desire to give passenger comfort. The gross weight is 4900 lbs. of which 1250 lbs. is useful load. The three-bladed rotor has a diameter of 48′ 0″. Equipped with a 450 hp. Pratt & Whitney Wasp, the top speed is reported at 103 m.p.h. and cruising at 80 miles. (It is understood, however, that in both the Bell Model 47 and the Sikorsky S-51, the CAA has not granted license for the highest attainable speed, but has reduced the placarded speed by perhaps 20 miles below top speed—on the ground that higher speeds produce stall effects at the tip of the retreating blade, vibration and possible decrease in control.) (Dr. Alexander Klemin.)

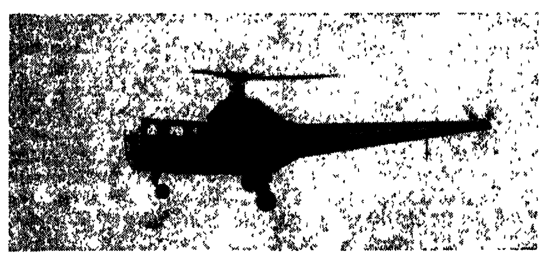

Fig. 10. The four-seater Sikorsky S-51 in which three passengers are seated behind the pilot.

HELICOSPORIDIA. Sporozoa.

HELIOTHERAPY. The treatment of disease by exposure of the body to the rays of the sun or to ultraviolet rays from an artificial source. The method consists either of general exposure of the body as a tonic measure or a stronger local exposure for use in various skin diseases and in indolent ulcers or slow-healing infected wounds. In tuberculosis, heliotherapy has proved of little value in the pulmonary form, but in

other forms, such as tuberculosis of bone, **lymph** glands, spine, abdomen, it may be of some value. (R.S.M., D.M.H.)

HELIOZOA. Sarcodina.

HELIUM. Symbol: He. Atomic number: 2. Atomic weight: 4.003. Density: 0.1785 gram per liter, 0° C., 760 mm., or 0.138 when air equals 1.000. Melting point: −272.2° C. Boiling point: −269.0° C. No isotope but of single atomic form: 4.

Helium is a colorless, odorless gas, of negative chemical properties with ordinary materials, except under the influence of electric glow discharge or **electron** bombardment helium forms compounds with **tungsten, iodine, sulfur, phosphorus.** In a **vacuum** electric discharge **tube** shows green to canary-yellow glow. Discovered first in the vapors surrounding the sun by Lockyer in 1868, through the yellow spectral line near the two yellow lines of sodium, then by Ramsay in 1895 in the mineral **clevite.**

Helium occurs (1) in minerals of **uranium** and **thorium,** such as **clevites, pitchblende, carnotite, monazite,** and also in **beryl,** (2) in mineral waters (1 part He per thousand of water, in some Iceland waters), (3) in volcanic gases, (4) especially in certain natural gases of the United States. The first discovery of this kind was made in Kansas. The richest helium wells are in Utah. In northeastern Texas, four wells have produced 55 million cu. ft. of helium. The fields in which are located the wells having the greatest percentage (1.3–8.0%) of helium are now held as government reserves. The primary use for helium is in inflating airships. Helium is a very light gas. Its lifting power is 92.64% that of hydrogen (of course, the comparative net buoyancy in **airships** is much less than this), and it is non-inflammable, (5) in ordinary air, about 1 part in 200,000.

The most striking properties of helium are its radioactivity, when emitted as the positively charged (+2) alpha particles in **radioactive changes,** its formation in radioactive change by uranium-**radium** and thorium-containing substances, emitting alpha particles, later losing the charge to become helium, and recently, its production artificially by bombardment of **lithium** or **boron** with high-velocity **protons** or alpha rays.

The liquefaction of helium was accomplished by Onnes in 1908 in Leiden, and Keosom in 1926 succeeded in solidifying helium in the same laboratory. Helium is the most difficult of all the gases to liquefy. An astonishing property of certain metals is that at the temperature of liquid helium they possess electrical **super-conductivity,** e.g., mercury, lead, and tin.

Helium-oxygen atmospheres are utilized in high-pressure breathing work, such as diving suits, caisson work, because helium is inert, less soluble in the blood stream than nitrogen, and diffuses 2.5 times more rapidly than nitrogen. The time for de-gassing is materially reduced, as also the hazard resulting from the gas collecting in the joints. (R.K.S., R.M.F.)

HELIX. A helix is a **skew curve** or twisted curve in space which is defined as the **locus of a point** which moves on a right circular **cylinder** in such a way that the distance it moves parallel to the axis of the cylinder varies directly as the angle it turns through around the axis.

Parametric equations of the helix are:

$$x = a\cos\theta, \quad y = a\sin\theta, \quad z = b\theta,$$

where θ is a parameter. (L.L.S.)

HELIX ANGLE. Helical Gearing.

HELLBENDER. Amphibia, Urodela. A large aquatic **salamander,** *Cryptobranchus alleghenensis,* of the Mississippi river system. It reaches a length of 18″ and has a flattened head and body, short legs, and a compressed tail. The gills are concealed, but otherwise it resembles the mudpuppy. (A.W.L.)

HELLGRAMMITE. Insecta, Neuroptera. The large aquatic larva of the dobson fly, *Corydalus.* It lives in running water and is an excellent bait for bass. (A.W.L.)

HELMINTHOLOGY. A biological science dealing with the **worms.** Since many worms are parasitic, the term parasitology is more commonly used. The study of roundworms is important in agriculture and has resulted in the science of nematology (see **Nematoda**) which is properly a subsidiary of helminthology. (A.W.L.)

HELVE HAMMER. Forging.

HEMATEMESIS. The vomiting of blood which arises from hemorrhage high in the gastro-intestinal tract, usually in the stomach or duodenum. The hemorrhage may be massive. Benign peptic ulcer is the commonest cause. Other causes are alcoholic gastritis, **cancer** of the stomach, and ruptured esophageal varices in **cirrhosis** of the liver. Vomited blood is dark brown in color and is described as "coffee ground" material. (D.M.H.)

HEMATITE. The mineral hematite, **ferric oxide,** Fe_2O_3, occurs as thick or thin tabular **rhombohedral** forms, sometimes in pyramids but rarely in **hexagonal** prisms. It also assumes **botryoidal,** columnar and lamellar shapes, and may be granular or compact. Its hardness is 5.5–6.5; specific gravity varies from as low as 4.2 to as high as 5.25; luster, metallic to earthy or dull; color, dark gray to black; earthy forms may be different shades of red; streak, red to red-brown; translucent (in very thin flakes) to opaque. Hematite with a metallic luster is called specular iron. It is a widely distributed and common mineral, found in **igneous, sedimentary** and **metamorphic** rocks as beds and veins, having probably been formed in many different ways under very different conditions. Beautifully crystallized hematite has been found in the Urals of Russia; Rumania; Switzerland; the Island of Elba; Alsace, France; Cumberland, England; and Brazil. Perhaps the greatest hematite region in the world lies along the southern and northwestern sides of Lake Superior in Michigan, Wisconsin and Minnesota where this mineral has long been mined. Extensive beds of hematite are found throughout the Appalachian region from New York to Alabama, being principally mined near Birmingham in the latter state. Hematite occurs in quantity in Nova Scotia and Newfoundland. It is the most important ore of iron, and has other industrial uses in paint manufacture, polishing compounds, etc. The name hematite is derived from the Greek word meaning blood. (E.S.C.S.)

HEMATOLOGY. That branch of medicine having to do with the study of the **blood,** the blood-forming **tissues** and the diseases of the blood. (R.S.M.)

HEMATOMA. An accumulation of free blood in the body tissues forming a localized mass. This usually follows an injury in which rupture of blood vessels takes place. (R.S.M.)

HEMATURIA. The presence of **blood** in the **urine.** This condition is found in certain forms of **nephritis** and with injury, tumors, stones, or calculi in the urinary tract. It is also seen in **scurvy** and in some cases of severe **sepsis.** (R.S.M.)

HEMICHORDATA. A subphylum of the phylum Chordata containing only a few primitive marine animals without common names. The genus *Balanoglossus* has lent its name to the forms most commonly seen, al-

though some belong to other genera. They are worm-like animals which live in mud and sand at the bottom of the ocean. The central nervous system is dorsal in this group but it remains partly or wholly at the surface. The **notochord** is limited to the anterior part of the body and is sometimes connected with the alimentary tract. Gill slits vary from one to many pairs. The group is also commonly named Enteropneusta and rarely Adelochorda.

There are two orders:

Order Balanoglossida. Worm-like animals with many gill slits and with a fleshy proboscis before the mouth. *Balanoglossus* and related forms.

Order Pterobranchia (Cephalodisca). Sessile animals, some solitary and some colonial. One pair of gill slits. A proboscis and branching tentacles lie before the mouth and the intestine is U-shaped. *Cephalodiscus* and *Rhabdopleura*. (A.W.L.)

HEMIGALE. **Civet.**

HEMIMETABOLA. A division of the **insects** characterized by incomplete metamorphosis. The immature insect differs conspicuously from the adult in form and is adapted to an entirely different mode of life; in this the group resembles the **Holometabola.** The young have compound eyes, however, and the wings develop externally as in the **Paurometabola.** The group includes the three orders, **Plecoptera, Ephemerida,** and **Odonata,** all with aquatic larvae which are called naiads. (A.W.L.)

HEMIMORPHITE. **Calamine.**

HEMIPLEGIA. **Apoplexy.**

HEMIPODE. Aves, Golliformes. *Turnix.* The **bustard-quails** of the Australian, Oriental, and Ethiopian regions. They are unusual in the larger size and brighter colors of the female and in the fact that the male incubates the eggs and cares for the young. (A.W.L.)

HEMIPTERA. The true **bugs,** an order of insects containing about 21,000 species, many of economic importance. They have a piercing and sucking mouth and live on the blood or juices of animals or the sap of plants. The wings, when present, are usually distinctive. The basal half is thicker than the terminal, and the tips overlap partially so that the margins of the wings form an X on the back. The chinch bug and bedbug are species of economic importance.

Bugs of several families are aquatic and some forms live on the surface of the water, supported by the surface film. The swimming forms are the **water boatmen, back swimmers,** and giant water bugs and the **water striders** skate on the surface. One of the last, *Halobates,* is the only marine insect known. Shore forms include the **toad bugs.** On dry land the order is represented in almost every possible habitat. (A.W.L.)

HEMITROPIC. Used by mineralogists to describe a crystal that appears to be composed of two halves of the same crystal turned partly around. (R.M.F.)

HEMLOCK, POISON. **Carrot Family.**

HEMOGLOBIN. A chemical compound which is the coloring matter of red **blood** cells. Its composition is complex. One portion of the molecule is a protein known as globin; the other portion is hematin, and contains iron. (See **Aminoacids, Polypeptides, and Proteins.**)

Hemoglobin, having the power of combining with oxygen, is the means of supplying the body cells with oxygen. When oxidized, it is oxy-hemoglobin. In the circulation when the oxygen is liberated, the hemoglobin is known as reduced hemoglobin.

The amount of hemoglobin may easily be estimated from a fresh specimen of the blood. Normally it varies from 80 to 100% or 12.0 to 14.5 grams. In **anemia** the percentage is reduced. (R.S.M.)

HEMOLYTIC JAUNDICE (Congenital jaundice, familial jaundice). A chronic disease due primarily to increased fragility of the red **blood** cells accompanied by destruction of these cells, with resultant **anemia** and **jaundice.** The jaundice is due to the presence of excessive amounts of the blood pigment, bilirubin, in the circulation. The congenital or familial form is hereditary; it is treated successfully by removal of the **spleen.**

Acute hemolytic anemia and jaundice occur as toxic reactions to certain drugs, the **sulfonamides,** lead, etc., and occasionally in severe infections. (D.M.H.)

HEMOPHILIA. An hereditary disease marked by excessive and prolonged **hemorrhage** after trauma. Often the injury is so minor that it would normally not cause bleeding; occasionally the hemorrhage seems to start spontaneously. Hemophilia is a disease of males, transmitted from generation to generation only through females. It behaves as a sex-linked Mendelian recessive (see **Heredity**). A female capable of transmitting the disease does so to about ⅔ of her male children, while ⅔ of her female offspring are conductors of the disease.

The cause of hemophilia is unknown. The characteristic pathologic finding in the blood is failure of the **coagulation** mechanism. The clotting time is therefore much prolonged, but once formed, the clot retracts normally.

The treatment of hemorrhage in a hemophiliac is rest, **morphine,** and the local application of thrombic material such as thromboplastin (see **Coagulation**) derived from rabbit lung. **Transfusion** of small amounts of blood will decrease the clotting time and control the hemorrhage. Since the patient is subject to bleeding throughout his life, he must always take special care to avoid trauma. It is wise for him to know the whereabouts of a suitable blood donor for emergencies. (D.M.H.)

HEMOPTYSIS. The expectoration of blood which arises from hemorrhage in the **lungs.** The blood is usually bright red and frothy. **Tuberculosis** and lung **tumors** are the commonest causes of hemoptysis. (D M.H.)

HEMORRHAGE. Marked bleeding in any part of the body. The common types of hemorrhage, excluding hemorrhage following accident and injury or occurring operatively or post-operatively are: 1. Pulmonary. Pulmonary hemorrhage varies markedly in degree. The blood is usually bright red and frothy due to mixture with air. Tuberculosis and cancer are common causes of pulmonary hemorrhage and **hemoptysis.** 2. Gastric hemorrhage occurring in **peptic ulcer** when a blood vessel is eroded in the ulcer bed. The blood is vomited (**hematemesis**) and is usually dark red or brown due to admixture with the gastric juices. 3. Uterine hemorrhage, due to premature separation of the **placenta,** or occurring after delivery. It may also be due to malignant or benign **tumors** of the **uterus,** various glandular disorders causing excessive bleeding with the menses, and abortion. 4. Rectal bleeding usually due to acute infection (**dysentery, typhoid**) or to ulceration or malignant growths in the intestinal tract. In this type of hemorrhage the expelled blood may be black or tarry in color. Occasionally bleeding from **hemorrhoids** is severe enough to be called a hemorrhage, although slight

blood loss is more characteristic. 5. Nasal hemorrhage, the common nose bleed which is not usually serious. 6. Cerebral hemorrhage, hemorrhage from an **artery** in the **brain,** causing the so-called "stroke" or **apoplexy.** (R.S.M.)

HEMORRHOIDS. Hemorrhoids are small **tumors,** made up of dilated varicose veins, occurring at or near the rectal outlet. They are popularly called "piles." Hemorrhoids are divided into three groups: external, internal and a combination of the two. External hemorrhoids occur at the external margin of the rectum beneath the skin. Internal hemorrhoids are situated just inside the rectum and are covered by mucous membrane which lines the rectum. Long-standing internal hemorrhoids, however, may protrude through the anal opening. In cases of long duration, both internal and external hemorrhoids may be present.

The chief factor in the development of hemorrhoids is **infection** of the veins in this region. The main predisposing factor is chronic **constipation.**

The chief symptoms of hemorrhoids are bleeding, pain, and spasm of the anal muscles. The diagnosis can be made only on careful proctoscopic examination of the rectum and anus.

The treatment of choice of all varieties of hemorrhoids is surgical excision, which when expertly done is a simple procedure causing little or no post-operative pain. If internal hemorrhoids alone are present, and there is no acute infection at the site, they can be treated by the multiple-injection method, consisting of the injection of a sclerosing substance into the veins, causing them to be obliterated by scar tissue. This can be done in the surgeon's office and when done by experts in the technique, fairly satisfactory results can be obtained. If the causative factors are not corrected, hemorrhoids will usually recur no matter what treatment is used. (D.M.H.)

HEMP. *Cannabis sativa.* Cannabinaceae. Hemp is obtained from the stem pericycle of a tall hollow-stemmed annual which is a native of central and western Asia. In cultivation the slight branching which characterizes the plant is considerably reduced by planting thickly. The plants grow from 5–16′ in height. They have digitately compound dark green leaves and small inconspicuous flowers which are of two kinds, occurring on different plants. The staminate (see **Stamen**) flowers appear in small axillary (see **Axil**) clusters on male plants, and the pistillate (see **Pistil**) flowers are borne in leafy spikes on female plants. The fruit, an **achene,** is a hard ovoid structure, often called hemp seed. Cultivation of hemp has been carried on in China for many centuries. From that country its culture has spread to many countries, Europe taking it up long before the Christian era dawned. It is widely grown in the United States, although extensively in only a few states, such as Wisconsin and Kentucky. Hemp grows best in regions having a warm humid growing season of about five months; the plants grow rapidly, soon shading the ground so effectively as to suppress all other plants present, for which reason its culture is sometimes recommended as a way to eradicate obnoxious weeds. When the staminate flowers are mature, the plants are ready for harvest; to delay after that is not desirable, since the male plants die soon after flowering; furthermore, after flowering the fibers become coarser. Harvesting and the treatment of the plants after harvesting are very similar to those of **flax** plants. The hemp plants are cut off or pulled up, denuded of leaves, roots and tops, and tied in bunches and left to dry for about 2 weeks. They are then immersed in water to ret. In retting the intercellular substance of the stems is acted upon by **bacteria** and softened so that the fibers are readily cleaned of surrounding tissues. Scutching removes the woody tissue, after which the rough hemp fibers are hackled, or drawn over coarse combs which pull out the fibers.

Hemp fibers are coarse and rather harsh, and much less pliable than flax fibers. Furthermore, they are dark colored and not easily bleached without injury. So the principal use made of them is in the making of rope and coarse twine, sail cloth, the warp of carpet and belt and upholstery webbing, all products where strength and durability are the principal aim, and appearance of little consequence. Short fibers of hemp, called tow, are used in packing joints in iron pipes, and as pump packing, also as a stuffing for upholstery. The woody waste from hemp fiber production has been used in paper making.

From hemp seeds, a valuable oil is pressed out; it is used in the making of soft soaps, and also in mixing paints and varnishes. The seeds themselves are used as bird food.

From the hemp plant also a drug is obtained. This substance is located in the glandular hairs of the leaves and stem. From the pistillate flowers and fruits is obtained a resinous substance, which is smoked in the Orient under the name of hashish or bhang. As a medicine the drug may have a quieting effect on the nervous system, but large doses are dangerous. The Mexican preparation, marihuana, is very similar to hashish in its ill effects. (See also **Manila Hemp.**) (R.M.W.)

HENNA. *Lawsonia inermis.* Lythraceae. This plant, a native shrub of Africa and Asia, is widely cultivated in tropical countries. The small flowers are inconspicuous, but very fragrant. The leaves are powdered and made into a paste which applied to the hair or beard gives it a bright red color. It stains the skin yellow and is used by some Oriental people to color the hands and feet. From the fragrant flowers, a rich perfume is obtained, which is used in oils and ointments. (R.M.W.)

HENRY. **Inductance; Electric and Magnetic Units.**

HENRY'S LAW. **Gas Absorption; Solutions.**

HEPATICS. **Bryophytes.**

HEPATITIS. Inflammation of the liver, due to infection, chemical poisons or obstruction of the bile channels.

Acute infectious hepatitis (infectious jaundice) is an epidemic disease which is common during war time and a serious problem on military fronts because of its high incidence. The etiological agent is a **virus** whose characteristics are not yet completely known. Fever, malaise, gastro-intestinal symptoms and jaundice constitute the clinical picture. The signs and symptoms persist for about 6 weeks; the mortality is low. Fatal cases show extensive destruction of liver cells. Infectious hepatitis is probably transmitted by the oral route; the virus is excreted in the stools during the acute phase of illness. The disease can be prevented by the intramuscular injection of gamma globulin. The incubation period is long—averaging 30 days, and the progress of an epidemic can be halted by the early administration of gamma globulin to susceptible individuals who have been exposed, i.e., children and young adults.

Acute catarrhal jaundice is thought to represent the **endemic** form of infectious hepatitis. It is a similar but milder disease, usually occurring sporadically. Syphilitic hepatitis is rare.

Homologous serum jaundice is a form of jaundice produced by a virus similar to that responsible for infectious hepatitis. It has a longer incubation period (60 to 90 days) and is often a more severe disease, but patients have the same type of symptoms and signs in the two conditions. Homologous serum jaundice does not occur naturally but only on the injection of human blood prod-

ucts into the body. Since the virus circulates in the blood for several weeks before the clinical disease becomes manifest, blood drawn from an apparently healthy donor who is actually in the incubation period will contain the virus. When such blood is given in the form of a transfusion, convalescent serum, or a vaccine, to a susceptible recipient, the latter will develop jaundice 2 to 3 months or more later. It is not yet known whether gamma globulin will prevent homologous serum jaundice.

Acute yellow atrophy is an inflammatory disease of the liver, which may occur without known cause, as in **toxemia of pregnancy**, or as a reaction to toxic chemicals such as arsphenamine, trinitrotoluene, etc. The liver undergoes rapid necrosis and shrinks to half its normal size. The patient is acutely ill, with headache, delirium and deep jaundice. Death in coma usually follows within a few days. In the subacute form, recovery sometimes occurs.

Obstruction to the biliary system from stones or infection may lead to inflammation of the liver cells and secondary hepatitis. (D.M.H.)

HEPATOPANCREAS. A digestive gland of the mollusks (**Mollusca**) and **arthropods** which discharges into the stomach. (A.W.L.)

HERCULES. (Map, page 380.) A large and important **constellation** between **Lyra** and Corona Borealis. The constellation contains no strikingly bright stars and hence is somewhat difficult to locate. Once found, however, it is a fertile field for a small **telescope.** In 1934 Hercules received considerable notice because of the brilliant **Nova** that appeared in it just before Christmas. Perhaps the most interesting object in the constellation is the remarkable star **cluster** which was first noted by Halley in 1714. While the cluster can be distinguished as such in a telescope of only 2-in. aperture, it requires a telescope of larger than 6-in. to really appreciate the magnificence of the object. In addition to the star cluster there are several **double stars** to be observed with small telscopes, many of them having components of different colors. (W.K.G.)

HERCYNIAN REVOLUTION. **Permian.**

HEREDITY. The transmission of developmental potentialities from one generation of living things to the next through the process of **reproduction.** The materials of the parent bodies from which a new individual develops are its actual heritage. During its own embryonic (**embryology**) development the potentialities of this heritage are expressed in the structural characteristics of the new body, normally like those of the parents or those of a more remote generation of ancestors. This fact leads to the common statement that the organism inherits certain characters; while not precisely true, the interpretation is permissible for all ordinary purposes of description.

The fact of inheritance is obvious. It has been expressed for ages in unscientific observations. Attempts to determine the scientific foundations of inheritance are relatively recent, however, and the establishment of a sufficient body of facts relating to heredity to constitute a science has occurred only during the 20th century. This science is called genetics.

The first steps in genetics were taken by plant hybridizers of the 18th and 19th centuries, chiefly in Europe, and culminated in the experiments of Gregor Johann Mendel, a monk at Brno, Czechoslovakia, then Brünn in Austria. Mendel's results were published in 1866 and lay almost unnoticed until 1900, when they were corroborated by three scientists in the birth of modern genetics. The published report of Mendel's work repeated the significant observations of his predecessors and added a simple mathematical analysis that had not previously been expressed. As a result of the far-reaching importance of this work the term Mendelian heredity is now commonly applied to the established fundamentals with which all subsequent discoveries have been correlated.

Mendelian heredity depends on three fundamental concepts: 1. The organism is a mosaic of **unit characters** capable of separate hereditary transmission. 2. A unit character may mask a related unit character completely when the potentialities for the development of both are present in the same individual. This principle is called **dominance**, and the masked character is said to be recessive. 3. Unit characters may be **segregated** during reproduction, regardless of the combinations in which they have been associated.

To these concepts modern genetics has added that the association of different related unit characters in one individual may result in the development of both in different parts of the body, in a mosaic inheritance, or in an intermediate condition through blending inheritance.

Some characters, particularly of a quantitative nature, are not amenable to these rules unless through a very complex association of underlying hereditary unit characters. Such characters must be studied by statistical methods. They were the foundation of another attempt to formulate laws of inheritance made by Sir Francis Galton, from which we retain the law of ancestral inheritance and the law of filial regression. The former indicates that each parent contributes one-quarter of the total heritage of the individual, each grandparent one-sixteenth, and so on in a rapidly diminishing percentage. The law indicates the great reduction of the possibility of a hereditary character reappearing after a lapse of generations. Filial regression is the tendency of extreme parents to produce offspring less extreme than themselves. Thus tall parents beget tall children, but usually shorter than themselves. Galton studied human inheritance and in addition to his mathematical analyses, so necessary in this field, took the initial steps in proposing deliberate control, which led to the modern science of **eugenics.**

Modern science has also added to early discoveries the definite recognition that hereditary potentialities are resident in the **chromosomes** of body cells and that definitely located **genes** within these chromosomes are the determiners through which specific unit characters are brought to expression. The behavior of chromosomes is strictly in harmony with the transmission of characters by Mendelian heredity (**Meiosis; Fertilization**). Since nothing was known of chromosomes during Mendel's life, this **correlation** had to await further advances in cytology.

Mendel's chief contributions were derived from the study of garden peas, in which he observed seven pairs of unit characters, all similar in behavior. He noted, for example, that seed colors included two unit characters, yellow and green. When he crossed parent plants of the two strains the resulting hybrid seeds were entirely yellow, indicating the dominance of this color over green. He then inbred the hybrids, and in their offspring both yellow and green seeds appeared in the ratio of three yellow to one green. Related unit characters of this kind are said to be alleles or allelomorphs. It is now known that their genes occupy the same position in the paired chromosomes of the cell, while only one can be represented in the single chromosome of a **germ cell.** Since each parent contributes one chromosome to each pair in its offspring, it may also contribute one gene of an allelic pair. The one parent plant contributed a gene for yellow, the other for green, and through dominance the offspring were yellow. Segregation, however, enabled these hybrids to transmit either yellow or green during their reproduction, and through random fertilization all possible combinations of these determiners were established. The characters are commonly represented by symbols, using a capital letter for the dominant and a small letter for the related recessive,

as Y and *y* for yellow and green respectively. For the pair of characters mentioned, the following diagram is representative:

Parental generation (P):	YY	*yy*
Germ cells:	Y	*y*
Hybrids of first filial generation (F_1):	Y*y*	

Gametes of F_1 generation and their combinations in the F_2 generation, in a Punnett square:

	Y	*y*
Y	YY	Y*y*
y	Y*y*	*yy*

The YY and *yy* individuals in this diagram are homozygous, while the Y*y* individuals are heterozygous. Since all YY and Y*y* individuals look alike, due to the dominance of Y, they belong to the same phenotype, but since their hereditary potentialities are different they belong to different genotypes. The *yy* individuals from hybrid parents are known as extracted recessives. There are twice as many heterozygotes as homozygotes of either kind in this 3:1 ratio because similar individuals in this category result from reciprocal combinations of genes, half of the individuals receiving the dominant from one parent and half from the other. Examples of this kind, involving only one pair of allelic characters, are known as monohybrids.

Additional complexity arises in dihybrids, trihybrids, and polyhybrids of still more characters through the free reassortment of the unrelated pairs of alleles. Thus peas from smooth yellow seeds crossed with others from wrinkled green seeds, a dihybrid combination, produce only yellow smooth seeds in the F_1 generation, but when inbred these plants give rise in the F_2 generation to the four possible combinations: smooth yellow, smooth green, wrinkled yellow, and wrinkled green, in the ratio 9:3:3:1. The reason is evident in the following diagram:

	SY	Sy	sY	sy
SY	SY SY	Sy SY	sY SY	sy SY
Sy	SY Sy	Sy Sy	sY Sy	sy Sy
sY	SY sY	Sy sY	sY sY	sy sY
sy	SY sy	Sy sy	sY sy	sy sy

In this diagram each pair of symbols above and at the left side represents the contribution of one parent in one of its germ cells, and in the small squares the possible combinations from the two parents are shown. Dominance prevails as in the monohybrid.

In a trihybrid free reassortment results in an F_2 ratio of 27:9:9:9:3:3:3:1. The number of phenotypes is always a power of two indicated by the number of pairs of alleles under consideration.

The study of heredity in animals has shown that these principles are applicable in that kingdom as well as in plants, but relatively few animals are sufficiently prolific to demonstrate complex ratios. The fruit fly, *Drosophila melanogaster,* has been the most productive of all genetic subjects, while man and the domestic animals yield very limited Mendelian data.

Modern genetics, largely from studies of the fruit fly, has disclosed many principles as corollaries of simple Mendelian heredity. The more important are as follows:

Multiple alleles: More than two unit characters may be related to each other as alleles. In such cases only two of the series may be present in any one individual, and dominance is in a graded series, as may be determined by experimental results.

Multiple factors: More than one gene may be necessary for the production of a single unit character. If two genes are essential for its appearance and either alone is incapable of expression, they are said to be **complementary.** If one expresses itself alone, a gene that modifies this expression is **supplementary.** If two are capable of producing the same effect whether present singly or in combination, so that the resulting character is absent only from homozygous recessives, they are said to be **duplicate** genes. In all cases recombination of the genes during reproduction follows the same course as in simple Mendelian heredity but the resulting phenotypic ratios differ because fewer unit characters are involved.

Lethal genes: Some genes completely inhibit development or modify it in such a way that the individual dies. They also modify the usual ratios of associated characters.

Linkage: Some characters, although not allelic, are inherited in definite groups; they are said to be linked. Modern genetics shows that linkage is due to the presence of genes for the linked characters in the same chromosomes.

Crossing over: Linkage relations are sometimes interrupted in a limited number of individuals, permitting some reassortment of normally grouped characters. This change is due to the breaking of paired chromosomes in **synapsis** and the reunion of their fragments in new combinations to form similar chromosomes, sometimes with new combinations of genes.

Translocation: This change is a shifting of the relations of genes in the chromosomes, due to looping, fusion, and rupture, or to the attachment of fragments to other chromosomes. It may result in the duplication of genes within a chromosome or in a change in the serial arrangement of the included genes.

The inheritance of sex has also been shown in many cases to depend on a simple chromosomal mechanism. Males of many species have an *x* chromosome without a synaptic mate or with a *y* chromosome mate that is evidently abortive. The females of such species have two *x* chromosomes. In the formation of germ cells all eggs receive an *x* chromosome while half of the sperm cells receive an *x* chromosome and half a *y* or none. Random combination of these cells restores the *xx* combination in one-half and *x* or *xy* in the other, thus producing half females and half males. Other investigations have shown that the quantitative balance between the sex and other chromosomes is the active factor in conditioning the differentiation of the sexes.

This disclosure also explains the phenomenon of sex linkage. Genes lying in the sex chromosomes, mostly in the *x* chromosomes but a few in the *y*, are inevitably transmitted and expressed in some definite relation with sex, hence they are said to be sex linked. Such characters need have no active sexual role.

The findings of genetics have been of great practical value in plant and animal breeding. Although the improvement of cultivated plants and domestic animals by **selection** preceded by many years the formulation of scientific principles of heredity, the discovery of these principles has made possible much more precise and efficient procedure in the establishment of useful strains. **Hybridization** and selection together are the chief means of improvement. Applied by scientists they have brought about many modifications of living things and have disclosed many facts concerning heredity. Corn has been studied in detail and subjected to many experiments,

both practical and purely scientific. Tomatoes, radishes, various cereals, and flowers of many species have also commanded attention. More has been done with plants than with animals because the domestic animals are less amenable to experiment. From the practical point of view plants are more satisfactory subjects because desirable hybrid strains may often be propagated by cuttings, grafting, and other asexual methods which avoid the segregation that is inevitable in sexual processes. Only rigid selection can establish desired hybrid combinations in plants or animals that must be produced sexually.

The study of human heredity depends entirely on observation of the family, since controlled mating is impossible. Genealogical records have furnished a large amount of valuable material and the records of public institutions such as prisons and asylums have been equally useful to the geneticist. Such records are not to be compared with scientifically assembled experimental data, but they leave no doubt that the principles of heredity worked out in the study of other organisms are also applicable to man. In a few cases they have also disclosed adequate evidence of a specific type of Mendelian inheritance of human characters.

The clearest evidences of human heredity are found in the behavior of simple structural defects, such as the appearance of extra digits (polydactylism), the fusion of bones in the digits (symphalangism), and shortness of the fingers (brachydactylism). These defects are transmitted as Mendelian unit characters allelic to normal structure. Red-green color-blindness (**vision**) is one of the most striking examples of inheritance in man. It is a sex-linked recessive allele of normal vision. Both x chromosomes of the female must carry the gene for the defect if she is to be color-blind, whereas the male may be color-blind if he receives such a gene in his one x chromosome. Females may be heterozygous carriers of the defect, with normal vision; males are either strictly normal or defective. In this type of inheritance the male always receives the genes for his characters from his mother, therefore a carrier mother may have some color-blind sons. A color-blind man and a genotypically normal woman cannot produce color-blind children, but all of their daughters are carriers. On the other hand, a color-blind woman and a normal man will produce carrier daughters and color-blind sons. **Hemophilia** is inherited in a like manner, except that the recessive genes for hemophilia are lethal in the homozygous condition in the female.

Since man is concerned chiefly with his behavior, in the broad sense of the term, the inheritance of ability is much more important. It is, however, extremely complex, depending upon many simpler heritable unit characters that are only slightly understood. Nevertheless the inheritance of specific types of ability, and particularly of various degrees of ability, are well established by our records. Deficient families usually produce deficient children, and superior families normally maintain their superiority. There are occasional exceptions in both cases but in the long run superiority, mediocrity, and mental and social inadequacy tend to persist generation after generation in family lines. These general terms are not to be taken to indicate hereditary traits in the strict sense of scientific genetics, but the heritage of individual organization whose expression in the behavior of the individual is quite evidently amenable to the principles so readily appreciated in the study of simpler structural unit characters. The possibility of practical application of this knowledge is the field of **eugenics**.

The study of all aspects of heredity is now pursued extensively and is the foundation of a voluminous and constantly increasing literature. (A.W.L.)

HERMAPHRODITE. An animal with functional reproductive organs of both sexes. The condition is common among the flatworms and segmented **worms** and occurs in a few species of **echinoderms** and mollusks (**Mollusca**). Among the vertebrates the occurrence of both sexes in one individual is rare and the sexes appear at different periods. Animals in which such a transition is possible are sometimes influenced by external conditions and during the transformation may be functionally hermaphrodite. This is true of some **fishes** and **amphibians.** (A.W.L.)

HERMAPHRODITE DUCT. The duct of the ovotestis (**gonad**) of certain **snails.** (A.W.L.)

HERMAPHRODITISM. Only about twelve cases of supposedly true hermaphroditism in the human race have been reported. The term signifies the presence of all of the functioning genital organs of both sexes in one individual. The cases mentioned above were supposed to have both testicles and ovaries present. The ability to impregnate as well as to conceive has never been reported in the one individual.

Many cases of pseudo-hermaphroditism have been seen. In this condition the genital organs, internal or external, do not conform either totally or in part with the sexual glands (testicles or ovaries) present. In the male hermaphrodite, testicles are present but may be abdominal in position. The penis is small and more nearly resembles a large **clitoris**; the **scrotum** is divided by a cleft resembling the female labia with a small short **vagina.** **Uterus** and tubes are not present.

The female hermaphrodite has a large clitoris more like a small penis, rudimentary vagina, a uterus and ovaries. Various in-between stages may be present, giving a very bizarre picture where the sex can only be determined by operation or in some instances by determination of the amount of sex **hormone** in the blood and urine.

In general an hermaphrodite is best raised as a female. The bodily characteristics may not be sharply differentiated in regard to sex. (R.S.M.)

HERMITE POLYNOMIALS. The Hermite polynomials $H_n(t)$ are defined by

$$H_n(t) = \frac{(-1)^n}{e^{-\frac{t^2}{2}}} \frac{d^n e^{-\frac{t^2}{2}}}{dt^n}.$$

We list the first few $H_0(t) = 1$, $H_1(t) = t$, $H_2(t) = t^2 - 1$, $H_3(t) = t^3 - 3t$, $H_4(t) = t^4 - 6t^2 + 3$, $H_5(t) = t^5 - 10t^3 + 15t$, etc. They satisfy the recurrence relationship $H_{n+1}(t) = tH_n(t) - nH_{n-1}(t)$. When n is odd $H_n(t)$ is a polynomial of $\frac{n+1}{2}$ terms and contains only odd powers beginning with t^n. When n is even $(n > 0)$ $H_n(t)$ is a polynomial of $\frac{n}{2} + 1$ terms in even powers starting with t^n. The Hermite polynomials are orthogonal with weight function $\frac{e^{-\frac{t^2}{2}}}{\sqrt{2\pi}}$ that is,

$$\int_{-\infty}^{\infty} H_m(t)H_n(t)\frac{e^{-\frac{t^2}{2}}}{\sqrt{2\pi}}\,dt = 0, \quad m \neq n$$

$$\int_{-\infty}^{\infty} H_m(t)H_n(t)\frac{e^{-\frac{t^2}{2}}}{\sqrt{2\pi}}\,dt = n!, \quad m = n.$$

The Hermite polynomials may also be found by expansion of the generating function in powers of x.

$$e^{xt-\frac{x^2}{2}} = H_0(t) + H_1(t)x + H_2(t)\frac{x^2}{2!} + H_3(t)\frac{x^3}{3!} + H_4(t)\frac{x^4}{4!} + \cdots$$

The Hermite polynomials find applications in **statistics** in the **Gram-Charlier** Type A series and are also useful in certain applications in physics to problems of heat and quantum mechanics. (L.A.A.)

HERNIA (Rupture). The protrusion of a portion of tissue or organ through a weakness or abnormal opening in any part of the body. Thus it is possible to have a herniation of the brain through an opening in the skull, or herniation of muscle if an opening occurs in the covering membranes of the muscle.

Common types of hernia such as femoral, inguinal, umbilical (navel) occur as protrusions of a sac-like process of the lining membrane of the abdominal cavity—the **peritoneum**—through a weakness at certain sites in the abdomen. These sites are usually where structures such as blood vessels pass out from the abdominal cavity, or did during uterine life. These sites are frequently congenitally weak, so that if any strain causing increased abdominal pressure occurs, this weakness is accentuated and a hernia results. Chronic cough, constipation, heavy lifting, violent games, etc., are all precipitating causes of hernia since they increase the pressure within the abdomen. As continued pressure increases the size of the sac-like process, there may be forced into it a loop or small portion of intestine or some easily movable organ in the abdomen. Sometimes, when the opening through which the rupture occurs is small, the intestinal organ forced into the sac cannot be pushed back into the abdomen. Such a condition is known as an incarcerated hernia. This produces acute symptoms with local pain, often vomiting, and an emergency operation is necessary. If this is not performed, the blood supply may be shut off, resulting in a strangulated hernia. **Gangrene** may develop in the strangulated portion.

Common types of hernia are:

1. *Inguinal Hernia.* Develops along the course of or through the wall of the inguinal canal, where, in the male, the ducts leading from the testicle pass upward along the lower portion of the abdomen above the groin into the abdominal cavity. In the female the corresponding structure, the round ligament of the **uterus**, runs through the inguinal canal. Inguinal herniae are of several varieties; they are more common in men than in women. Some herniae of long standing will push their way downward into the **scrotum**.

2. *Femoral Hernia.* Occurs in the upper anterior portion of the thigh just below the groin. The weakness here results from imperfect closure around the large femoral blood vessels which pass from the abdomen into the thigh. Femoral herniae are more common in women.

3. *Umbilical Hernia.* This type of hernia occurs at the navel, where, during fetal life, the blood vessels connecting the fetal and maternal circulations passed. Imperfect closure after birth produces a weak navel through which a hernia may develop.

4. *Ventral Hernia.* May occur in any portion of the abdominal wall where a weakness develops or occurs around an operative wound. Post-operative herniae are apt to occur in fat or weak abdominal walls where there has been an infected or drained wound, or some post-operative complication which has increased the abdominal pressure. Prolonged coughing, vomiting or distention of the abdomen before complete healing has occurred may thus produce herniation.

There are other less common sites for hernia, such as the diaphragm, where the hernial sac protrudes through the diaphragm into the chest. (R.S.M.)

HEROIN (Di-acetyl morphine). This drug is rarely used at present in medicine because it is more toxic than **morphine**, is more markedly habit forming, and its powers to allay pain and promote sleep are decidedly less than those of morphine or **codeine**. It is much used by drug addicts. More than any other narcotic, it destroys the emotional values of a subject, obliterates all traces of remorse or responsibility and gives a sense of exhilaration and inflation of the ego. It is taken as snuff, as pills, or hypodermically. (R.S.M.)

HERON. Aves, Ciconiiformes. Long-legged wading birds (**Aves**) with a sharp slender beak and when adult with plumes or a crest. They live chiefly on fish.

Herons are found throughout the world. The most widely known North American species are the great blue heron, *Ardea herodias,* the green heron, *Butorides virescens,* and the egret, *Egretta.* The last is a white bird which bears beautiful plumes known as aigrettes during the breeding season. It was once threatened with extinction through the use of these plumes as ornaments for hats, but the remaining birds are adequately protected. (A.W.L.)

HEROTA. Mammalia, Artiodactyla. An African **antelope**, also known as Hunter's hartebeest. (A.W.L.)

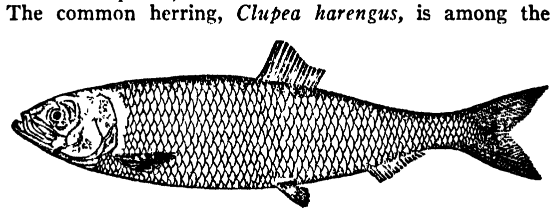
HEROULT FURNACE. **Electric Furnace.**

HERPES SIMPLEX (Fever blisters). An acute eruption of tiny blisterlike lesions occurring usually in groups on the lips, face, or genitalia, due to infection with a specific **virus**, herpes virus. This agent is related to the virus causing herpes zoster, but is distinct from it. The lesions are self-limiting, but tend to be recurrent.

Herpes simplex occurs following exposure to wind and sun, in association with the common cold, and gastro-intestinal disturbances, and during the course of certain febrile diseases. Pneumonia, malaria, and meningitis are frequently accompanied by herpetic lesions. (D.M.H.)

HERPES ZOSTER OR SHINGLES. A disease due to infection and inflammation of sensory nerves, caused by a **virus**, which appears to be closely allied to the virus of chicken-pox. In some instances it occurs in epidemics. The first symptom is usually severe pain over the course of a nerve. Constitutional symptoms characteristic of an acute infection may appear—that is, malaise, fever, chills, etc. Within a few days a rash breaks out in that portion supplied by the irritated nerve. Small blisters appear which may ulcerate, healing in 3–6 weeks. Scarring often results. The disease is self-limited, although injections of **pituitary** extract or **sodium** iodide may shorten the course of illness and lessen the pain. In older people the neuralgic pains are often particularly severe and may persist for months or years after the acute disease has disappeared. (R.S.M.)

HERRING. Pisces, Teleostei. Food fishes (**Pisces**) of numerous species, found in both fresh and salt water. The common herring, *Clupea harengus,* is among the



Herring.

most important of the smaller food fishes on the New England coast and northward, and several fresh-water species of the genus *Leucichthys* are equally important in the fisheries of the Great Lakes. The smaller sizes are canned as "sardines," especially in the United States and Norway. (A.W.L.)

HERRING OIL. **Esters.**

HERRINGBONE GEARING. ***Helical Gearing.***

HERSCHEL EFFECT. A photographic effect observed first by F. W. Herschel in 1839. In that year Herschel observed that an image on printing-out-paper (silver chloride) is destroyed (bleached out) upon exposure to red light. This is now known as the visual Herschel effect. The destruction of a latent image in a gelatin emulsion (which must not be dye-sensitized) is now known as the latent Herschel effect. Non-color sensitive materials may be made sensitive to the infrared by exposing to red light after exposure. (See Clark, *Infra-Red Photography.*) (C.B.N.)

HERTZIAN RADIATION. Electric Oscillations and Electric Waves; Electromagnetic Radiation.

HESPERIDIUM. Fruit.

HESSIAN FLY. Insecta, Diptera. One of the worst pests of wheat. It is a small 2-winged fly, *Phytophaga destructor*, a member of the **gall-gnat** family, which was introduced into the United States in the Revolutionary period. The larva lives between the base of a leaf and the stem of the wheat plant and either kills or weakens the plant so that no grain develops. Other cereals are attacked to some extent.

Fall plowing and burning stubble aid in destroying many insects. The most effective means of avoiding damage to winter wheat is to sow late enough to avoid the attack of most of the adults. They live no more than ten days and the date of emergence is known for various regions, hence late planting subjects the crop only to the light infestation due to the eggs deposited by the relatively few flies which emerge late. (A.W.L.)

HESSITE. A mineral telluride of silver, Hg_2Te, with some gold. Crystalline form not obvious at normal temperatures. Hardness, 2–3; specific gravity, 8.24–8.25; color, gray with metallic luster; opaque. Named after H. G. Hess (1802–50) of St. Petersburg. (R.M.F.)

HESSONITE. Garnet.

HETEROCYCLIC COMPOUNDS. This is a class of organic compounds containing one or more rings in which there are elements other than carbon present. Examples are **furane, pyrrole,** and **pyridine.** (See **Carbon** for index to articles on heterocyclic compounds.) (R.K.S.)

HETERODYNE. This term is used in communications terminology as an adjective or a verb, but in either case it concerns the beating together in an electrical circuit of two **frequencies** to produce new frequencies which are the sum or difference of the original ones. When two voltages of different frequencies are applied simultaneously to a circuit containing a non-linear impedance, i.e., one in which the current does not vary proportionally with the voltage, the output of the circuit will contain new frequencies, among them one equal to the sum and another equal to the difference of the applied frequencies. Either one or both of these may be selected by properly tuning or filtering the output. In heterodyne **detection** the principle is utilized to make audible the **continuous wave** code signals received. By applying to the input circuit of the vacuum tube detector the incoming signal and another locally generated signal which differs by some audio amount, say 1000 cycles, the output of the detector will contain a signal whose frequency is the difference, 1000 cycles. This 1000-cycle signal will go on and off with the **keying** of the original signal. A similar system is used in the first detector of the **superheterodyne** receiver where the difference frequency is made high (in the radio-frequency range) and this new radio frequency is further amplified. In both radio and telephone applications the principle of heterodyning is used to shift the location of a single frequency or a frequency **channel** in the spectrum. (See **Beats.**) (L.R.Q.)

HETEROGAMY. Gamete. In addition to the widely accepted application of the word to the occurrence of male and female gametes of different form, it has been applied in one work to the peculiar life cycle of the plant lice, in which generations with different characteristics succeed each other. The latter use is not to be recommended. (A.W.L.)

HETEROMORPHOSIS. Deviation from normal form. Malformation or deformity and also less extreme departures incidental to slightly different conditions in the animal or its environment. (A.W.L.)

HETERONEMERTEA. Nemertea.

HETEROTHALLISM. Phycomycetes.

HETEROTRICHIDA. Ciliata.

HEULANDITE. The mineral heulandite is a **monoclinic zeolite** whose crystals are often quite suggestive of **orthorhombic** forms. Its chemical composition is probably $(Ca,Na_2)O \cdot Al_2O_3 \cdot 6SiO_2 \cdot 5H_2O$; strontium may be present. Heulandite has one good cleavage; is brittle with a conchoidal fracture; hardness 3.5–4; specific gravity, 2.18–2.22; luster, vitreous to pearly; color, white to gray, red or brown; streak white; transparent to translucent. Occurs chiefly in cavities in **basaltic** rocks with other **zeolites**, but may be found in **granites, pegmatites, gneisses,** and **schists.** Famous localities are in Iceland, India, the Harz Mountains, Italy, Switzerland, Scotland, Nova Scotia; and in the United States at Bergen Hill and West Paterson, New Jersey. This mineral was named for the English mineralogist Heuland. (E.C.L.S.)

HEXACTINELLIDA. The glass **sponges**, constituting a class of the phylum Porifera. The spicules of the skeleton are silicious (see **Silicon**) and of 6-rayed form. Many of the species have a large central cavity, resulting in a tubular or vase-like form, and when freed of organic matter appear to be made of spun glass. These sponges are found in deep water in the ocean. Venus' flower basket, ***Euplectella,*** and the glass-rope sponge, ***Hyalonema,*** are the most common examples. (A.W.L.)

HEXAGONAL SYSTEM. Crystallography.

HEXAGONITE. Tremolite.

HEXAMETHYLENE TETRAMINE. A compound of formaldehyde and ammonia. (See **Formaldehyde.**) (R.K.S.)

HEXAPODA. Synonymous with **Insecta.** (A.W.L.)

HIBERNATION. The passing of the winter in a state of torpor. The condition is unavoidable to the cold-blooded animals when the surrounding temperature falls low enough to slow the chemical processes of their **metabolism** below the level necessary for normal activity. Under such conditions they live through the winter if the body is able to endure the lowest temperatures to which it is subjected. Even in such cases preparation may be made for the winter by entering a more resistant form. Some **rotifiers** and plant lice, for example, produce specially formed winter eggs and many insects pass the winter in the inert pupal stage.

Hibernation is more striking in warm-blooded animals, since their bodily processes are not necessarily slowed by low surrounding temperatures. The species that hibernate, like some of the bears, store up reserve energy

through the warm season and hide away for the winter. During this period their activity is reduced to the very slow respiration and reduced circulation. By spring they have used up the fat stored during the previous year.

Many animals hide away in nests or burrows for the winter without hibernating in the strict sense. Their activities are, of course, lessened, but they seek food or live on stores accumulated previously, like the squirrels and beavers. The honey-bee is an exceptional example of this kind among cold-blooded animals. The colony maintains its warmth by the activity of some of the bees, and all individuals are intermittently active throughout the winter. (A.W.L.)

HICCOUGH OR HICCUP. An intermittent sudden contraction of the **diaphragm.** The condition is due to a great variety of causes which may irritate either the nervous pathways leading to the motor centers controlling the diaphragm, the motor centers themselves, or the pathways from the centers to the diaphragm. The condition occurs at any age.

Hiccough commonly follows swallowing very hot or irritating substances, or occurs with disorders of the esophagus or stomach, such as **gastritis** or dilation of the stomach. Hiccough may occasionally occur after operations and at times may prove very severe. It occurs quite often in **peritonitis** or in any severe infection such as **typhoid.** In severe toxic conditions, especially **uremia** and alcoholism, hiccough may be severe and exhausting. An inflammation or tumor near the centers controlling the diaphragm will cause hiccough. An epidemic variety of hiccough has been described, the disease lasting about a week. Many cases of prolonged hiccough are of psychogenic origin. Attacks in such people may last for weeks, but the disorder is not present while eating. Many of these attacks may be aborted by sudden emotion such as fear, anger, etc.

To stop hiccough, the well-known measures such as holding the breath, drinking cold water, sudden fright, etc., are usually effective in mild cases. In severe ones, the insertion of a stomach tube, the injection of apomorphine or hyoscine, or the inhalation of 5–10% carbon dioxide in oxygen may be necessary. (R.S.M.)

HIDDENITE. **Spodumene.**

HIGH. A region over which the atmospheric pressure is greater than the surrounding area; an abbreviation for region of high pressure. Anticyclonic winds blow about a high. (P.E.K.)

HIGH BLOOD PRESSURE. **Hypertension.**

HIGH CONTACT. A **probability function** (or a **frequency distribution**) is said to possess high contact, if the function and all its derivatives vanish at the upper and lower limits of the **variable** x. (L.A.A.)

HIGHER DERIVATIVES. The **derivative** of the derivative of a function $y = f(x)$ is called the second derivative of $f(x)$, and is denoted by $D_x{}^2y$ or $\frac{d^2y}{dx^2}$ or $f''(x)$ or y''. Similarly, the derivative of the second derivative is called the third derivative, and is denoted by $D_x{}^3y$ or $\frac{d^3y}{dx^3}$ or $f'''(x)$ or y'''. In general, the n^{th} derivative is the derivative of the $(n-1)^{st}$ derivative, and is denoted by $D_x{}^{(n)}y$ or $\frac{d^ny}{dx^n}$ or $f^{(n)}(x)$ or $y^{(n)}$.

The curves $y = f'(x)$, $y = f''(x)$, $\cdots$ are called the first, second, $\cdots$, derived curves corresponding to the curve $y = f(x)$.

The relations between the derived curves are best brought out by drawing the curves one below the other. The **ordinate** of the first derived curve is the **slope** of the original curve at corresponding points. Corresponding to points on the original curve which are **maxima and minima,** the first derived curve crosses the X-axis; corresponding to **points of inflection** of the original curve, the first derived curve has maxima and minima. Corresponding to points of inflection of the original curve, the second derived curve crosses the X-axis; corresponding to a maximum point on the original curve, the second derived curve has a negative ordinate, and for a minimum point, a positive ordinate. (L.L.S.)

HIGHER MOMENT. The higher moments about any origin a are $\mu'_{3:x-a}$, $\mu'_{4:x-a}$, $\mu'_{5:x-a}$, where

$$\mu'_{n:x-a} = \frac{\Sigma(x-a)^n f_x}{\Sigma f_x}, \quad n > 2.$$

The higher central moments are defined by

$\mu_{n:x} = \dfrac{\Sigma(x-\overline{X})^n f_x}{\Sigma f_x}$, where $\overline{X}$ is the **mean.** The **higher product moments** in two **variables** x and y are defined by

$$\mu'_{n,\,m:x-a,\,y-b} = \frac{\Sigma(x-a)^n(y-b)^m f_{xy}}{\Sigma f_{xy}}$$

n and m either or both greater than one. Similarly

$$\mu_{n,\,m:x,\,y} = \frac{\Sigma(x-\overline{X})^n(y-\overline{Y})^m f_{xy}}{\Sigma f_{xy}}$$

where $\overline{X}$ is the mean of the x's and $\overline{Y}$ is the mean of the y's. The results for the higher moments are in terms of integrals for a **probability function** of a **continuous variate.** (L.A.A.)

HIGHER PLANE CURVES. By the term "higher plane curve" is usually meant any plane **curve** which is not a **straight line** or a **conic section.**

Among the most important and most interesting higher plane curves are the following: **bipartite cubic, cardioid, Cartesian oval, catenary, cissoid, conchoid, cubical parabola, cycloid, epicycloid, folium of Descartes, hyperbolic spiral, hypocycloid, lemniscate, limacon, lituus, logarithmic spiral, ovals of Cassini, parabolic spiral, rose curves, semi-cubical parabola, serpentine, spiral of Archimedes, strophoid, trisectrix of Maclaurin, trochoid, witch of Agnesi.** (L.L.S.)

HIGHER PRODUCT MOMENT. The higher product moment for a bivariate distribution in x and y is given by

$$\mu'_{n,\,m:x-a,\,y-b} = \frac{\Sigma(x-a)^n(y-b)^m f_{xy}}{\Sigma f_{xy}}$$

where n and m are both greater than one. Similarly the higher central product moments are defined by

$$\mu_{n,\,m:x,\,y} = \frac{\Sigma(x-\overline{X})^n(y-\overline{Y})^m f_{xy}}{\Sigma f_{xy}}, \quad n > 1, \quad m > 1.$$

In the case of the **probability function** in two **variables** $P_{xy}\,dx\,dy$ of two continuous variates the summation is replaced by a double integral over the **range** of x and of y. (L.A.A.)

HIGHEST COMMON FACTOR. The highest common factor of several **polynomials** is the polynomial of highest degree that is a factor of each of them. It is usually found by factoring the given polynomials separately, and picking out the highest common factor by inspection.

In cases where the polynomials are not readily factored, the following method, known as Euclid's algorithm, may be used.

Let P and P' denote two polynomials and suppose that the degree of P is greater than or equal to the degree of P'. Divide P by P' until a remainder R_1 is

obtained whose degree is less than the degree of P'. Divide P' by R_1 and obtain a remainder R_2 whose degree is less than that of R_1. Continue this process until the remainder $R_k = 0$; then R_{k-1} (the preceding remainder) is the highest common factor of P and P'. (L.L.S.)

HIGH-FREQUENCY PHOTOGRAPHY. High-frequency photography includes both still and motion-picture photography, the latter being much the more important. In still photography an ordinary camera is used, the lens being left open, and a series of exposures made at the desired frequency on the same film by means of an intermittently flashing light source. Photographs of this kind are practical only if the time interval is relatively short, as, for example, a golfer's "swing" or a batter's "cut" at a pitched ball. Even then their usefulness for analytical purposes is, in some cases, seriously affected by the overlapping of parts of the image.

In high-frequency (slow-motion) cinematography the exposing rate may range from 32 to several thousand frames per sec. When the film is projected at the usual rate, the time interval recorded on the film is expanded accordingly. If, for example, the exposing rate is 128 pictures per sec. and the projection rate 16 per sec., the time interval recorded on the film is expanded 8 times; i.e., $128/16 = 8$. Thus motion photographed in one second requires 8 seconds in projection. With higher taking speeds, the expansion of time is correspondingly greater. At 3200 exposures per sec., for example, the time interval is expanded—or magnified—200 times, assuming projection at the rate of 16 images per sec.

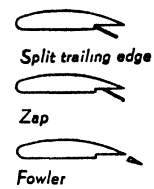
The usual form of motion-picture camera with intermittent film movement may be employed if the exposing rate is not much above 200 per sec. To reach higher exposing speeds, the intermittent movement must be discarded for a continuously moving film. Sharp images can be obtained on a continuously moving film by one of two methods: (1) by employing an intermittently flashing light such as the stroboscope, the duration of each flash being made sufficiently short to produce a sharp image on the moving film, and (2) an optical system consisting of rotating (a) lenses, (b) mirrors, or (c) prisms which cause the image to move during the exposure at the same rate as the film and thus produce a sharp image.

High-frequency cinematography with the stroboscope has been brought to a high degree of perfection by Edgerton and his coworkers at the Massachusetts Institute of Technology, who have developed equipment capable of making 10,000 exposures per sec., or even greater if necessary. High voltages, however, are required for such high speeds and the equipment is quite bulky. (C.B.N.)

HIGH-HOLE. Flicker.

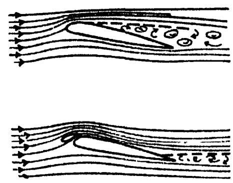
HIGH LIFT DEVICES. The lifting ability of an airfoil is improved by increasing its camber (over limited range), also by delaying the separation of the air flow from the lifting surface as **angle of attack** is increased. Most airfoils employed as airplane wings are of low camber because their drag coefficients at low attack angles (high speed) are more favorable than those of the thick highly cambered airfoils.

It is known that the maximum lift coefficient of a highly cambered airfoil is greater than that of a flat, thin one. Safety in landing an airplane demands low landing speed, which is obtainable by using wings with high maximum lift coefficients. On the other hand, high maximum speed is only to be obtained with the thin, low-drag type airfoil Many manufacturers of aircraft have adopted the **flap** as a means for securing low landing speeds on aircraft fitted with inherently high-speed wings. The flap, as illustrated in the accompanying figure, is akin to a flexible trailing edge, and by depressing the flap, the effective camber of the airfoil may be increased. The **drag** is also increased, giving a steeper gliding angle with flap down than without the use of the flap. Apart from any disadvantage, this factor may actually be beneficial, since with flap position variable and under control of the pilot, the angle of normal gliding is alterable, permitting steep approaches to small obstructed fields. Among the flaps having received a great deal of attention, have been the simple flap, the split flap, Zap flap, and the Fowler flap. The split flap is simplest to apply, and has been extensively used. The operation is simply that of a rotation of a panel on the lower side of the trailing edge about its forward edge. In the Zap flap, the rotation is accompanied by a backward movement of the pivoting point. In the Fowler flap, the motion is not one of simple rotation, and the effect is one of increase of airfoil area as well as change of camber. Most flap designs are patented.

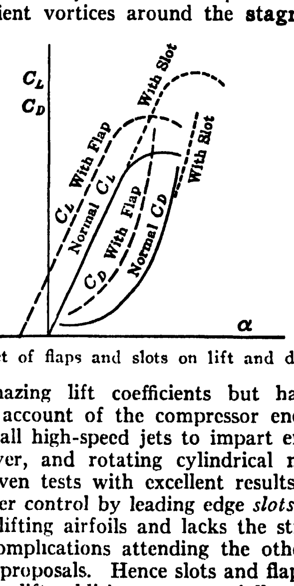


Flaps.

Increasing lift by delaying separation in the **boundary layer** is an independent action. Both flaps and boundary layer control could be added to the same airfoil—and have been on some airplane wings. Tests by the **NACA** on a basic Clark Y airfoil equipped with slot and flap revealed that the high lift devices were capable of doubling the maximum lift coefficient. Delay of air-flow separation by sucking off the incipient vortices around the **stagnation point** produced amazing lift coefficients but has not been exploited on account of the compressor energy needed. Also very small high-speed jets to impart energy to the boundary layer, and rotating cylindrical nose sections have been given tests with excellent results. However, boundary layer control by leading edge *slots* is definitely valuable for lifting airfoils and lacks the structural and mechanical complications attending the other boundary layer control proposals. Hence slots and flaps have been the only high lift additions commercially employed to date. In the light of probable future aeronautic development, the other possibilities should not be discounted. Some attempts have also been made to intensify the action of the flap by using multiple-hinged flaps, although such flaps do not appear thus far to have gone beyond the wind tunnel stage. (F.T.M.)



Air flow at high angle of attack with and without slot.



Effect of flaps and slots on lift and drag.

HIGH LINE TELEPHONE. This is a **carrier** system of telephone communication superimposed on the regular electric power transmission lines. It is used quite extensively by power companies for interplant communication. Basically the system does not differ in principle from the ordinary carrier systems. The signals are applied to and taken from the lines by coupling capacitors which allow the high frequencies to pass but

stop the 60-cycle power currents to a large extent. To reduce the effect of various stray 60-cycle signals which leak through the system, **filters** to take out the interference are often provided. (L.R.Q.)

HIGH-PRESSURE PHENOMENA. The earlier researches in this field were associated with the study of the liquefaction and the **critical states** of gases; for example, the work of Andrews (1861). The critical pressure of water, for example, is something over 2000 kilograms per sq. cm. The hydrostatic pressure at the greatest ocean depths must be about 1000 kilograms per sq. cm. But these would now hardly be considered "high" pressures, since with modern technique it is possible to attain pressures as great as 30,000 kilograms per sq. cm. The usual means of attaining high pressures is the "intensifier," which is merely a double free piston, that is, a straight rod with a large piston on one end and a small one on the other, each in its own cylinder. Any pressure applied to the larger piston is multiplied in the smaller cylinder by the ratio of the two areas. The chief problem is that of packing to prevent leaks, and this has been met by special devices perfected by Bridgman, Poulter, and others. (See **Pressure Gauges.**)

Substances often exhibit unfamiliar properties at high pressure. For example, the minimum volume of water, at 4° C. under normal pressure, occurs at lower and lower temperatures as the pressure is increased; and finally, at about 2500 kilograms per sq. cm., a minimum no longer exists. Solid bismuth kept at 250° C. melts at a pressure of 5600 kilograms per sq. cm.; but liquid sodium at 150° C. solidifies at 7200 kilograms per sq. cm. Some oils behave like sodium, so that they cannot be used as the media in high-pressure apparatus. The thermal expansion of liquids under great pressure decreases with temperature instead of increasing as it normally does. When liquids are subjected to 12,000 kilograms per sq. cm., the work of compression causes them to become almost boiling hot. Many other properties have been studied in detail, such as density, electrical resistance, thermal conductivity, viscosity, dielectric constant, and polymorphic transitions.

It is interesting, but at present futile, to speculate as to the state of matter subjected to such pressures as must exist in the far interior of the earth or of the sun—millions of times greater than anything artificially attainable—and especially at the inconceivable temperatures also prevailing there. It is not improbable that states of aggregation quite unknown to us are produced under these conditions. (L.D.W.)

HIGH-SPEED PHOTOGRAPHY. The term high-speed photography is applied both to single photographs made with extremely short exposures and to high-frequency photography which consists of a number of high-speed photographs made in rapid succession. (See **High-Frequency Photography.**)

Since the shortest exposure practical with mechanical shutters is not much over 1/1000 of a second, high-speed photography has employed the electric spark and, in recent years, the gaseous discharge lamp, the development of which for photographic purposes is due largely to the work of Edgerton and his coworkers at the Massachusetts Institute of Technology. With either of these a highly intense source of illumination is obtained the duration of which may be as short as 1/1,000,000 of a second, although an exposure of 1/25,000 of a second is sufficient for all except extremely high-speed subjects.

The photographs are made (1) in a darkened room using an ordinary camera with the uncovered lens focused on the subject and the exposure made by discharging the condenser across the spark gap, or through the discharge tube, or (2) in daylight using a synchronizer which opens the shutter immediately before the discharge and closes it directly thereafter. When the photograph is made in daylight with a synchronizer the time which the shutter is open must be sufficiently short to prevent the exposure of the film from the pervailing daylight. In either case, the duration of the actual exposure is determined by the duration of the flash.

Spark photographs of bullets in flight were made as early as 1865. Since the development of the gaseous discharge lamp, high-speed photography has been employed extensively in the study of machinery moving at high speed, chemical reactions which occur at high speed such as the detonation of explosives, etc., as well as for the analysis of athletic form, acrobatic dancing, the ballet, etc. (C.B.N.)

HIGHWAYS. Of the historical importance of highways as aids in the progress of civilization, and the closer association of peoples of the earth, little can be said in this article. The highly interesting way in which development in road building is interwoven with the affairs of man as he stumbled forward from a barbaric state has, however, been adequately treated in literature. Suffice to say here that the modern highway reaches a degree of perfection attained only through many years of attempts to suit the road type to the vehicular traffic carried by it with due regard to existing economic factors. Usually perfection of types lags behind progress in the invention and building of vehicles which travel over them. It seems necessary for vehicular improvement to precede roads satisfactory for the operation of the vehicle.

A road system plays a very important part in the economic affairs of a country such as the United States, particularly in these days of widespread automobile ownership. Nowhere else in the world are there to be found such conditions of congested, high-speed, or long-distance traffic. The large sums collectible through automotive taxation have made possible a network of hard-surfaced highways, the main arteries of which are representative of great progress in the accommodation of large amounts of high-speed traffic. The special intersections where it is unnecessary for any cross traffic to exist, but in which the full choice of direction of travel of an ordinary crossroads is still available to the driver; aerial highways, in which the roadway is carried over congested districts, and entirely removed from local traffic; highway tunnels driven under rivers; and many other gigantic engineering enterprises, are part of the highway picture of the present time. Roads and highways are comparatively expensive, seldom costing less than $2000 per mile for the most elementary form of earth road, ranging from that upward to $30,000 per mile for an ordinary two-lane concrete road, and into the hundreds of thousands of dollars per mile for super highways. These gigantic sums are raised through taxation which reaches nearly every person in the United States. The rates, however, direct and indirect, are not exceptionally high in that there are few persons indeed who do not make considerable use of highways.

The simplest form of road is that which is constructed by leveling a right-of-way about 10′ wide by excavating, filling, blasting, felling trees, grubbing roots, and providing ditches for drainage. Such roads are satisfactory only for the lightest form of horsedrawn traffic. If the type of road just described is adequately drained by deepening the ditches on the side and lowering the water table, then provided with an earth surface which is more of a road material than the original soil, a road is produced which is serviceable for light traffic the year round.

The most important element of a highway is its foundation. This should be firmly compacted, and have sufficient bearing power to keep a tire or rim of a vehicle from cutting through, and it should also be sufficiently porous so that water will readily drain from it. Deep side ditches are provided to drain the water from this foundation, keep it firm and hard, and reduce frost heavage. Earth as a road foundation is not altogether

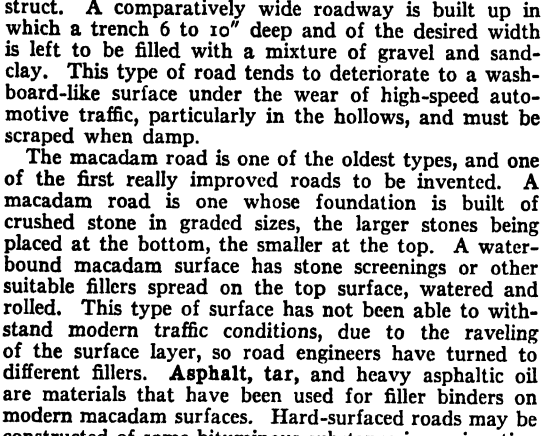
satisfactory unless it happens to exist in proportions of sand and binder which are suitable. The sand is necesary for bearing power, while clay or silt is necessary for binding the particles of sand together.

A sand-clay road is made by forming the sub-grade, properly drained, and spreading on top of that from 8 to 12" of sand-clay mixture in proportions of about 40% clay and silt to 60% sand. If the natural soil is to be used, and is deficient in either clay or sand, the deficiency may be made up by spreading the other material in proper amounts, after which it is mixed with harrows or plows. The sand-clay road must be crowned so as to shed water directly and at low velocity to the ditches, otherwise it will wash badly under heavy rains. Maintenance consists of scraping from ditches into the road and crowning up the surface, also adding more topsoil as needed.

The gravel road is suitable for heavier traffic than the sand-clay or earth, and is more expensive to construct. A comparatively wide roadway is built up in which a trench 6 to 10" deep and of the desired width is left to be filled with a mixture of gravel and sand-clay. This type of road tends to deteriorate to a washboard-like surface under the wear of high-speed automotive traffic, particularly in the hollows, and must be scraped when damp.

The macadam road is one of the oldest types, and one of the first really improved roads to be invented. A macadam road is one whose foundation is built of crushed stone in graded sizes, the larger stones being placed at the bottom, the smaller at the top. A waterbound macadam surface has stone screenings or other suitable fillers spread on the top surface, watered and rolled. This type of surface has not been able to withstand modern traffic conditions, due to the raveling of the surface layer, so road engineers have turned to different fillers. **Asphalt, tar,** and heavy asphaltic oil are materials that have been used for filler binders on modern macadam surfaces. Hard-surfaced roads may be constructed of some bituminous substance in conjunction with crushed stone, or of concrete with or without a bituminous surface. Practically all hard-surface mileage is of this type, and surfaces like brick, cobble stone, or blocks are but little used except for special traffic conditions in and around cities.

Bituminous hard-surfaced roads will be briefly described. Bituminous macadam roads have a sub-base of



Road sections.

gravel or stone. An old waterbound macadam road can readily be converted, using the existing waterbound macadam as a foundation or base. Upon this, when suitably leveled and smoothed, may be placed a binder course of about 2½" of ½" to 1½" stone. Upon this layer is sprayed the bituminous binder from a pressure-distributing truck, following which stone chips are spread and brushed into the interstices. A penetration of at least 1" should be secured. After lightly rolling the stone chips a second application of bituminous binder is made and the surface rolled with a heavy roller to shape. Various other methods may be employed dependent upon the size and void space of the binder course. This type is known as penetration macadam. A bituminous concrete road is built upon a well-compacted base of stone or gravel, or upon a **concrete** slab. It is essentially a premixed, bituminous concrete, consisting of asphalt, sand, and finely crushed rock. It is laid hot, and immediately rolled to about a 2" wearing course. Most bituminous concrete mixtures are patented.

The concrete road is made up of Portland cement concrete from 6 to 10" thick, poured in slabs. Unless the foundation is exceptionally well compacted, the concrete slab should have metal reinforcement. Adjacent slabs should be separated by a small space to allow for expansion. The spaces should be filled with asphalt to keep moisture from the sub-grade. A typical concrete section is shown in the accompanying figure. After the slab is poured it must be kept moist for several days in order properly to cure the concrete and develop its full value as a road surface. While the concrete mixture employed is not standardized, a 1:2:3 mixture is about what is ordinarily used. The coarse aggregate may be either gravel or crushed rock, and the fine aggregate washed sand.

A standard 2-lane highway should have a pavement surface from 18 to 20' wide, with 4 to 6' earth shoulders on the side of that. Where traffic conditions are exceptionally severe, it has been necessary to increase this width and add more lanes for traffic. The 3-lane highway should not be used, if at all avoidable, since it does not increase the traffic capacity of the road in proportion to the added expense, and statistics show such roads to be extremely productive of traffic accidents. The 4-lane highway is far superior in that cars going the same direction may pass without invading an area set aside for traffic moving in the opposite direction. In spite of this fact, however, many head-on collisions have occurred on 4-lane highways, and are particularly disastrous because of the high average speed of traffic on these highways. It appears that it may eventually be necessary to separate traffic moving in opposite directions by a central strip which is unpaved, creating, in effect, two parallel roadways. (F.T.M., E.W.S.)

HILL MYNA. Aves, Passeriformes. The **grackles** of India and adjacent regions. They are glossy black birds with brightly colored wattles and in some species other bright marks. When kept in captivity they learn to talk readily and imitate the inflections of the human voice much more faithfully than the parrots. (A.W.L.)

HIND. The female **deer,** especially of the European red deer. (A.W.L.)

HINGE LIGAMENT. A tough elastic connection between the dorsal margins of the two valves of the shell of **bivalve** mollusks. (A.W.L.)

HINNY. The hybrid offspring of a stallion and a jennet, reciprocal of the cross of jack and mare by which mules are produced. The difference between mules and hinnys is a disputed point. Some writers claim that hinnys are smaller and lacking in the qualities desired in mules, while others say that both forms fall within the range of variation to be expected in the hybrid. (A.W.L.)

HIP. The joint at the attachment of the human thigh to the body. Also the adjacent portion of the thigh where it merges with the buttocks and less commonly the corresponding part of the leg in other animals. (A.W.L.)

HIPERNIK. **Nickel Alloys; Magnetic Materials.**

HIPPOPOTAMUS. Mammalia, Artiodactyla. A large African animal with a bulky body, short strong legs, and a very broad muzzle. Hippopotami have been known to attain a length of 12′ and a weight of 4 tons. They are largely aquatic in habits and live entirely on vegetation, including both water plants and terrestrial species. They sometimes do great damage to crops.

A second species, the pigmy hippopotamus of western Africa, reaches only half the length of the larger animal and is found in the forests and swampy lands. (A.W.L.)

HIRUDINEA. The leeches, a class of segmented worms (Phylum **Annelida**), well known for their habit of sucking blood. Marine and fresh-water species are known, and in the moist tropical forests terrestrial species occur. They often attach themselves to bathers.

The members of this class are distinguished from other annelids by the following characters: 1. The body is relatively short, usually with thirty-two segments. 2. The external segments are annuli numbering from two to fourteen to each metamere. 3. Each end of the body bears a sucker. 4. The mouth is usually provided with three toothed plates or jaws. 5. The alimentary tract is provided with an enormous pouched crop in which blood is stored prior to digestion. 6. The anus opens dorsal to the posterior sucker. 7. The **coelom** is partially obliterated by a peculiar **mesenchymal tissue.** 8. At the anterior end of the ventral nerve cord several ganglia (**ganglion**) are fused to form a large mass.

Leeches were once extensively used in medicine for letting blood and are still of minor importance for this purpose. Otherwise they are of no importance to man save as an occasional annoyance. They eat small aquatic animals as well as the blood of vertebrates and some species are entirely predacious.

Two orders are recognized:

Order Rhynchobdellida. With a protrusible proboscis, colorless blood, and no jaws. Marine and fresh-water.

Order Gnathobdellida. With jaws and red blood. No proboscis. Fresh-water and terrestrial. The medicinal leech belongs to this order. It is native to Europe but is naturalized in ponds and streams of the eastern United States. (A.W.L.)

HISTIDINE. **Aminoacids; Polypeptides; Proteins.**

HISTOBLAST. A group of cells in the immature stages of **insects** from which some organ of the adult is developed. The forerunners of the wings in insects with complete metamorphosis, for example, are small thickened layers of cells in the **larva.** Also called imaginal disks. (A.W.L.)

HISTOLOGY. The science which deals with the minute structure of living things. The study of the struc-

GEOLOGICAL TIME-SCALE (See **Historical Geology.**)

ERA = time GROUP = rocks	PERIOD = time SYSTEM = rocks	LIFE RECORD (FOSSILS) BOTH ANIMALS AND PLANTS
CENOZOIC Age of mammals and modern flora	QUARTERNARY TERTIARY upper lower	Periodic glaciation and origin of man (Pleistocene). The transformation of the ape-like ancestor into man may have begun in the Pliocene. Culmination of mammals (Miocene). Rise of higher mammals (Oligocene). Vanishing of archaic mammals (Eocene).
MESOZOIC Age of reptiles	CRETACEOUS JURASSIC TRIASSIC	Rise of the archaic mammals in the interval between the Mesozoic and the Tertiary. This ERA is remarkable for the great development of the ammonites which became extinct at the end of the Cretaceous. The mollusks are more highly developed in this ERA than in the preceding one. Culmination and extinction of most reptiles (Cretaceous). Rise of flowering plants (Comanchean); birds and flying reptiles (Jurassic); dinosaurs (Triassic).
Upper PALEOZOIC Age of amphibians and lycopods	PERMIAN CARBONIFEROUS	Periodic glaciation and extinction of many Paleozoic groups during and after the Permian. Rise of modern insects, land vertebrates and ammonites (Permian); primitive reptiles and insects (Pennsylvanian); ancient sharks and echinoderms (Mississippian).
Middle PALEOZOIC Age of fishes	DEVONIAN SILURIAN	First known land floras (Devonian) not very different from those of the Carboniferous. Earliest evidence of a terrestrial vertebrate in the form of a single footprint from the Devonian of Pennsylvania. Rise of lungfishes and scorpions (first terrestrial air-breathers) in the Silurian.
Lower PALEOZOIC Age of higher (shelly) invertebrates	ORDOVICIAN CAMBRIAN	Rise of nautiloids, armored fishes, land plants and corals. Also the first evidence of colonial life (Ordovician). First known marine faunas; dominance of trilobites; rise of animals with hard shells or exo-skeletons (Cambrian).
PROTEROZOIC Primordial life ARCHEOZOIC Most ancient life	PRE-CAMBRIAN	Fossils almost unknown except for a few problematical forms in the Proterozoic. Fossils unknown in the Archeozoic.

NOTE. Geological time-tables are so constructed as to show the oldest periods at the bottom and the youngest periods at the top. *To get the proper order and sequence of events always read from the bottom to the top.* (Field, *Geology Manual,* Princeton University Press.)

ture and functions of cells is the special province of **cytology**, leaving the study of special forms of **cells** and their association in **tissues** and **organs** as the field of histology, but histology necessarily includes much cytological matter.

The science is made up of two subordinate fields, general and special histology. In the former are considered the specialization of cells in the multicellular body and the characteristics and classification of the tissues in which they are grouped. The details of minute structure of the organs and organ systems are the materials of the latter. This field of histology is necessarily extensive and detailed, even in the study of a single species.

Histology recognizes five principal kinds of tissues, epithelium, nervous tissue, mesenchymal (connective and supporting) tissues, muscular tissue, and vascular tissue. All organ are made up of these components and further detail of histology are included under the various organs and organ systems and under the topics **epithelium, connective tissue, nervous tissue, mesenchyme, cartilage, bone, muscular tissue, blood,** etc. (A.W.L.)

HISTONES. **Aminoacids; Polypeptides; Proteins.**

HISTORICAL GEOLOGY. The study and description of the origin and evolution of the earth and its inhabitants (animals and plants). The technical methods employed are included under the general term, **stratigraphy.** The outstanding events or important "chapters" in the history of the earth are outlined in the form of a geologic Time-Scale or Time-Table; see page 713. The study of the extinct forms of life, from the earliest known **fossils** up to, but not including, the Recent epoch, is called **Paleontology.** The history of the earth from its astral stage up to the oldest known rocks is included under the general term **cosmogony.** The numerous methods for determining the age of the earth as well as the relative ages of geological events are included under the term **chronology,** which in turn may be considered as included under the more general term Stratigraphy. The fundamental data of geologic history are local sequences of formations, and the chronologic equivalences of formations in different regions. Through correlation all formations are referred to a general time scale, of which the (fundamental) units are periods. The formations made during a period are collectively designated a system. The fundamental criteria used in delimiting geologic periods are (1) **Unconformities,** (2) Cycles of Sedimentation, (3) Index Fossils. The ultimate aim of the historical geologist is paleogeography, or the reconstruction of the consecutive geographies of the past. (R.M.F.)

HISTORY AND EVOLUTION OF CHEMISTRY.

Pure Chemistry

1755 Black. Studies on carbonic acid and carbonates.

1766 Cavendish. Discovered inflammable air (named hydrogen by Lavoisier in 1783) as a distinct substance.

1772 Rutherford. Isolated nitrogen.

1774 Priestley. Discovery of oxygen.

Scheele. Discovery of oxygen.

1776 Scheele. Discovery of oxalic acid and uric acid.

1777 Lavoisier. Fundamental studies of combustion and of respiration.

Wenzel. Law of Mass Action.

1778 Scheele. Discovery of chlorine.

1779 Scheele. Discovery of glycerol.

1780 Scheele. Discovery of lactic acid.

1781 Cavendish. Showed hydrogen burns to form water.

1782 Scheele. Discovery of hydrogen cyanide.

1782 Lavoisier. First quantitative synthesis of water. Fermentation of sugar yields ethyl alcohol and carbon dioxide.

1784 Charles. Law of expansion of gases. Pressure varies directly as the absolute temperature.

1785 Scheele. Discovery of malic acid.

1787 Lavoisier. Classification of compounds.

1791 Richter. Law of neutralization of acids and bases.

1796 Lampadius. Discovery of carbon disulfide.

1799 Walter. Discovery of picric acid.

1800 Nicholson and Carlisle. Quantitative electrolysis of water.

1801 Hare. Oxyhydrogen blowpipe.

1802–06 Proust-Berthollet controversy on constancy of chemical composition, Proust winning by proving the constancy.

1805 Northmore. Liquefaction of chlorine.

1806 Proust. Law of constant chemical composition.

1807 Dalton. Law of multiple combining proportions.

Dalton. Law of partial pressures of gases in mixtures.

Dalton. Atomic theory.

Davy. Isolated sodium and potassium.

Davy. Electrochemical theory.

1808 Gay-Lussac. Law of simple combining volumes of gases.

Gay-Lussac. Law of expansion of gases. Volume varies directly with absolute temperature.

Davy. Isolated magnesium, calcium and barium.

1810 Berzelius. Isolated silicon.

Davy. Elementary nature of chlorine.

1811 Avogadro. Molecular hypothesis

Berzelius. System of chemical nomenclature.

Berzelius. Dualistic theory.

1814 Frauenhofer. Solar spectral lines.

1815–22 Gay-Lussac. Work on cyanogen

Prout. Hypothesis that other elements are composed of hydrogen.

Biot. Optical activity of sugar solutions.

1817 Arfvedson. Discovery of lithium.

Berzelius. Exact ratios of atomic weights. A revised table in 1826.

1819 Mitscherlich. Isomorphism of crystals.

Garden. Isolated naphthalene.

1821 DuLong and Petit. Law of atomic heat.

Cagniard de la Tour. Critical phenomena of gases and liquids.

1823 Faraday. Liquefied chlorine, sulfur dioxide, hydrogen sulfide, carbon dioxide, ammonia, nitrous oxide, and cyanogen.

1824–32 Gay-Lussac. Methods of volumetric analysis.

Carnot. Studies in themodynamics.

1825 Faraday. Discovery of benzene and butylene.

1826 Unverdorben. Discovery of aniline.

Balard. Discovery of bromine.

1827 Dumas. Molecular weights by vapor density methods.

Wöhler. Isolated aluminum.

1828 Wöhler. Formation of urea from ammonium cyanate.

1829 Döbereiner. Triads of elements.

1830 Robiquet. Discovery of the enzyme emulsin in almonds and in the seeds of Rosaceae.

Liebig. Modern combustion furnace and method for carbon and hydrogen determinations in organic substances.

1831 Dumas. Method for nitrogen determination in organic compounds.

Liebig. Discovery of chloroform.

Leuchs. Discovery of the enzyme ptyalin of saliva.

1832 Dumas and Laurent. Isolated anthracene.

Liebig. First theory of radicals.

1832 Liebig and Wöhler. Studies on the radical benzoyl; benzoin condensation.
1832 Serullas. Discovery of iodoform.
1833 Faraday. Laws of electrolysis, ions carry simple or multiple charge.
1833 Mitscherlich. Discovery of benzene sulfonic acid.
Graham. Studies on basicity of such acids as phosphoric.
1834 Dumas. Discovery of substitution in organic compounds.
Mitscherlich. Preparation of benzene and of nitrobenzene from benzoic acid.
Payen and Persoz. Discovery of the enzyme diastase from malt.
1835 Thilorier. Solidified carbon dioxide.
Schwann. Discovery of the enzyme pepsin of gastric juice.
1835 Dumas. Quantitative synthesis of water by passing hydrogen over heated copper oxide.
1836 E. Davy. Discovery of acetylene.
Laurent. Preparation of phthalic acid from naphthalene.
1837 Bunsen. Studies on the radical cacodyl.
1840 Hess. Law of constant heat summation.
1840–70 Stas. Researches on atomic weights.
1843 Laurent. Definition of atomic and molecular equivalents.
Pasteur. Dextro and laevo tartrates.
1844 Gerhardt and Laurent. Classification of organic compounds.
1847 Dumas. Preparation of acetamide.
1849 Fehling. Reduction of cupric salt in alkaline medium to cuprous oxide as test for sugars.
Frankland. Ethyl iodide plus zinc at 150° C. yields butane.
Kolbe Electrolysis of acetates yielded ethane.
1850 Wilhelmy. Studies on the rate of inversion of sucrose solutions.
Hofmann. Prepared alkyl amines.
1851 Graham. Diffusion, dialysis, and osmosis in solutions.
1852 Frankland. Principle of valency.
1852–62 Joule and Thomson. Observations of change of temperature by emergence of compressed gas through small orifice.
1853 Hittorf. Migration of ions.
1853–1908 Thomsen. Thermochemical investigations.
1854 Wurtz. Alkyl iodide plus sodium heated to yield paraffin hydrocarbon.
Deville. Thermal dissociation of substances.
1857 Bunsen. Methods of gas analysis.
1858 Cannizzaro. Rational symbols and formulas.
Gerlach. Introduced biological stains.
Kekulé and Couper. Quadrivalent carbon atom.
1859 Kirchhoff. Black body radiation.
Griess. Discovered diazo compounds.
1860 Bunsen and Kirchhoff. Invention of the spectroscope; discovery of cesium.
1861 Bunsen and Kirchhoff. Discovery of rubidium.
1862 Graham. Crystalloids and colloids.
1863 Reich and Richter. Discovery of indium.
Fittig. Aryl haloid plus sodium heated yields benzenoid hydrocarbon.
1864 Guldberg and Waage. Law of Mass Action.
1867 Kekulé. Formula of benzene; oscillation of double bond, 1872.
1867–70 Meyer, L. Molecular volumes and the periodic system.
1868 Hofmann. Determination of molecular weights by vapor displacement.
Janssen and Lockyer. Discovery of helium in the sun.
1869 Andrews. Variation of volume of carbon dioxide with change of pressure.
Mendeléeff. Periodicity of the elements.
1869–85 Berthelot. Thermochemical investigations.
1873 Meyer, V. Determination of molecular weights by vapor displacement.
van der Waals. Equation of state of gas and vapor.
Maxwell. Theory of electricity and magnetism.
1874 Boisbaudran. Discovery of gallium.
Volhard. Volumetric titration of silver as thiocyanate.
Le Bel and van't Hoff. Stereoisomerism of tetrahedral carbon atom.
1875 Gibbs, Willard. The phase rule.
Stoney. The electron.
1876 Kohlrausch. Electrical conductivity of solutions.
1877 Cailletet. Liquefied methane, ethylene, acetylene, nitric oxide.
Friedel and Crafts. Organic reactions with anhydrous aluminum chloride.
1878 van't Hoff. Stereochemistry of the nitrogen atom.
Raoult. Properties of solutions.
1878–87 Ostwald. Electrical conductivity of organic acids.
1879 Crookes. Suggested the nature of cathode rays.
1880 Crookes. Cathode rays.
1881 van der Waals. Gas equation.
1883 Kjeldahl. Estimation of nitrogen as ammonia in organic compounds.
Wroblewski and Olszewski. Liquefied nitrogen.
1884 Dewar. Vacuum-walled flask for liquefied gases at low temperature.
Le Chatelier and van't Hoff. Principles of shifting of chemical equilibrium.
1885 Le Chatelier. Thermocouple for measuring temperature perfected.
Callender. Resistance thermometer introduced.
1886 Goldstein. Discovery of anode rays.
Moissan. Isolation of fluorine.
1887 Arrhenius. Ionic theory of electrolytic dissociation.
1888 Nernst. Diffusion theory of electromotive force of solutions.
1892 Le Chatelier. Optical pyrometer invented.
1893 Amagat. Variation of the product of pressure and volume with change of pressure for gases.
Ramsay. Work on the rare gases.
Cleve. Discovery of helium in minerals.
Roentgen. Discovery of x-rays.
Linde and Hampson. Oxygen and nitrogen by fractionation of liquefied air.
1893–1908 Landolt. Conservation of matter in chemical reactions re-proved
1894 Rayleigh and Ramsay. Discovery of argon.
1895 Olszewski. Liquefaction of hydrogen.
Morley. Composition of water by direct weighing of hydrogen, oxygen, and water.
1896 Becquerel. Radioactivity of uranium.
1897 Thomson. Nature of cathode rays as streams of electrons.
Sabatier. Catalytic hydrogenation of unsaturated organic compounds.
1898 Wien. Nature of anode rays.
Curie, P. and Marie. Discovery of radium.
1899 Walden. Investigation of active malic and chlorosuccinic acids.
1900 Guye. Atomic weights from gas densities.
Grignard. Magnesium—ether—organic halide as organic reagent.
Gomberg. Triphenylmethyl free radical (at least 2 aryl groups to each C).
1902 Rutherford and Soddy. Spontaneous decomposition hypothesis of radioactive changes.
Morse. Optical pyrometer improved by use of glow lamp filament.
1904 Barkla. X-rays as (1) ether impulses, (2) characteristic rays.

Pure Chemistry (Continued)

1905 Dewar. Charcoal as gas absorbent at low temperature.
1906 Miers. Refractive index of crystallizing solution.
1907 Willstätter. Structure of chlorophyll.
1908 Onnes. Liquefaction of helium; approach to absolute zero.
Rutherford and Geiger. Detection and counting of single alpha particles.
Millikan. Precision measurements of the charge on an electron.
1911 Rutherford. Hypothesis of nuclear atom.
Soddy. Mesothorium isotopes.
1912 Laue and W. H. and W. L. Bragg. Structure of crystals by x-rays.
1913 Thomson. Spectrum of neon in anode-ray tube.
Fajens, et al. Alpha and beta particle shift in periodic table.
1914 Moseley. Atomic numbers by x-ray spectra of the elements.
1917 Hull. Structure of crystals by x-rays.
Debye and Scherer. Structure of crystals by x-rays.
1918 Kendall. Thyroxine isolated.
1919 Aston. Mass-spectrograph for ascertaining the atomic weight of isotopes.
Rutherford. Artificial disintegration of elements.
1921 Harkins and Hayes. Fractionation of chlorine isotopes.
Bronsted and Hevesy. Fractionation of mercury isotopes.
Bragg, W. H. Structure of naphthalene by x-rays.
1922 Banting and collaborators. Insulin isolated.
1923 Coster and Hevesy. Discovery of hafnium.
Debye and Hückel. Strong electrolytes ionized completely. Quantitative treatment of same.
1925 Noddack, W. and Ida. Discovery of rhenium.
Niewland. Synthetic chemicals from acetylene, namely, monovinylacetylene and divinylacetylene.
1929 Paneth and Hofeditz. Methyl free radical of half life 0.006 second.
Fleming. Penicillin discovered; 1939, Florey extended investigation; 1941, Florey and Heatley visited U. S. A. with the result that the U. S. Northern Regional Research Laboratory, Peoria, Illinois, undertook a study of production to which A. J. Moyer contributed largely.
1930 Bothe and Becker. Discovery of neutron.
Mauss and Mietsch. Synthesis of the antimalarial drug "Atabrine."
1932 Urey. Discovery of deuterium.
Anderson. Discovery of positron.
1934 Joliot, F., and Joliot-Curie, Mme. Artificial radioactivity.
1937 Protactinium recognized by the International Committe on Atomic Weights.
1939 Meitner, Hahn, Frisch, Fermi, Bohr, Dunning. Fission of uranium.
1944 Woodward and Doering. Synthesis of quinine.

Applied Chemistry

1620 Coal used for smelting iron ore.
1635 Winthrop. Survey of American chemical resources.
1650 Glauber. Hydrochloric acid from sodium chloride and sulfuric acid.
1746 Roebuck. Chamber process for sulfuric acid.
1747 Marggraf. Discovered sugar in beet juice.
1755 Nordhaussen. Fuming sulfuric acid.
1769 Coke manufactured.
Watt. Steam engine patent.
1778 Baumé. Hydrometer scale.
1779 Achard. Manufacture of beet sugar.
1784 Cort. Puddling process for wrought iron.
1788 Le Blanc. Soda process for conversion of sodium chloride into carbonate via sulfate and sulfide.
1792 Murdoch. Manufacture of coal gas.
1793 Harrison. Manufacture of sulfuric acid in U.S.A.
1800 Volta. First electric battery.
1801 duPont Company founded.
1806 Coal gas used for lighting in U.S.A.
1823 Braconnot. Discovered guncotton.
1827 Gay-Lussac. Tower for absorbing nitrogen oxide gases from sulfuric acid chamber process at Chauncy, France.
1828 Neilson. Introduced use of hot air for iron blast furnace.
1830 Kuhlmann. Discovered platinum as catalyzer for ammonia oxidation.
1831 Ure. Fulminates as detonators.
Phillips and Peregrine. Patented essential details of contact process for sulfuric acid.
1834 Runge. Discovered phenol and pyrrole in coal tar.
1836 Daniell. Electric battery (copper-zinc).
de la Rive. Introduced electroplating.
1839 Goodyear. Vulcanization of rubber.
1841 Bunsen. Electric battery (carbon-zinc).
1842 Kingsford. Production of corn starch.
1844 Burt. Discovered Lake Superior iron ore deposits; 1877, first shipment of ore.
1845 Hofmann. Discovered aniline in coal tar.
Petroleum discovered in Pennsylvania.
1847 Maynard. Collodion made in U.S.A.
1850 First fertilizer plant in U.S.A.
1853 Watt and Burgess. Soda process (sodium hydroxide) for paper pulp from wood.
1856 Perkin. Discovered mauveine.
Bessemer. Steel process using air blast converter.
1858 Hofmann. Discovered aniline in coal tar.
Hofmann. Prepared rosaniline.
1859 Drake drilled first oil well (Titusville, Pa.). First petroleum refinery in Pennsylvania.
Glover. Tower for supplying nitrogen oxide gases to sulfuric acid chamber process.
Plante. Lead-lead dioxide storage battery.
1861 Solvay. Soda process for conversion of sodium chloride into carbonate by ammonium hydrogen carbonate forming sodium hydrogen carbonate.
1862 Nobel. Introduced dynamite.
1867 Caro. Prepared Bismarck brown.
Tilghman. Sulfite process (calcium hydrogen sulfite plus sulfurous acid) for paper pulp from wood.
1868 Weldon. Process for chlorine by hydrochloric acid and manganese dioxide with recovery of manganese.
Pasteur. Studies in acetic acid fermentation.
Leclanché. Dry cell electric battery.
1869 Gräbe and Liebermann. Alizarin from anthracene.
Hyatt, J. W. and I. S. Manufacture of celluloid at Albany, N. Y.
1872 Baeyer. Introduced fluorescein.
Electrolytic refining begun in U.S.A.
Saylor. Portland cement manufactured in U.S.A.
1873 Linde. Ammonia compression refrigeration.
1875 Winkler. Contact process for sulfuric acid.
1878 Fischer, O. Introduced malachite green.
Behr. Glucose from corn.
1880 Deacon. Process for chlorine by hydrogen chloride-air mixture over cupric salt catalyzer.
1881 Brin. Process for oxygen, using barium peroxide

1882 **Baeyer. Synthesis of indigo.**
Edison. Introduced incandescent carbon electric lamp.
1884 De Laval and Parsons. Steam turbine.
First Solvay soda plant in U.S.A. at Syracuse, N. Y.
1885 Welsbach. Incandescent gas mantle.
Bradley. Heating of ores by electricity.
Castner and Kellner. Electrolytic process for sodium hydroxide from sodium chloride, using mercury cathode.
Gayley. Dry air blast used in the pig iron blast furnace; 1894, perfected.
1886 Hall (U.S.A.); Héroult (France). Electrolytic process for aluminum from oxide; 1888, commercial production at New Kensington, Pa.
Mond. Nickel carbonyl for volatilizing and refining nickel.
1888 Florida phosphate deposits discovered.
Willson. Manufacture of calcium carbide in electric furnace.
1889 Introduction of cyanide in gold metallurgy.
1890 Castner. Electrolytic process for sodium from fused hydroxide.
Acheson. Manufacture of silicon carbide in electric furnace.
1891 Chardonnet. Manufacture of artificial silk at Besançon, France.
Frasch. Mining of sulfur by superheated water in Louisiana.
1892 Le Sueur. Diaphragm type of electrolytic cell.
1893 Moissan. Electric arc furnace.
Moissan. Silicon carbide.
1894 Moissan. Calcium carbide.
Cross and Bevan. Viscose for artificial fiber.
Power plants started at Niagara Falls, N. Y.
1895 Hampson-Linde. Liquefaction of air and fractional distillation of same.
1896 Acheson. Graphite from coal in electric furnace.
1897 Large-scale manufacture of indigo in Germany.
1898 Sabatier. Catalytic hydrogenation of unsaturated organic compounds; 1902, Norman. Commercial hydrogenation of liquid fatty oils to semisolid or solid fats.
Goldschmidt. Thermite reaction of aluminum powder and iron oxide for production of high temperature.
Knietsch. Contact process for sulfuric acid patented.
Dow. Electrolytic chlorine for bleaching powder.
1900 Héroult. Industrial smelting of steel in electric furnace.
Edison. Nickel-nickel dioxide storage battery.
Ostwald. Patented oxidation of ammonia by air, using platinum catalyzer.
Wesson. Vacuum deodorization of fatty oils.
Taylor. Carbon disulfide manufactured in electric furnace at Torrey, N. Y.
1901 First contact process sulfuric acid plant in U.S.A.
1902 Readman and Parker. Manufacture of phosphorus in electric furnace.
1903 Birkeland and Eyde. Electric fixation of atmospheric nitrogen in Norway.
1904 Betts. Electrolytic refining of lead, using fluosilicate.
1905 Frank and Caro. Cyanamide process from nitrogen and calcium carbide; 1907 commercial production at Niagara Falls, N. Y.
Becket. Pure ferroalloys by reduction of oxides by silicon.
1906 De Forest. Invention of radio tube detector.
Hybinette. Electrolytic process for refining of nickel.
1906 U. S. Food and Drugs Act.
Cottrell. Electrostatic precipitation of suspended dust and mist particles from air.
1908 Baekeland. Phenol-formaldehyde resins and plastics.
1909 Bradley and Lovejoy. Electric fixation of atmospheric nitrogen at Niagara Falls, N. Y.
1910 Langmuir. Gas-filled electric lamp.
Coolidge. Ductile tungsten filament.
1911 Dreyfus. Cellulose acetate for artificial fiber.
1912 Brearley. Stainless or corrosion resistant steels.
Burton. First cracking still for petroleum.
1913 Haber. Perfected process for synthesis of ammonia from nitrogen and hydrogen.
Coolidge. Filament x-ray tube.
1914 Sullivan and Taylor. Pyrex, a hard borosilicate glass.
1915 McAfee. Introduced aluminum chloride anhydrous in petroleum refining.
Weizmann. Fermentation of starch to produce acetone and normal butyl alcohol.
Activated sludge process of sewage recovery.
Gas carbon black in rubber for tires.
High chromium iron alloys introduced.
1916 Commercial production of artificial leathers.
Mustard gas used in warfare.
1917 Pyrethrum extract in kerosene as insect spray.
1918 Dubbs. Cracking of petroleum by continuous process.
Gibbs. Phthalic anhydride by oxidation of naphthalene vapor by air, using vanadium pentoxide catalyst.
1919 Sperry. Electrolytic process for white lead.
1920 Phosphoric acid by electric furnace smelting.
Downs. Sodium metal by electrolysis of fused sodium chloride.
John. Urea-formaldehyde resin; 1929, commercial production in U.S.A.
1921 Potash beds discovered in Texas and New Mexico; 1931, developed.
1922 Fink. Chromium plating.
Sheppard and Eberlein. Electrolytic deposition of rubber.
Continuous cracking in petroleum refining.
1923 Midgley. Tetraethyl lead as anti-knock compound in motor fuel.
Quick-drying, low-viscosity nitrocellulose lacquer by du Pont Company, using spraying method.
1924 High alumina early strength cement.
Amyl compounds from pentanes in natural gas.
1925 Ethylene glycol and related solvents made from petroleum still gases by Carbide and Carbon Chemicals Corp.
Langmuir. Welding by use of atomic hydrogen.
Antioxidants for rubber.
Steenbock and Hess. Ultra-violet irradiation of sterols, producing vitamin D.
1926 Ethylene ripening of citrus fruits.
Quick freezing of foods.
Regenerated cellulose films and tubes.
1927 Vanadium pentoxide as catalyzer for sulfur trioxide from sulfur dioxide plus air.
1928 Cellulose acetate rayon produced in U.S.A.
Detergents composed of sodium salts of sulfuric acid esters of higher aliphatic alcohols (C_{10} to C_{18}) produced in Germany; 1934, in U.S.A.
1929 Egloff. Gum inhibitors for gasoline.
1930 Vinylite resins from acetylene.
Commercial production of synthetic ethyl alcohol from ethylene by Carbide and Carbon Chemicals Corp.
Carothers and Collins. Neoprene synthetic rubber (chloroprene).

Applied Chemistry (Continued)

1930 Iodine from California oil well brines.
Hydrogenation of petroleum at Bayway, N. J.
Midgley. Dichlorodifluoromethane (Freon) as refrigerant.

1931 Hill. Methylmethacrylate resin; 1937, produced commercially in U.S.A.

1932 The alkene polysulfide rubber "Thiokol" produced in U.S.A.

1933 Synthetic camphor from turpentine.
Ipatieff. Polymerization of olefin hydrocarbons, and alkylation of aromatic hydrocarbons with olefins, using calcined phosphoric acid catalyst.
Ascorbic acid (vitamn C) synthesized.

1934 Bromine from sea water at Cape Fear, N. C.
Isooctane as aviation fuel; 1936, first tank carload produced in U.S.A.

1935 Synthetic rubber, Buna type, in U.S.A.; 1940, butyl type; 1941, large-scale production of Buna-S type started in U.S.A.; 1943, GR-S type plant at Institute, W. Va., including both styrene from benzene plus ethylene followed by dehydrogenation, and butadiene from ethyl alcohol.
Sulfanilamide recognized as a medicinal chemical; 1939, licensed for sale in U. S. interstate commerce; 1938, sulfapyridine; 1939, sulfathiazole; 1940, sulfadiazine and sulfaguanidine.
Kodachrome motion-picture process for amateurs by Eastman Kodak Company.
Thiamine chloride (vitamin B_1) synthesized.

1937 Ethylcellulose produced in U.S.A.
Houdry. Fixed bed catalytic cracking of petroleum.
Grosse. Butenes to butadiene, using aluminum oxide plus chromium oxide catalyst.
Hickman. High-vacuum distillation of fish oils; 1941, centrifugal still for the fractionation of oils.

1938 Synthetic fiber nylon produced at Seaford, Del., by du Pont Company.

1938 Vinylidene chloride resin produced in U.S.A.
Butadiene from ethyl alcohol produced commercially.

1938 Linn and Grosse. Alkylation of hydrocarbons, using anhydrous hydrogen fluoride; 1942, commercial production in U.S.A.

1939 Heavy metal non-silicate glasses, having high refractive index for a given dispersion, introduced by Eastman Kodak Company.
Polyvinyl acetal resin.
Nicotinic acid (vitamin PP) and riboflavin (vitamin B_2) synthesized.

1940 Dichlorodiphenyltrichloroethane (DDT) antilouse agent; 1943, commercial production in U.S.A.
Nitroparaffins (C_1 to C_3) produced commercially by Commercial Solvents Corporation.

1941 Toluene produced from petroleum in U.S.A.
Extraction of magnesium from sea water at Freeport, Tex., by Dow Chemical Company.

1942 High-speed continuous tin electroplating.

1943 Penicillin produced commercially in U.S.A.
Fluid catalytic (catalyst falling through the reaction zone) cracking of petroleum.
Polyethylene resin produced commercially in U.S A.

1944 Methylolurea resin treatment of wood.
Organic silicon resins (Silicones) produced commercially in U.S.A.

1945 Uranium atomic bomb.

AWARDS, MEMORIALS, AND LECTURES. Nobel Prize Awards, Perkin Medal Awards, Memorial Lectures, Faraday Lectures.

Nobel Prize Awards. The Nobel prize awards have been made annually beginning in 1901, five years after the death of the donor, Alfred Bernhard Nobel. The amount of each prize varies with the income from the fund, but is usually about $40,000. The awards in chemistry and physics are made by the Swedish Academy of Science, Stockholm, and in physiology or medicine by the Caroline Medical Institute, Stockholm. The following awards have been made:

Year	Chemistry (Most important discovery or improvement)	Physics (Most important discovery or improvement)	Physiology or Medicine (Most important discovery)
1901	J. H. van't Hoff	W. C. Roentgen	E. A. von Behring
1902	Emil Fischer	H. A. Lorenz and P. Zeeman	Sir Ronald Ross
1903	Svante Arrhenius	H. Becquerel, P. and Mme. Curie	N. R. Finsen
1904	Sir Wm. Ramsay	Lord Rayleigh	I. P. Pawlow
1905	A. von Baeyer	Ph. Lenard	R. Koch
1906	H. Moissan	J. J. Thomson	C. Golgi and S. Ramon

Perkin Medal Awards. The Perkin medal awards have been made annually, beginning in 1906, fifty years after the discovery of the first synthetic dyestuff, mauveine, by William Henry Perkin. The award is made by the Society of Chemical Industry, American Section, to a chemist residing in the U.S.A., for the most valuable work in applied chemistry. The work may have been done at any time during his career. The selection is made by a committee representing the Society of Chemical Industry, American Chemical Society, Electrochemical Society, American Institute of Chemical Engineers, and Société de Chimie Industrielle.

The following awards have been made:

1906	Perkin, W. H.	1928	Langmuir, Irving
1908	Herreshoff, J. B. F.	1929	Sullivan, E. C.
1909	Behr, Arno	1930	Dow, Herbert H.
1910	Acheson, E. G.	1931	Little, A. D.
1911	Hall, Charles M.	1932	Burgess, Charles F.
1912	Frasch, Herman	1933	Onslager, George
1913	Gayley, James	1934	Fink, Colin G.
1914	Hyatt, John W.	1935	Curme, G. O., Jr.
1915	Weston, Edward	1936	Lewis, W. K.
1916	Baekeland, L. H.	1937	Midgley, Thomas, Jr.
1917	Twitchell, Ernest	1938	Tone, F. J.
1918	Rossi, A. J.	1939	Landis, Walter S.
1919	Cottrell, F. G.	1940	Stine, C. M. A.
1920	Chandler, Chas. F.	1941	Dorr, J. V. N.
1921	Whitney, W. R.	1942	Ittner, M. H.
1922	Burton, W. M.	1943	Wilson, Robert E.
1923	Whittaker, M. C.	1944	Du Bois, Gaston F.
1924	Becket, F. M.	1945	Bolton, E. K.
1925	Moore, H. K.	1946	Frary, F. C.
1926	Moore, R. B.		
1927	Teeple, John E.		

Chemical Society, London, See Memorial Lectures; Faraday Lectures.

Memorial Lectures. The memorial lectures are delivered, since 1893, before the Chemical Society, London, following the death of an eminent foreign chemist. These lectures furnish a valuable source of information concerning the life and work of these eminent non-British chemists. The following lectures have been delivered:

Year	Memorial Lecture	Year	Memorial Lecture
1893	Stas	1896	Hofmann
1893	Kopp	1896	Helmholtz
1895	Marignac	1896	L. Meyer

Year	Memorial Lecture	Year	Memorial Lecture
1897	Pasteur	1912	Becquerel
1898	Kekulé	1913	van't Hoff
1900	V. Meyer	1913	Ladenburg
1900	Bunsen	1920	E. Fischer
1900	Friedel	1923	Baeyer
1900	Nilson	1923	van der Waals
1901	Rammelsberg	1927	Onnes
1902	Raoult	1928	Arrhenius
1905	Wislicenus	1930	Richards
1906	Cleve	1932	Wallach
1909	Wolcott Gibbs	1933	Ostwald
1909	Mendeléeff	1935	Mme. Curie
1910	Thomsen	1935	Brauner
1911	Berthelot	1936	Hantzsch
1912	Moissan	1937	Le Chatelier
1912	Cannizzaro	1938	Franklin

Faraday Lectures. The Faraday lectures are delivered, since 1869, before the Chemical Society, London, upon invitation, by an eminent foreign chemist. These lectures furnish a valuable source of information concerning the work of these eminent non-British chemists. The following lectures have been delivered:

Year	Faraday Lecturer	Title
1869	Dumas	Eulogy of Faraday
1872	Cannizzaro	Some Points on the Theoretical Teaching of Chemistry
1875	Hofmann	Liebig
1879	Wurtz	On the Constitution of Matter in the Gaseous State
1881	Helmholtz	Modern Development of Faraday's Theory of Electricity
1889	Mendeléeff	Periodic Law of the Chemical Elements
1895		Presentation of the Faraday Medal to J. W. Strutt by Lord Rayleigh
1904	Ostwald	Elements and Compounds
1907	Emil Fischer	Synthetic Chemistry in Relation to Biology
1911	Richards	Fundamental Properties of the Elements
1914	Arrhenius	Theory of Electrolytic Dissociation
1924	Millikan	Atomism in Modern Physics
1927	Willstätter	Problems and Methods in Enzyme Research

YEAR	FARADAY LECTURER	TITLE
1930	Bohr	Chemistry and the Quantum Theory of Atomic Constitution
1933	Debye	Relation Between Stereochemistry and Physics
1937	Haber	
1938	Pictet	

(R.K.S.)

HISTORY OF GEOLOGY.

B.C.
400 "If one is sufficiently lavish with time, everything possible happens" (Herodotus).
A.D.
200 The first appreciation of changes in sea level.
1500 Fossils generally recognized by students of geology as the evidence of extinct organisms.
1517 Formations now well above sea level recognized as having been originally deposited beneath the sea.
1570 Description of the stratigraphy of the coal beds of Great Britain (Owen).
1564 The earth thought to be 4004 years old (Lightfoot).
1740 Recognition of difference between igneous and sedimentary rocks (Guettard).
1760 Earth considered to be about 75,000 years old.
1795 The first treatise approaching the modern concept of dynamical geology (Hutton).
1809 The first geological map of a wide region (Maclure).
1822 The first extensive and careful use of fossils for the purpose of correlation (William Smith).
1830 The emphasis of the important doctrine of "Uniformitarianism" and the development of the modern systemic division of the Cenozoic (Lyell).
1840 The development of the modern systemic division of the Paleozoic (Sedgwick and Murchison) and the importance of facies (Murchison and Lonsdale).
1841 The recognition of continental glaciation (Agassiz).
1842 The appreciation of the true structure of a folded mountain range and the birth of the idea of the geosyncline (Rogers Brothers and Dana).
1846 The appreciation of the permanency of ocean basins and continents (Dana).
1855 The recognition of isostasy (Airy).
1863 First paleogeographic map of a specific period (Dana).
1870 The recognition of Permian glaciation (Fedden).
1872 The earth thought to be 20 million years old (Kelvin).
1873 The recognition of the importance of cycles of sedimentation (Newberry). The recognition of the geosyncline as fundamental to structural and stratigraphical geology.
1878 The introduction of the theory of nappes (Heim).
1884 The recognition of the full effect of low-angle overthrusts (Peach and Horne).
1899 The earth thought to be 89,222,900 years old as determined by the age of the oceans (Jolly).
1907 The recognition of pre-Cambrian glaciation (Coleman).
1911 The European concept of the geosyncline (Haug).
1929 The lithic history of the earth thought to be over 1 billion, 500 million years, as determined by the lead-uranium method.
1934 Discovery of lineal distribution of negative gravity anomalies in relation to island arcs and the consequent development of tectonophysics (Meinesz).

(R.M.F.)

HITCH. Pisces, Teleostei. A fresh-water fish of the minnow family found in the Coast Range. (A.W.L.)

HIVES. **Urticaria.**

HOACTZIN. **Fossil Birds.**

HOARHOUND. **Mint Family.**

HOATZIN, HOACTZIN. Aves, Galliformes. A peculiar South American bird (**Aves**) of doubtful relationship. It lives along streams of the Amazon valley and eats fruit and other vegetation. The young have a clawed digit on the margin of the wings which they use to grasp boughs in climbing. (A.W.L.)

HOB. A milling cutter with form-type teeth of helicoidal shape and with profiles such that conjugate surfaces on cylindrical parts may be machined by rotating the work and the hob at a constant velocity ratio. Hobs are extensively used for cutting spur gears, and hobbing is the only really precise method of cutting heavy-duty worm wheels. (See **Worm Gearing.**) Two types of gear hobs are commonly used; the radial or infeed type, and the tapered or tangential feed hob. The latter is superior, particularly for hobbing worm gears with high helix angles and high pressure angle. Hobbing processes are also used for spline cutting, and for generating ratchet teeth.

The term hobbing is also used to designate a method of die sinking, in which a hardened master punch, a duplicate of the part to be formed, is pressed into an unheated die blank so that the shape of the hob is reproduced in the die impression. This method of producing die cavities is simpler than die sinking by cutting away the material, since it is considerably easier to machine the surface of the hob than to machine the die cavity. It is also advantageous in the production of multiple die cavities, since a single hob can be used for a series of duplicate dies. The process is also referred to as "hubbing." (H.C.H.)

HOBBY. Aves, Falconiformes. A **falcon** of moderate size. It ranges over Europe and Asia and migrates into Africa. (A.W.L.)

HOCHEUR. **Guenon.**

HOCK, HOUGH. The joint at the attachment of the foot and the leg in animals which walk on the toes (digitigrade or unguligrade), commonly applied to domestic animals. It corresponds to the ankle joint of other species. Also the back of the human knee. (A.W.L.)

HODGKIN'S DISEASE. A disease of unknown origin characterized by non-painful enlargement of the **lymph nodes** accompanied by fever, anemia, and in the later stages, wasting.

The disease seems to be an infection with neoplastic manifestations. At one time it was thought to be a kind of tuberculous infection. As yet nothing specific is known either as to cause or treatment. Pathologically, the lymph nodes and spleen show increased numbers of lymphoid and endothelial cells, eosinophiles, and giant cells. Necrosis and fibrosis of varying degree are present.

The non-painful swellings of the lymph glands in various parts of the body—particularly the neck and within the chest—at first may not be accompanied by symptoms. Soon, however, weakness, wasting, and anemia become marked. The disease usually results in death after 2 or 3 years either from secondary infection or through pressure on the **trachea** from enlarged glands.

The disease may occur in an acute form, death developing in a few weeks.

In some cases, the abdominal organs may be involved primarily, with little or no involvement of the

peripheral lymph nodes. In the generalized form, lymph nodes and internal organs are all involved.

Palliative treatment is obtained by the use of **radium** or **x-ray** over the enlarged masses. Transfusions control the anemia and give symptomatic relief. There is nothing known, to date, that will arrest or cure the disease. (R.S.M., D.M.H.)

HODOSCOPE. **Cosmic Rays.**

HOFMANN REACTION. **Rearrangements.**

HOGBACK. Ridge-like topographic features, the result of the differential **erosion** of highly tilted hard and soft strata. The steeper, or dip-slope, side is developed on the harder or less soluble formation, while the gentler slope is developed on the opposite side, on the softer rocks. (Compare with **Escarpment; Scarp; Cuesta.**) (R.M.F.)

HOG SUCKER. Pisces, Teleostei. A fish (**Pisces**) of moderate size found in clear streams in the northeastern quarter of the United States. (A.W.L.)

HOHLRAUM. **Black Body.**

HOIST. Any device for lifting materials, weights, articles, etc., may be called a hoist. Hoists often compose a part of other apparatus whose purpose may extend to movement of material other than vertically. For example, the bridge **crane** incorporates within it a hoist for vertical lift. The energy required for lifting is derived ultimately from a number of various sources. For example, in the hoisting field one finds such varied power sources as compressed air, internal combustion engines, hydraulic power, steam and electric power. The pneumatic drives may be either a direct lift supplied by air acting on a **piston** connected directly to the load, or it may be employed in compressed air engines, whose crankshaft is geared to the hoisting apparatus. In the **internal combustion engine** type hoist, the gasoline engine is generally used for the light-capacity hoist, and the **Diesel engine** for heavier hoists. It has the advantage over other drives for portable service, such as locomotive cranes, power shovels, etc. Hydraulic drives of hoisting machinery take the form of water pressure applied to a piston which slides in a long cylinder. The hydraulic drive usually requires some other source of power for driving the pump required to force the water into the cylinder. Hydraulic drives were once quite popular for elevators in buildings of moderate height, but the type has lost favor because of the speed of electrically driven hoists.

The hoist which is driven by an electric motor is probably the type most used today. It will be found in a variety of sizes ranging from the high-speed passenger elevator of the tall office building to the small electrically driven chain hoist. Steam as a drive for hoisting machinery is used principally for stationary hoists moving heavy loads such as mine lifts, and is used to a certain extent for portable hoisting. An example in the latter class is the steam shovel.

The essential parts of a hoist are a rope or chain which is wrapped around a drum or drive sheave. A hook, grapnel magnet, or other device for handling the load is attached to the free end. The rotation of the drum winds up the rope, thus shortening the distance between the drum and the load. If the drum is fixed in position over the load, naturally the load must be hoisted. To drive the drum, one of the power supplies just mentioned is connected with the drum through a suitable speed-reducing, torque-increasing mechanism. A gear train is often used. These component parts when supplied with a brake controlling the speed during lowering of weights, are the essential elements of all hoists except the direct acting. The rope employed in hoists is either good quality Manila rope, or twisted steel rope. Manila is used principally for small or relatively unimportant hoists; multiple strand, greased flexible wire rope for others.

Various small hand-operated lifting devices may also be truly classified as hoists. Among these might be mentioned the winch, the **capstan**, the screw jack, hydraulic jack, and the **chain block**. (See **Elevators.**) (F.T.M.)

HOLLYHOCK. **Mallow Family.**

HOLMIUM. Symbol: Ho. Atomic number: 67. Atomic weight: 164.94. No isotope, but of single atomic form: 165. Type of compound: Ho_2O_3. Color of salts: Yellow. Discovered by Cleve in 1879. A member of the **yttrium** sub-group of the rare earth metals. (R K.S.)

HOLOCRYSTALLINE. The term applied by **petrologists** to **igneous** rocks composed entirely of **crystals;** in contradistinction to igneous rocks which are partly or entirely composed of natural glass, such as **obsidian.** (R.M.F.)

HOLOGAMY. A type of **fertilization** of 1-celled organisms in which interchange of material takes place between two cells indistinguishable from ordinary individuals. Conjugation. Also called macrogamy. (A.W.L.)

HOLOGONIA. **Nematoda.**

HOLOMETABOLA. A division of the insects characterized by complete **metamorphosis**. The insect as it hatches from the egg is a **larva** which differs conspicuously from subsequent stages and is adapted for a different mode of life in many species. It has no compound eyes and the wings develop internally. Caterpillars, grubs, and maggots are larvae of this type. When fully grown the larva transforms into a **pupa**. This stage is relatively inert and in some species is incapable of movement. It is often hidden in a subterranean cell or in a cocoon prepared by the larva before its transformation. The adult or imago emerges from the pupa.

The insects included here make up the orders **Coleoptera, Strepsiptera, Neuroptera, Mecoptera, Trichoptera, Lepidoptera, Hymenoptera, Suctoria,** and **Diptera.** (A.W.L.)

HOLOSTEI. The **garpikes** and **bowfins**, a small order of the class **Pisces**. (A.W.L.)

HOLOTHUROIDEA. The sea cucumbers, a class of the phylum **Echinodermata.**

These animals differ from other echinoderms in several particulars: 1. The principal axis is elongated and the animal rests on its side. 2. The body wall is soft because of the reduction of the calcareous ossicles. 3. A branching respiratory tree extends from the alimentary tract into the body cavity.

Sea cucumbers are used as food in the Oriental region. They are dried for the market and in this form are called trepang or bêche-de-mer.

The class includes five orders:

Order Aspidochirota. Tropical species with shield-shaped tentacles. In shallow water.
Order Elasipoda. Benthonic species of deep water.
Order Dendrochirota. Shallow water species with branching tentacles.
Order Molpadonia. Burrowing species. Tentacles unbranched or slightly branched.
Order Apoda. (Synaptida, Paractinopoda). Burrowing species without respiratory trees. (A.W.L.)

HOLOTRICHIDA. **Ciliata.**

HOLOTYPE. As used by biologists and paleontologists to mean the specimen to which all others should be

ultimately referred to determine the species. The holotype does not necessarily have to be the originally described species (type) and frequently is not. (R.M.F.)

HOMEOTYPE. As used by biologists and paleontologists for a specimen which has been identified by an authority by comparing it with the type. (R.M.F.)

HOMOATROPINE. **Alkaloids.**

HOMOCLINE. Group of strata which dip in one and the same direction. Never a complete structure and usually representing the limb of an **anticline** or syncline. (R.M.F.)

HOMOGENEOUS COORDINATES. If the ratios of **coordinates** (one more than necessary) are used instead of the coordinates themselves, we have homogeneous coordinates. Their use renders equations involving them homogeneous. (L.L.S.)

HOMOGENEOUS DIFFERENTIAL EQUATIONS. **Ordinary Differential Equations of First Order and First Degree,** also **Linear Differential Equations.**

HOMOGENEOUS FUNCTIONS. A homogeneous function is a type of mathematical expression, defined as follows:

A **function** $f(x, y)$ is called homogeneous in x and y if $f(\lambda x, \lambda y) = \lambda^n f(x, y)$; the **exponent** n is then called the degree or order of the function. (L.L.S.)

HOMOGENEOUS SYSTEMS OF LINEAR ALGEBRAIC EQUATIONS. **Linear Algebraic Equations, Systems of.**

HOMOIOTHERMY. Warm-bloodedness. The maintenance of a body temperature above that of the environment is common among animals, hence the usual terms warm- and cold-blooded are inaccurate. Cold-blooded forms are those whose body temperature fluctuates with that of the surrounding air or water, so that the animal's activity is directly conditioned by external temperatures. They are more accurately described as poikilothermal. In contrast, homoiothermal animals tend to maintain a constant body temperature in spite of external fluctuations. Fluctuations are normal, although the human body usually maintains a constant temperature.

Only birds and mammals are homoiothermal. Both regulate the body temperature by producing excess heat and by regulating its radiation from the surface. Regulation is accomplished by nervous control of the blood vessels near the surface, by insulating vestiture, and by the evaporation of water from the body. When the surrounding air is warm the blood flows more freely near the surface of the body and more heat is radiated but when the air is cold less blood reaches the surface and the heat is conserved. In air too warm to permit adequate radiation the animal reduces its activity, exposes as much surface as possible, and either sweats or pants. The evaporation of water either from the mouth or from the sweat glands absorbs heat from the underlying tissues. Vestiture plays a passive role as an insulating coat but it is capable of some regulation, especially in the birds. The erection of the feathers provides a thicker and looser covering of high insulating value and their depression results in less interference with radiation.

Homoiothermy is one of the highest adaptations of living things, since it provides for the maintenance of optimum conditions for the vital processes of the body. Through it the animal becomes virtually independent of one of the most important of the fluctuating environmental conditions. (A.W.L.)

HOMOLOGOUS SERIES. Two organic compounds are said to be homologous if their molecular formulae differ by CH_2, or a multiple of CH_2. (R.K.S.)

HOMOLOGY. Fundamental structural relationship based on similarity of embryological development and evolutionary history. The antithesis of analogy, which is superficial likeness based on adaptation for similar uses.

The anterior appendages of terrestrial vertebrates, for example, are regarded as fundamentally similar structures, derived from the **pentadactyl appendage,** yet they include the wings of birds, flippers of aquatic mammals, and a great variety of less extreme adaptations, including the legs of animals and the arms of man. In contrast, the wings of birds and of insects are broad thin structures used for flight but in structure and origin they show no resemblance beyond this point and so are analogous. (A.W.L.)

HOMOPLASY. More commonly designated as analogy. **Homology.** (A.W.L.)

HOMOPTERA. The **cicadas, leaf hoppers, plant lice, scale insects,** and numerous other forms, constituting a large order of insects. They have sucking mouths which differ from those of most bugs in that the slender proboscis arises from the hind margin of the head and extends back between the legs. The wings, when present, are membraneous. The order includes about 16,000 species.

Many members of this order, particularly the plant lice, scale insects, and **phylloxerans,** are economically important. (A.W.L.)

HOMOSEXUALITY. Perverted sex practices among those of the same sex. (R.S.M.)

HOMOTHALLISM. **Phycomycetes.**

HONEY. A thick sweet liquid formed by **bees** from the nectar of flowers and to a limited extent from the juice of fruits and honey-dew. Honey contains a large percentage of simple sugars, **essential oils** of the flowers from which it is derived, and a minute amount of **formic acid** which acts as a preservative. Its flavor depends on the flowers from which it comes.

The honey produced by **honey-bees** is marketed in several forms and various grades. The lighter grades are more widely demanded for table use and the darker grades are sold for baking, candy making, and the compounding of medicines. In the United States, Californian white-sage honey ranks as the finest of the white honeys, with honey from orange blossoms and white and alsike clover next. Immense quantities of honey are produced from alfalfa in irrigated regions and from sweet clover in the Middle West. Both are very light in color but of poorer flavor. Dark honey comes chiefly from buckwheat, fall flowers such as goldenrod and asters, and from many plants in the southern states. Usually only the better grades of honey are produced in the small sections commonly called comb honey, but these grades and inferior honeys as well are removed from the comb and sold in jars or pails as extracted honey. A third form is chunk honey, consisting of pieces of comb honey in containers filled with extracted honey. (A.W.L.)

HONEY BUZZARD. Aves, Falconiformes. A bird (**Aves**) related to the eagles, named from its habit of robbing the nests of bees and wasps and eating the larvae. One species lives in Europe and Asia and others in the Oriental region. (A.W.L.)

HONEY CREEPER. Aves, Passeriformes. Small birds (**Aves**) of tropical South America and the West

Indies. Related to the warblers. They visit flowers like the hummingbirds but are incapable of hovering flight. One species is called the banana-quit. (A.W.L.)

HONEY DEW. A sweet secretion produced by **plant lice.** When these insects are abundant on trees it sometimes spots the leaves and anything below the tree like a heavy dew. It is freely sought by ants and is sometimes gathered by bees, but it makes a very inferior honey. (A.W.L.)

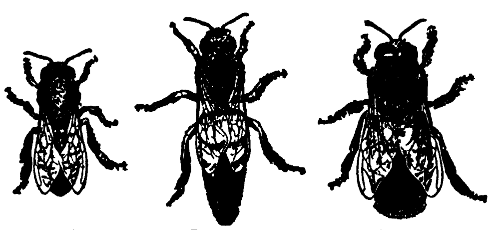
HONEY EATER. Aves, Passeriformes. Birds of the Australian region. They have long tongues with which they secure nectar from flowers. The group includes the parson bird, the stitch bird, and several species called white eyes. (A.W.L.)

HONEY GUIDE. Aves, Piciformes. Birds (**Aves**) of several African and Oriental species. They lay their eggs in the nests of other birds and are named from their reputed habit of leading the way to nests of bees. (A.W.L.)

HONEY PECKER. Aves, Passeriformes. Small brilliantly colored birds (**Aves**) of the Oriental and Australian regions, related to the sun birds. One Australian species is called the diamond bird. (A.W.L.)

HONEY-BEE. Insecta, Hymenoptera. Insects of several species which live in colonies, build combs of wax secreted by the body, and in the cells of these combs raise their young and store honey and pollen. They make up the family Apidae.

A single species, *Apis mellifica,* is kept for the production of honey and wax in Europe and North America. This species was introduced into North America from



Honey-bee.

Europe and is the chief species of economic importance in all parts of the world. It occurs in several varieties, including the dark German or black bee, the golden to leather-colored Italian, and the gray Carniolan. Italian bees predominate in the United States; the better strains are prolific, good-tempered, hardy, and otherwise desirable.

The honey-bee colony normally contains a single queen which may be active for 3 years. During the active summer season males or drones are produced in considerable numbers, but they are not tolerated in the winter or in times of scarcity of food. A strong colony for honey production also contains from 60,000 to 100,000 or more workers. The queen is the only normal female, although workers are also of this sex.

Owing to the economic importance of the honey-bee it has been observed in detail and an extensive literature has accumulated on the habits of bees, their structure, the organization of the colony, and all phases of the management of apiaries and the production and marketing of honey. (A.W.L.)

HOODOO. In geology, a columnar or pillar-like erosional remnant which has been carved and sculptured from relatively horizontal formations by differential erosion. The form and subsidiary features of Hoodoos may be partly governed by joint planes and the differential hardness of the stratified sediments. The term applies particularly to eccentric and peculiar forms which are especially noticeable because of their fancied resemblance to animals and artifacts. (R.M.F.)

HOOK GAUGE. Weir.

HOOKE'S LAW. Elasticity.

HOOKWORM. Nemathelminthes, Nematoda. A minute worm which develops in the soil and lives as an adult in the human intestine, causing a disease which is also called hookworm (Uncinariasis, Ankylostomiasis). This parasitic disease is quite widespread and has existed for thousands of years. The **parasite,** however, was not discovered until 1838 by Dubrin. It is found throughout the world and is most prevalent near the equator. In many countries of the world nearly 100% of the population is infected. In the southern United States it exists for the most part in the poorer rural districts. There it is a serious problem. Medical treatment for the elimination of the worms is available but to prevent reinfection in such climates is a difficult matter, even though the method is simply the protection of the hands and feet from contact with earth in which the worms are likely to occur.

The disease is spread by hookworm ova in the feces. A single female hookworm living in man's intestinal tract will pass several hundred eggs daily. Under favorable conditions, **embryos** hatch out in the soil in 1–3 days. Five days later in the larval stage the parasites are able to again infect humans. When the skin—usually the feet—comes in contact with mud the parasites are able to infect an individual, penetrating with ease through a break in the skin, and are then carried throughout the body by the bloodstream. The larvae reach the lungs, are carried by the bronchial mucus to the pharynx and are swallowed, thus reaching the intestinal tract. Six to eight weeks after an individual is infected, eggs are passed in the feces.

Since these worms feed upon the blood it is to be expected that a severe **anemia** would develop with infection of large numbers of the parasites. Practically all of the symptoms of this disease result from the profound anemia. Heavy infection in children results in stunted growth, apathy, lack of energy, and retarded mental development.

The diagnosis is made with ease by microscopic examination of the stools and identification of the ova.

The prognosis in hookworm infestation is excellent unless the disease has progressed too far. Rapid recovery ensues if treatment with thymol (see **Phenol**), oil of chenopodium, or other similar drug is used, and all worms expelled from the gastro-intestinal tract. Reinfection must be prevented. (R.S.M., A.W.L.)

HOOLOCK. Gibbon.

HOOPOE. Aves, Piciformes. Birds (**Aves**) of the Old World with a very high crest and a long sharp beak. One species, *Upupa epops,* lives in Europe and others in the Oriental region, Africa, and Madagascar. (A.W.L.)

HOPLOCARIDA. The mantis shrimps, **Crustacea.**

HOPLONEMERTEA. Nemertea.

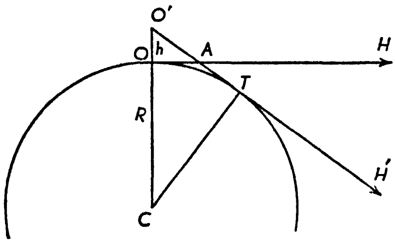
HOPLOPHONEUS. Fossil Mammals; Oligocene.

HOPS. Mulberry Family.

HORIZON. The visible horizon is the line where "earth and sky meet." In astronomy the term horizon is used to describe the great circle cut out on the **celestial sphere** by a plane perpendicular to the direc-

tion of **gravity**. In case this plane is tangent to the surface of the earth, the horizon so described is the apparent horizon; if the plane passes through the center of the earth, we have the geocentric horizon.

The difference in direction between the visible and the apparent astronomic horizon is known as the dip of the horizon. In the figure, $O'H'$ represents the direction of the visible horizon from an observer at a station O' elevated above the surface of the earth by an amount h. OH represents the direction of the astronomic horizon as defined above for the observer on the surface of the earth at O. The angle HAH' is the dip of the horizon and may be shown to be very



Visible and astronomical horizons.

approximately given by the relation: the dip of the horizon (expressed in minutes of arc) is equal to the square root of the height of the observer above the surface of the earth (expressed in ft.). The distance $O'T$ from the observer to the visible horizon is approximately given by: The distance of the visible horizon (expressed in miles) is given by the square root of 3/2 the height of the observer above the surface of the earth (expressed in ft.). This distance is frequently very much increased by an effect known as looming of the horizon, produced by **refraction** of light in heated (or cooled) layers of the air near the surface. Both the expressions for the dip and distance of the horizon are applicable only when the point of observation of the visible horizon (the point T) is actually on the surface of the earth, e.g., the sea horizon. (W.K.C.)

HORIZONTAL CONTROL. Station.

HORIZONTAL COORDINATE SYSTEM. The horizontal coordinate system is a system of **spherical coordinates** on the **celestial sphere** which uses the **horizon** as a fundamental plane. Planes perpendicular to the horizon cut out great circles on the celestial sphere known as **vertical circles**. The fundamental direction selected in the fundamental plane is true south. The **azimuth** of a point on the celestial sphere is the angular distance, measured in the plane of the horizon, from the true south direction to the point of intersection of the vertical circle through the object with the horizon. There are several different methods for expressing azimuth, but the astronomical method is to measure azimuth from the south through the west through 360°. The **altitude** of a point on the celestial sphere is the angular distance, measured along the vertical circle through the point, from the plane of the horizon to the point.

The horizontal system of spherical coordinates is frequently referred to as the altazimuth system. (W.K.G.)

HORMONE. A hormone is a distinct chemical substance formed by one organ and acting in a specific manner on the function of another organ (or organs) of the body. Hormones are produced mainly by the glands of internal secretion—the ductless or endocrine glands. They may also be liberated by glands having an external as well as an internal secretion, for example, the **pancreas, testicles,** and probably the **liver**. The duodenum produces a hormone called secretin which stimulates the flow of pancreatic juice into the intestine.

The endocrine glands and the hormones produced by them are listed below. A discussion of the function of each hormone will be found under the heading of the various glands.

Gland	Hormone
Adrenal	
Medulla	Epinephrine
Cortex	Cortin
Thyroid	Thyroglobulin
Pituitary	
Anterior lobe	Growth hormone
	Thyrotropic (thyroid stimulating)
	Adrenotropic (adrenal stimulating)
	Gonadotropic (gonad stimulating)
	Lactogenic (milk gland stimulating)
Posterior lobe	Pituitrin, composed of
	Pitocin (uterine stimulating)
	Pitressin (pressor substance)
Pancreas	Insulin
Parathyroid	Parathyroid hormone
Gonads	
Ovaries	Estrin (follicular hormone)
	Progestin (corpus luteum hormone)
Testes	Testosterone (androsterone)

There are a number of diseases associated with abnormalities of hormone production—both with increased and decreased function of the particular gland. The common ones occurring with underfunction are **myxedema** (hypothyroidism), **diabetes,** and the syndromes resulting from failure of the **pituitary** gland and the **gonads.** In these diseases, replacement therapy with commercial preparations—desiccated gland substance or synthetic hormones—may alleviate the signs and symptoms, or even control them completely. This is particularly true of insulin in the treatment of diabetes, and thyroid hormone in the treatment of myxedema. With the exception of thyroid hormone and stilbesterol (a synthetic **estrogen**), which are active when given orally, all the other hormones must be given hypodermically, because they are inactivated by the digestive juices.

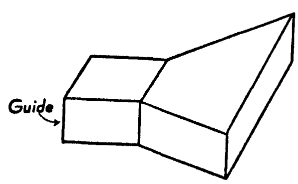
Hyperfunction of a gland and overproduction of hormone may occur with simple **hyperplasia** or may result from the development of a **tumor.** The ensuing disease picture is in general the opposite of that associated with underfunction. Hyperinsulinism, hyperthyroidism (Graves' disease), and hyperpituitarism (**acromegaly**) are the common diseases of this type. Hyperinsulinism and hyperthyroidism are treated by surgical removal of a part of the gland. This usually results in complete cure of the disease.

Hormones are also known to the botanist, occurring in minute quantities in various parts of the plant. Their presence, usually not where they are formed, produces very definite results. Growth substance, formed in the tips of plants, and especially in young seedlings, seems to be the cause of the great sensitiveness the plant has to light (see **Movements in Plants**). It seems to stimulate cells on the unlighted side of the plant to elongate greatly and so causes the plant to bend towards the light. Other hormones, called wound hormones, seem to be formed wherever the tissues of a plant are injured. Because of the presence of these hormones, cells in the vicinity of the wound are stimulated to rapid division, which causes tissue to form over the wound and close it. (R.S.M., R.M.W., D.M.H.)

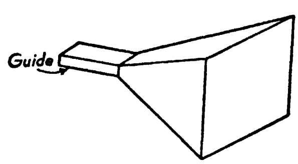
HORN. A hard translucent material formed by the development of epidermal cells containing a substance known as **keratin.** The outer layers of the skin are keratinized and the nails, claws and hoofs of mammals are formed of similar material. Horn is also developed in large amounts in the appendages of the head which

go by the same name. Horns may be bony cores sheathed in horn or solid bony growths. The former occur in cattle and the latter in deer. The median horn or horns borne on the head of rhinoceroses are quite unlike true horns. They are formed of aggregated hair-like components firmly based on roughened areas of the underlying bones. (A.W.L.)

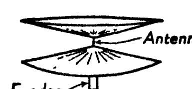
HORN, ELECTROMAGNETIC. Horn radiators are used to obtain directional radiation characteristics which could not be obtained as conveniently with simple antennae (see **Directional Arrays**). As such directors they are used both with conventional antennae and with wave guides, but in either case they serve to direct the radiation in a pattern from the open end of the horn in a manner determined by the dimensions of the horn. The important dimensions are the horn opening (in terms of wavelength of the radiation) and the flare angle. While theoretically an infinitely long horn will give a radiation pattern whose angle conforms to that of the horn, those of practical length do not confine the beam to quite this degree. For example a horn with an angle of 15° may give a radiation pattern which spreads 23°. The common horns may be divided into three classes, sectoral, pyramidal and biconical. The sectoral



Sectoral



Pyramidal



Biconical

horn has two sides which are parallel and the other two flared. The pyramidal horn has all sides flared. The conical horn is really a pyramidal horn with a circular cross-section. The biconical horn consists of two cones with their vertices coinciding or adjacent to one another. The first two types are used where a singly directed beam of radiation is desired, the exact pattern in both vertical and horizontal planes being determined by the dimensions. The biconical horn gives a uniform pattern in a plane perpendicular to the axis and highly directional in any plane containing the axis.

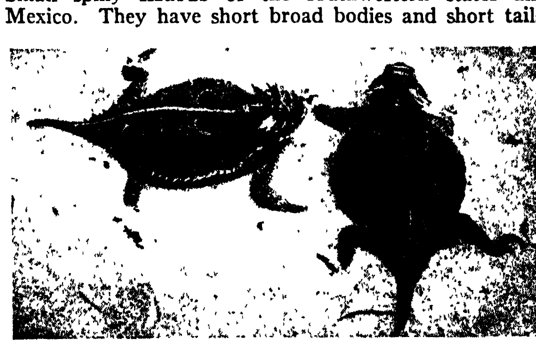
Sectoral and pyramidal horns may be excited by more or less conventional antennae or by wave guides. In the former case, a short section of wave guide is attached to the end of the horn and this is excited by the antennae. In the latter case, the horn is really a flared extension of the guide and may be looked upon as a impedance-transforming section for matching the impedance of the guide to that of free space. Biconical horns are excited by a variety of antenna arrangements in the space between vertices of the horns. Because of space considerations horns are not feasible except at ultra high frequencies, but in the microwave region they are widely used as radiators. (L.R.Q.)

HORNBILL. Aves, Coraciiformes. Large birds (**Aves**) of the African and Oriental regions, characterized by the very large beak, many species with a large prominence above the base of the upper mandible extending back onto the head. (A.W.L.)

HORNBLENDE. The mineral hornblende is a complex **silicate** which is probably an **isomorphous** mixture of three molecules, a **calcium-iron-magnesium** silicate, an **aluminum**-iron-magnesium silicate and an iron-magnesium silicate. Manganese and alkalis are sometimes present as is also **titanium.** It is **monoclinic**, with prismatic crystals, often pseudo-**hexagonal.** Bladed, fibrous, columnar, granular and compact massive varieties also are common. It has a perfect prismatic **cleavage**; hardness, 5–6; specific gravity, 2.9–3.4; color, green, greenish-brown, brown and black; luster, vitreous to silky; transparent to opaque. Hornblende is a common constituent of many of the **igneous** rocks such as **granite, syenite, diorite,** or **gabbro,** of **gneisses** and **schists** and is the principal mineral of the **amphibolites.** Hornblende alters easily to **chlorite** and **epidote.** A variety of hornblende that contains little (less than 5%) of iron oxides is gray to white in color and named edenite, from its locality in Edenville, N. Y. Very dark brown to black hornblendes which contain titanium ordinarily are called basaltic hornblende from the fact that they are usually a constituent of basalts and similar rocks. Well-known localities for hornblende are in Czechoslovakia, Mt. Vesuvius, Italy; Norway, Sweden and in the United States in Massachusetts, New Hampshire and New York. Black hornblende is found in Renfrew County, Canada. The word hornblende is derived from the German *horn,* and *blende,* to blind or dazzle. The term blende was often used to refer to a brilliant non-metallic luster, for example, zincblende. (E.S.C.S.)

HORNBLENDITE. A coarse-grained rock related to **gabbro** which consists almost wholly of **hornblende.** **Olivine** being present, this rock may grade into a hornblende-peridotite (cortlandtite). Hornblendite is a rare rock type and of relatively little importance. (E.S.C.S.)

HORNED TOAD. Reptilia, Sauria. *Phrynosoma.* Small spiny **lizards** of the southwestern states and Mexico. They have short broad bodies and short tails,



Horned toads. (*New York Zoological Society.*)

hence the confusion of terms in the common name. Horned lizard is a better term.

Horned toads are desert animals and are capable of living for incredibly long periods without food or water. They cannot, however, survive for the long periods of years which have sometimes been claimed. (A.W.L.)

HORNER'S METHOD. Horner's method is a method of successive approximations for finding the approxi-

mate value of an irrational root of a **polynomial equation** to any desired degree of accuracy.

It may be summarized in general terms as follows: Locate the root between successive integers; the smaller integer is the integral part of the root. Now **transform** the given equation $P(x) = 0$ into another equation $P_1(x) = 0$, whose roots are those of $P(x) = 0$ diminished by the integral part of the root, so that $P_1(x) = 0$ has a root between 0 and 1. Locate this root between successive tenths; the smaller tenth is the tenths part of the root. Next, transform the equation $P_1(x) = 0$ into a new equation $P_2(x) = 0$, whose roots are those of $P_1(x) = 0$ diminished by the tenths part of the root, so that $P_2(x) = 0$ has a root between 0 and 0.1. Locate this root between successive hundredths; the smaller hundredth is the hundredths part of the root. Continue this process as far as necessary to obtain the desired degree of accuracy. Special devices may be used in the location of the root between consecutive tenths or hundredths, etc. **Synthetic division** should be used for the various transformations. (L.L.S.)

HORNET. Insecta, Hymenoptera. A name loosely applied to many of the larger **wasps**, particularly the species which build paper nests. (A.W.L.)

HORNFELS. A more or less general term applied to fine-grained, massive, and frequently speckled rock, the result of contact **metamorphism** developed in **slates** by **granitic** intrusions. (R.M.F.)

HORNSTONE. Old English synonym for **flint** and **chert.** (R.M.F.)

HOROSCOPE. **Astrology.**

HORN-TAIL. Insecta, Hymenoptera. Large **sawflies** whose **larvae** bore in the trunks of trees. The adults have a cylindrical body and in the female sex a short strong ovipositor which is the source of the name horn-tail. With this organ holes are drilled into the wood of the tree for the deposition of the eggs. (A.W.L.)

HORSE. Mammalia, Perissodactyla. Hoofed animals with a single toe on each foot, encased in a massive hoof. The teeth are very high-crowned grinding structures. The term applies properly not only to the domestic horse, *Equus caballus,* but also to any member of the family Equidae though many of the wild species are commonly known by other names. Of these species the best known are the **zebras**, a number of species of animals marked with conspicuous stripes. The **quagga** or couagga is striped only on the anterior half of the body. Both zebras and quagga live in Africa. Wild asses occur in northeastern Africa and in the deserts of Asia, among them the **kiang** or kulan of Mongolia and Tibet and the **onager** or ghorkhar of western India and adjacent areas. These animals are among the fleetest and hardiest known. Two wild species of central Asia, the **tarpan** and Prejevalski's horse, *Equus przewalskii,* are most closely related to the domestic horse and probably represent the original stock from which it was derived.

Although much of the evolutionary history of the horses is known from North American fossils, no horses existed on this continent when it was dicovered by Europeans and the wild horses of the West are entirely feral.

Under domestication many varieties of horses have been developed for riding, driving, draft animals and other uses. They have also been crossed with the domestic ass to produce mules for various purposes, and have been **hybridized** experimentally with other species. (A.W.L.)

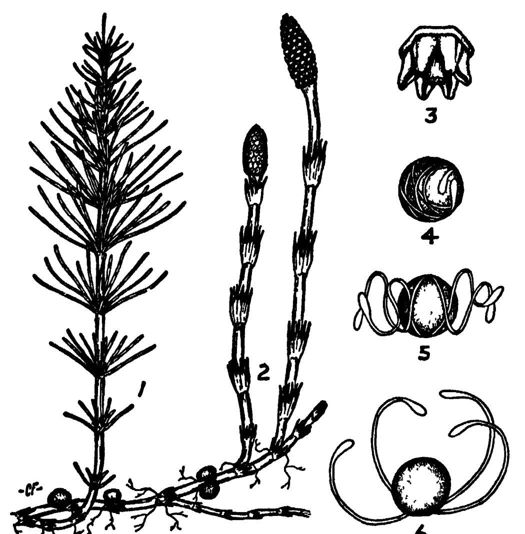
HORSEHAIR WORM. **Nematomorpha.**

HORSEPOWER. The survival of this old unit of **power** recalls the crude beginnings of the **English system** of measures. James Watt, in seeking for a means of expressing the power of steam engines and water wheels at the dawn of the industrial revolution brought about by the extensive use of machinery, turned to the horse as a familiar source of power and one in terms of which power values would be easily comprehended. It is said that he actually experimented with horses, using the best draft animals available, and that it was as a result of his observations that the horsepower has now become standardized as 550 **foot-pounds** of work per second. This is equivalent to about 746 **watts**, so that a kilowatt is approximately 1⅓ hp. (L.D.W.)

HORSES. A term used by miners to describe fragments of the wall rock included in the ore-bearing vein. (R.M.F.)

HORSESHOE CRAB. **Xiphosura.**

HORSETAILS, OR SCOURING RUSHES. Equisetales. The horsetails, or Equisetales, form a small section of the **Pteridophytes.** They are erect plants of various habit. Many species have erect columnar stems and minute scale-like leaves. Other species are much branched. In the outer part of their stems there is usually a thick deposit of silica (see **Silicon**). Therefore these plants were often used in early times for scouring pots and pans, and so gained their appellation of scouring rushes.



One of the horsetails, *Equisetum arvense.* 1, a vegetative shoot; 2, spore-bearing shoots, with a portion of the rhizome and a few roots; each shoot is terminated by a strobilus; 3, a portion of the strobilus much enlarged; the small white sacs are sporangia borne on scale-like sporophylls; the powdery dark masses beneath these are composed of spores; 4, 5 and 6, spores much enlarged; in 4 the elaters are closely coiled around the spore; in 5 and 6 the elaters are partially uncoiled.

At the tips of the ordinary stems or of special reproductive stems the **sporangia** are borne. These sporangia occur beneath the edges of small umbrella-shaped stalks which are aggregated into small cones. The **spores** are all alike. Each has four long flat appendages, called elaters, which curl and uncurl with changes of humidity, causing tangled masses of spores to be liberated. The spore develops into a small, much branched **prothallus** or gametophyte. On the upper surface of the prothalli **antheridia** containing **sperms**

or **archegonia** containing eggs are borne. The sperms, multiciliate spiral cells, swim to the archegonia and unite with the egg to form a **zygote.** This at once develops into a new horsetail. (See also **Paleobotany.**) (R.M.W.)

HORST. Fault.

HOST. An animal which is used as a source of food by a parasite. The parasite may live on the surface of the body or within it and may be harmless or harmful, but in all cases the host is the source of its food. (A.W.L.)

HOT WORK. Forging, rolling, pressing, extruding, swaging, drawing, or forming of metals at temperatures above their **recrystallization** temperature. (R.H.H.)

HOT-BULB. The semi-Diesel **engine** is not a true compression ignition engine in that the **piston** instroke does not compress the air sufficiently so that the resulting temperature rise is high enough to cause ignition in a cold engine. The semi-Diesel engine, however, does not use electrical **ignition** in the manner of the gasoline engine. It has a hot-bulb, which is a certain mass of metal incorporated in the cylinder head in such a way that a portion of it projects slightly in the combustion space. Before starting the semi-Diesel, the hot-bulb is thoroughly heated by applying a blow torch to its exterior surface. It thus provides a focal center of high temperature which produces ignition during the starting of this type of engine. A similar service is performed by "glow plugs" in engines so equipped. The glow plug resembles a common spark plug except that the insulated electrode instead of terminating in a gap connects to a loop of resistance wire. When a moderate voltage is impressed on the plug the resistance wire glows and provides a focal high-temperature point. (F.T.M.)

HOT-WATER HEATING. Heating Systems.

HOTWELL. A hotwell is a tank or container in which heated liquid collects. An example is the hotwell attached to and made part of a steam **condenser** of the surface type. As the steam is condensed, the condensate drops to the bottom of the condenser shell and flows into the hotwell, from which it is pumped. (F.T.M.)

HOUR ANGLE. The hour angle of a celestial object is the **spherical coordinate,** in the equatorial system of coordinates, which is measured in the plane of the celestial **equator** from the local **meridian,** in the direction of apparent rotation of the celestial sphere, to the intersection of the hour circle through the object with the equator. Since **time** and **hour angle** are practically synonymous (e.g., the hour angle of the **mean sun** is local mean time) the determination of hour angle is vitally necessary for the determination of local time and hence **longitude.**

At sea, hour angle is determined by measuring the **altitude** of the object by means of the **sextant,** reducing the observed altitude to true **geocentric,** and solving the **astronomical triangle.** For the solution of the triangle both the **declination** of the object and the **latitude** of the observer must be known. The declination may be immediately obtained from the tabulated **coordinates** of the object, but the latitude can be obtained only by some previous observation. In case the ship is in motion the latitude must be obtained by **dead reckoning** from the previously determined position. (W.K.G.)

HOUR CIRCLE. Equatorial Coordinates.

HOUSE FLY. Insecta, Diptera. A true **fly,** *Musca domestica,* well known for its habit of frequenting houses and alighting on all kinds of food. Since it also visits filth of any kind it is an important carrier of disease, especially typhoid fever, and has been the object of public health crusades for many years. With the improvement of sanitation the danger has been lessened, although it has not been entirely eliminated.

The house fly breeds in horse manure and in various kinds of decaying organic matter. Proper disposal of such wastes is an important measure in the control of the insect. (A.W.L.)

HOWLER. Monkey.

HUBARA. Bustard.

HÜBERNITE. Wolframite.

HUCHO. Pisces, Teleostei. A European fish (**Pisces**), *Hucho hucho,* related to the trout and salmon. (A.W.L.)

HUCKLEBERRY. Heath Family.

HUIA. Aves, Passeriformes. A New Zealand bird (**Aves**) related to the starlings. The male has a short straight beak while that of the female is long and curved. (A.W.L.)

HULL, AIRPLANE. Seaplane.

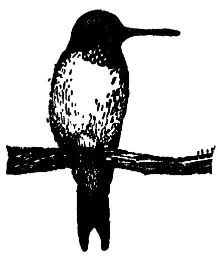
HUM. This is the annoying 60- or 120-cycle tone sometimes heard in the output of communication equipment. It may be introduced in the circuit in a number of ways, inductive or capacitive coupling with adjacent circuits carrying 60-cycle current, by the use of a.c. for heating the **filaments** of vacuum **tubes** or by induced effects from the **heaters** of indirectly heated tubes, by improper filtering of the output of the **rectifiers** supplying the d-c voltages for the operation of the system, etc. This tone is very annoying and sometimes difficult to eliminate, but fortunately careful design and layout of the equipment usually keep the hum level below the value which becomes noticeable. The use of shielded components in high gain **amplifiers,** indirectly heated **cathodes** in vacuum **tubes,** careful filtering, and the use of push-pull amplifiers are means commonly employed to reduce hum. (L.R.Q.)

HUMIDIFIER. Air Conditioning and Humidity.

HUMIDITY. The most obvious way of expressing the humidity or moisture content of the **air** is to state the percentage, by weight, of water vapor in its composition. This is the absolute humidity, and can be determined by passing a measured quantity of air through a tube containing an absorbing substance which removes all the vapor and may be weighed before and after the absorption. For many purposes, however, a more useful quantity is the relative humidity, which expresses the vapor content as a fraction or percentage of the concentration necessary to render the vapor saturated at the given temperature. (See **Vapors.**) Specifically, the relative humidity of the air at any temperature is the ratio of the actual vapor pressure of the water vapor contained therein to the maximum or saturated vapor pressure of water vapor at the same temperature. At the **dew point,** the relative humidity is 100%. A rise of temperature without the addition of more vapor reduces the relative humidity (but not the absolute humidity), while a fall of temperature increases it and may bring about saturation. Various forms of **hygrometer** have been devised to measure relative humidity. (L.D.W.)

HUMMINGBIRD. Aves, Micropodiformes. Small birds (**Aves**) of the New World whose wings are moved so rapidly in flight that they produce a low-pitched

sound. They are capable of hovering in one spot in the air, and habitually poise before the flowers which they visit for nectar and insects. Most species of hummingbirds inhabit tropical America but they range to Patagonia and several species enter the United States. Only one, the ruby-throated hummingbird, enters the eastern states. (A.W.L.)



Ruby-throated hummingbird, *Archilochus colubris*. Shiny green above, dusky underparts, with ruby-red throat in male but not in female. Length, three and three-quarter inches.

HUMUS. Soil.

HUNTING. The tendency of rotating mechanism which normally should operate at constant speed to pulsate in speed above and below the normal point, is known as hunting. It may occur in prime movers controlled by governors which are too isosynchronous, or in electric apparatus where rotating and stationary parts are electrically coupled. The nature of such **coupling** is essentially elastic, and may, under certain circumstances, lead to hunting action on the part of the rotor. (See **Damper Winding.**) Governors which hunt must be corrected by the use of **dash pots** or other damping devices, and the introduction to the governor characteristic of a slight amount of speed regulation. (F.T.M., L.R.Q.)

HURRICANES. Over all oceans, near the equator, with the exception of the South Atlantic there develop occasionally tropical cyclones which are intense vortices covering relatively large areas. They are particularly frequent over the western part of the Atlantic and Pacific, over the Indian Ocean, the Caribbean Sea and the Gulf of Mexico. Such storms are known as hurricanes over the ocean waters bordering on southeastern U.S.A. All are the same type of storm. Surface pressure in a hurricane is very low at the center or eye of the storm but rises rapidly outward toward the periphery. Because of the large pressure gradient, winds are of high velocity, blowing counterclockwise in the northern hemisphere and clockwise south of the equator. Velocities of 100 m.p.h. are relatively common near the storm's center, and 50–75 m.p.h. over a wide area can be expected. It is probable that velocities of 175 m.p.h. and perhaps more have occurred in more than one such storm. Mountainous waves and confused seas result from such winds. That quadrant of the storm where the velocity of wind and the velocity of the storm are additive is the quadrant where the greatest wind velocity is present; this is usually the north or east quadrant in the northern and the south or east quadrant in the southern hemisphere. Only in the center of the storm, the **"eye of the storm,"** is there little or no wind. The sea remains confused, however. A hurricane moving toward a coast line drives a rising sea before it in the dangerous quadrant. This apparent mound of water is known as the storm wave, or hurricane wave. This hurricane wave, driven by very strong on-shore winds, often lifts ocean water to great heights along coastal areas. Great depth of clouds and torrential rain normally occur over a fairly wide area about the storm center. Rainfall locally amounts to as much as 40–50"; a 20-in. rainfall during the passage of a single storm is common.

North American hurricanes originate near the equator over the Atlantic, the Caribbean, or Gulf of Mexico. From the point of origin they move in a westerly direction for several days, then begin to curve northward. After they pass the 30th latitude north, they usually assume a path somewhat east of north and begin to accelerate considerably. Hurricane season is that period from June to November but an occasional one may occur out of season. (P.E.K.)

HUTIA. Mammalia, Rodentia. Large arboreal **rodents** of the West Indies. They resemble rats but have a blunt muzzle and a moderately long tail. Related to the coypu. (A.W.L.)

HUYGENS' PRINCIPLE. A well-known method of analysis applied to problems of wave propagation. It recognizes that each point of an advancing wave front is in fact the center of a fresh disturbance, and the source of a new train of waves; and that the advancing wave as a whole may be regarded as the resultant of the secondary waves arising from points in the medium already traversed. This view of wave propagation facilitates the study of various phenomena, such as **diffraction.** For example, if two rooms are connected by an open doorway, and sounds are produced in a remote corner of one room, a person in any part of the other will hear the sounds as proceeding from the doorway, which is indeed the case. So far as the second room is concerned, the vibrating air in the doorway is the source, and from it sound waves enlarge in all directions through the second room. The same is true of light reaching a slit or passing the edge of an obstacle, though this is not quite so easily observed because of the short wavelength. The **interference** of light from variously distant areas of the moving wave front accounts for the maxima and minima observable as diffraction fringes. (L.D.W.)

HYACINTH. Lily Family; Zircon.

HYADES. The Hyades is an open V-shaped cluster of stars in the **constellation** of **Taurus.** References to this group are to be found in all of the ancient literatures, Virgil referring to them as the "rainy Hyades." The group is exceedingly rich in **double stars,** and even with a small telescope and low **magnifying power,** they present a beautiful appearance.

The Hyades form one of the best known of the so-called moving star **clusters.** The brightest star of the Hyades, **Aldebaran,** is not a member of the cluster, but has an independent motion through space and just happens to be in its present position at this time. (W.K.G.)

HYALITE. **Opal.**

HYBRID. An organism produced by parents belonging to different species or to different strains of the same species. A hybrid combines characteristics derived from the two parent stocks and in some cases is more desirable than either. Beauty of flowers, productivity of various plants, and appearance and hardiness of animals have been enhanced by controlled **hybridization.**

When a hybrid is once secured its propagation is hampered by the fact that the diverse hereditary characters are reassorted in hereditary transmission by sexual reproduction. Hybrids are often infertile but even when they are capable of producing offspring they rarely breed true. The **mule** is the only animal hybrid of great value and it is produced always by parents of the two species, horse and ass. Plant hybrids are not subject to this limitation for they can usually be propagated by **bulbs, cuttings,** or **grafts.** (A.W.L.)

HYBRID COIL. The bridging transformer used in coupling a two-way telephone circuit to the repeater station or for coupling two one-way circuits to a two-way circuit. The coil is so wound that when the line is properly balanced by a balancing network there is no reaction between the output and input connections of the transformer. (See **Telephony.**) (L.R.Q.)

HYBRIDIZATION. The cross breeding of different strains or species of organisms. The crossing of species is interspecific hybridization and the interbreeding of strains of the same species is intraspecific. Since the differences between species are greater than variation within a species, intraspecific hybridization is rarely impossible but crosses between species are usually possible only if the species are closely related.

The difficulty of making an interspecific cross is sometimes due to anatomical differences or mental reactions which prevent mating and sometimes to the failure of **germ cells** of the two species to unite normally in **fertilization.** If neither of these obstacles prevents, a hybrid individual results. Usually it shows some of the characteristics of each parent species. A familiar example is the mule. Crosses of this kind sometimes occur between closely related species in nature but most of the recorded examples have been produced under experimental conditions.

Intraspecific crosses between breeds of animals and varieties of plants are constantly being carried out by animal and plant breeders for the production of new forms. Among plants especially, the new varieties offered each year are usually produced in this way. (A.W.L.)

HYDATID. The bladder worm or cysticercus of a species of **tapeworm,** *Echinococcus granulosus,* which forms a large fluid-filled cyst in the liver or other organs of the hoofed animals and man. It may grow to a diameter of 6″ and contains many scolices. The adult lives in the dog. (A.W.L.)

HYDATOGENESIS. A term used by **petrologists** to designate the process by which rocks are formed from highly aqueous solutions. Some petrologists limit the use of the term to rocks which have been deposited from water-rich **magmatic** solutions. (R.M.F.)

HYDNOCERAS. **Invertebrate Paleontology.**

HYDRANTH. A form of individual which receives and digests food in colonies of **hydrozoan** coelenterates. It is a **polyp** attached to the remainder of the colony at its base and with a mouth surrounded by a circlet of tentacles at the free end. (A.W.L.)

HYDRARGYRUM. **Mercury.**

HYDRARIAE. **Hydrozoa.**

HYDRASTINE. **Alkaloids.**

HYDRASTININE. **Alkaloids.**

HYDRATES. **Water.**

HYDRATUBA. The attached form, resembling a polyp, which develops from the first larval stage of some **jellyfishes.** It may bud off other similar individuals and at certain seasons is subdivided by constrictions to form **ephyrae** which become jellyfishes. (A.W.L.)

HYDRAULIC FILL. An embankment or other fill in which the materials are deposited in place by a flowing stream of water, with the deposition being selective, is termed hydraulic fill. Gravity, coupled with velocity control, is used to effect the selected deposition of the material.

Where **borrow pits** containing suitable material are accessible at an elevation such that, after being washed from the bank by a powerful stream from a large, high-pressure **nozzle,** the earth can be sluiced to the fill, hydraulic fill is likely to be the most economical construction. Even where the elevation is not realized, the material can be washed into pools, then elevated to the **sluice** with a dredge pump. In the construction of a hydraulic fill **dam,** the edges of the dam are defined by low embankments or dykes which are carried upwards as the fill proceeds. The sluices are carried parallel to and just inside these dykes. The sluices discharge their water-earth mixture at intervals, the water then fanning out and flowing towards the central pool which is maintained at the desired level by discharge control. While flowing from the sluices, the coarse material is first deposited, then, as the central pool is reached, the water velocity is diminished and the fine materials are deposited to form an impervious central section. The water flow must be well controlled at all times, otherwise the central section may be bridged by tongues of coarse material which would allow the water a free passage through the dam. (F.T.M.)

HYDRAULIC FRICTION. **Fluid Friction.**

HYDRAULIC GRADE LINE. **Hydrokinetics.**

HYDRAULIC MACHINE TOOLS. Hydraulically actuated machine tools are coming into extensive use in the metal-working industry. They offer great flexibility of speed and feed control, elimination of shock, and possess the ability to stall against obstruction, thus protecting parts or tools from breakage. Hydraulic actuation also permits slip, or slowing-up motion, when the cutting tool is overloaded If a hydraulic drive were used to actuate the carriage of a lathe, accurate thread cutting would not be possible because the slip would not be compensated for at the end of the movement. In mechanically actuated feeding mechanisms, any slip that may result from slight deformations of the mechanism must be made up, and may therefore result in an increased rate of motion during some portion of the total movement.

One form of hydraulic circuit employs a constant-delivery pump which may move the piston at a rate corresponding to only a fraction of the displacement of the pump. The excess displacement escapes through a relief valve in the feed line into the oil reservoir. The rate of motion of the piston is therefore controlled by the setting of the relief valve.

Another form of hydraulic circuit receives its energy from the displacement of a variable-delivery pump, where the piston speed is changed by varying the amount of liquid delivered by the pump. Hydraulic circuits for intermittent or varying rates of feed and for rapid tra-

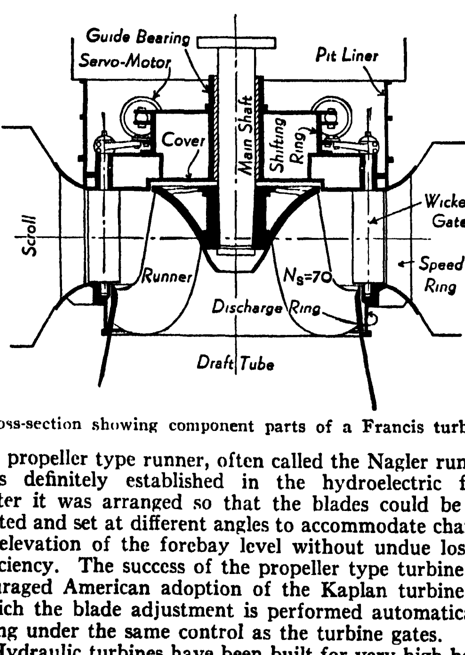
versing motions in combination with feeding motion are in extensive use on various types of machine tools. Two or more cylinders, with varying rates of motion, may be driven from the same pump by proper application of valves and control equipment. Rotary motion may be obtained by using a rotary hydraulic motor instead of a feed cylinder. (H.C.H.)

HYDRAULIC PRESS. Hydrostatics; Press Working.

HYDRAULIC RADIUS. The theory of **hydraulics** indicates that the ratio of the frictional area to the volume of the fluid stream is an important dimension governing the friction loss. The hydraulic radius, which expresses this fact, is the cross-sectional area of flow divided by the wetted perimeter of a cross-section of the **conduit.** The hydraulic radius of a circular pipe flowing full of water is one-fourth of the diameter. The hydraulic radius of an open canal is the cross-sectional area of the stream divided by the wetted perimeter of the cross-section excluding the length in contact with the air. (F.T.M.)

HYDRAULIC TURBINE. The fundamentals of the turbine were incorporated into the wheels built before the turn of the nineteenth century, but its principal development has occurred since that time. Beginning with Fourenyon and his outward flow turbine, Jonval, Boyden, Swain, and Francis rapidly brought the reaction turbine to an advanced stage of development. By 1875 the inward flow turbine, as perfected by Francis, and which now bears his name, had established itself in the lead, a position which it maintained until about 1900 when the impulse, or Pelton, type of wheel had progressed to the point of dominating the high head field.

The inherent slow speed of the Francis type runner on low heads was a fault that the propeller type runner was designed to cure. During the decade 1910-1920 progress was made with this type of wheel and by 1920



Cross-section showing component parts of a Francis turbine.

the propeller type runner, often called the Nagler runner, was definitely established in the hydroelectric field. Later it was arranged so that the blades could be adjusted and set at different angles to accommodate changes in elevation of the forebay level without undue loss of efficiency. The success of the propeller type turbine encouraged American adoption of the Kaplan turbine, on which the blade adjustment is performed automatically, being under the same control as the turbine gates.

Hydraulic turbines have been built for very high heads as well as large capacities. Heads as high as 5000′ have been utilized (3000′ in the U. S.) and runners have been constructed to develop as much as 70,000 hp. At present though, a 30,000-hp. turbine is a large one, and ordinary sizes range from 1000 to 10,000 hp.

As between impulse and reaction types, the action in the impulse turbine is easiest to understand. There is no difficulty in visualizing the transformation of pressure head into velocity head at the nozzle, nor of understanding the push, or impulse, that is given to the buckets by the stream of water. The jet is directed upon the rotor tangentially, and hence this type is also called the tangential turbine. The velocity of the jet of water is only slightly less than the free spouting velocity under the effective head h. Impulse buckets are divided into two halves by a "splitter" and the axial thrusts which would otherwise have to be borne by special bearings are equalized.

The essential difference between the impulse and reaction types is that, in the former the entire energy received by the wheel is in the velocity form, while in the latter it may be partially in the velocity form, but is also, in a large measure, still in the pressure form. The reaction of conversion of residual pressure into velocity in the runner is the source of much of the torque delivered to the reaction turbine. If the turbine were blocked stationary and had its gates opened, the water would issue from the turbine as from a nozzle. Now, by removing the blocking, let these nozzles begin to rotate and the absolute velocity of water leaving them is found to be diminishing, the energy having been absorbed by the runner. At the best speed the final velocity will be just sufficient to enable the water to clear the runner. At this time the wheel may be absorbing from 90–95% of the energy that the water had in the pressure form just before reaching the turbine gates.

In a Francis turbine the water flows inward, then downward and into the draft tube.

The various types of hydraulic turbines are classified according to the kind of runner each employs. This is logical because the runner is the most important part of the turbine. Turbine runners are made of bronze, plate steel, cast steel, and cast iron.

The Pelton wheel is either a solid or open disk, to the rim of which are attached buckets upon which a jet of water is played from a stationary nozzle. A horizontal shaft is the usual arrangement but vertical shaft units have also been put into operation. The advantage of using the vertical arrangement is that more than one jet can be played on the buckets; this is obtained, however, at the expense of some loss of efficiency. The Pelton wheel is overhung on the bearing and often, for additional capacity, two wheels are overhung on the same generator. Variable power demand is met by decreasing the amount of water in the jet, by deflecting the jet from the buckets, or both. Some turbines of this type have a relief jet which opens as the main jet closes. Afterwards, a **dash pot** slowly closes the relief jet—slowly enough to prevent a large pressure rise in the penstock. The same thing is also accomplished by deflecting the jet from the wheel upon loss of load, then slowly closing the valve controlling the jet.

The Francis turbine is rarely a horizontal shaft machine, except in small sizes and where it is desired to avoid the expense of excavation for a vertical setting. The standard runner consists of two crowns between which the buckets or blades are placed. It is best adapted to vertical setting. In order to pass the large discharges possible in a high **specific speed** wheel, the buckets are curved downward. Some axial flow action is present in runners of high specific speed. Water is admitted to the runner through guide vanes and gates.

Loss of efficiency at part load is sometimes a serious fault as, for instance, where only one or two units are installed in an isolated plant. The feature of the Kaplan turbine is that the blade angles and gates are adjusted simultaneously by the governor mechanism so that the blades are always in the position best suited for full utilization of the flow, through the reduction of eddying and shock losses. The result is that the efficiency at part load holds up remarkably well.

Conveying the water from the **penstock** and directing the proper amount of it correctly against the runner requires first, a scroll case; second, a speed ring; and third, turbine gates.

The scroll case for medium and high head development is circular in form. In plan, it leads from the penstock and wraps, in spiral form, around the speed ring. The cross-section of the spiral at any point should be such that the water flows with uniform velocity. This leads to the spiral form because the water is being delivered to the turbine uniformly around the entire circumference.

The speed ring is that part of the turbine which joins the discharge ring with the turbine cover and pit liner. The ribs between the top and bottom portions must be strong enough to support the dead weight above the casing, consisting of concrete, generator, and turbine rotative parts; hence the speed ring is a very important part of the turbine.

Inside the speed ring and rigidly bolted to it is the inlet gate mechanism. The mechanism is operated by the governor which, by opening or closing the gates, can maintain a control of speed under variable load. Gates are of the guide vane type and, while various types of gates have been used, the wicket gate is in general use at the present time. Its principal advantage is its efficiency. Shock losses at part gate opening are reduced to a minimum in the wicket gate. It is not particularly tight and has many wearing parts, most of which are bronze bushed and grease lubricated. (F.T.M.)

HYDRAULICS. Hydraulics is the dynamics of liquids (hydrodynamics), especially applied to the practical problems of engineering. Although this general definition is entirely correct, in common usage hydraulics is the study of water at rest or in motion. This conception of hydraulics is used in this article. A basic proposition of hydraulics is that water is incompressible. While this condition is not completely met in fact, the compressibility of water is so small as to be negligible for practically all propositions of hydraulics. The viscosity of water varies with the temperature and is one reason for change of conditions of water flow in pipes with changing temperature. The unit weight of fresh water is usually taken as 62.4 lbs. per cu. ft.

The science of hydraulics is divisible into **hydrostatics** and **hydrokinetics.** Hydrostatics is the hydrodynamics of liquids considered apart from their motion: hydrokinetics is the hydrodynamics of moving, especially flowing liquids. Among the subjects included in any study of hydrostatics are the following: (1) the pressure on a submerged area of any shape or inclination, (2) the measurement of pressure on water at rest by manometers or pressure gauges, (3) buoyancy and flotation. Practical application of (1) is to be found in problems associated with water gates, large valves, pressure against dams, tanks, hydraulic presses, etc.

Hydrokinetics includes a great many different phases of hydraulics. Most of these will be found treated in specialized articles, references to which are given below. The flow of fluids supplies many cases of the application of hydraulic science. Flows of steady, uniform, unsteady and non-uniform types, and the friction losses occasioned thereby, in closed or open conduits; the measurement of flows and the discharges under given conditions, are part of this phase of hydraulics; also, there is to be considered the flow of water through openings, such as **orifices, nozzles,** and **weirs.** The flow of water in pipe lines offers a great many problems in addition to friction: the discharge through different sections of branching and looping pipes, siphons, fittings, valves, etc., is included. Measurement of discharge of large amounts of water, as in stream and river flow, offers problems different from those met in closed conduits. Furthermore, the forces occasioned by deviated flows of water, as met in hydraulic turbines, the pump, and other hydraulic machinery, are fit subjects to be included in any study of hydromechanics. (See **Fluid Flow, Fluid Friction, Dams, Hydrostatics, Hydrokinetics, Flow Meter, Orifice, Weir, Hydraulic Turbine, Head.**) (F.T.M.)

HYDRAZINES, HYDRAZONES AND OSAZONES. Hydrazine ($H_2N \cdot NH_2$) is a colorless, fuming liquid, melting point 1° C., boiling point 113° C, when heated to about 350° C. decomposes into **nitrogen** and

TABLE SHOWING OTHER HYDRAZINES

Other Hydrazines	Formula	Melting Point, °C.	Boiling Point, °C.
10. Ethylhydrazine	$C_2H_5NHNH_2$		100 (710 mm.)
11. Diethylhydrazine	$(C_2H_5)_2NNH_2$		97
12. 1,2-Diethylhydrazine	$C_2H_5NH\cdot NHC_2H_5$		
13. 1,1-Ethylphenylhydrazine	$\begin{matrix}C_2H_5\\C_6H_5\end{matrix}\!\!>NNH_2$		237
14. 1,2-Ethylphenylhydrazine	$C_2H_5NH\cdot NHC_6H_5$		237–240
15. Benzylhydrazine	$C_6H_5CH_2NHNH_2$	26	135 (30 mm.)

ammonia, burns when ignited in air with violet-colored flame, forms hydrate with water ($H_2N\cdot NH_2\cdot H_2O$), which hydrate yields hydrazine and water in a vacuum or upon heating moderately, and at about 180° C. nitrogen and ammonia. Hydrazine is a base, slightly weaker than **ammonium** hydroxide, and forms two series of salts (1) hydrazine monohydrochloride ($H_2N\cdot NH_2\cdot HCl$), mononitrate ($H_2N\cdot NH_2\cdot HNO_3$), hemisulfate ($H_2N\cdot NH_2\cdot \frac{1}{2}H_2SO_4$), (2) hydrazine dihydrochloride ($H_2N\cdot NH_2\cdot 2HCl$), dinitrate ($H_2N\cdot NH_2\cdot 2HNO_3$), monosulfate ($H_2N\cdot NH_2\cdot H_2SO_4$), all soluble in water except the last. Hydrazine azide ($H_2N\cdot NH_2\cdot HN_3$) is a soluble solid, melting point 65° C. Hydrazine hydrate attacks glass, rubber, cork, and therefore silver vessels are preferred in its manipulation.

Hydrazine may be made by converting one-half of a given amount of ammonia into chloramine (NH_2Cl) by sodium **hypochlorite** solution in the presence of a **colloid** such as glue or gelatin, by heating. The remaining one-half of ammonia reacts with chloramine to form hydrazine. The product is then cooled to 0° C. and **sulfuric acid** added in amount to react with the hydrazine to form hydrazine monosulfate ($H_2N\cdot NH_2\cdot H_2SO_4$), insoluble solid, melting point 254° C. ($H_2N\cdot NH_2\cdot \frac{1}{2}H_2SO_4$ is soluble in water).

Hydrazine is a powerful reducing agent, for example, cupric salt solutions changed to **cuprous** chloride (in HCl) or to copper (in NaOH), silver salt solutions to **silver,** mercuric salt solutions to **mercury, sulfur trioxide** to sulfur sesquioxide (S_2O_3), and may be determined by titration with potassium permanganate solution.

Phenylhydrazine is a colorless liquid, slightly soluble in water, miscible in all proportions with alcohol or ether, forms salts with acids, e.g., phenylhydrazine hydrochloride ($C_6H_5NH\cdot NH_2\cdot HCl$), melting point 241° C. appr., is a powerful reducing agent, with alkaline **cupric** salt solution (Fehling's solution) yields cuprous oxide precipitate, reacts with carbonyl group (=CO) of **aldehydes** or **ketones** yielding phenylhydrazones, white solids, of definite melting point and utilized in identification of aldehydes and ketones, e.g., acetaldehyde phenylhydrazone ($CH_3CH{:}NNHC_6H_5$).

Phenylhydrazone of	Melting Point, °C.	Boiling Point, °C.
Acetaldehyde	99	236 (20 mm.)
Acetone	27	163 (50 mm.)
Acetophenone	105	
Benzaldehyde	155	
Benzophenone	137	
Benzoin, alpha	156 appr.	
Benzoin, beta	106	
Cinnamaldehyde	168	
Cyclohexanone	77	
Glyoxal	180	
Salicylaldehyde	142	
d-Glucose, alpha	159	
d-Glucose, beta	140	
1-Arabinose	152	

Phenylhydrazines, as hydrochloride solution plus **sodium** acetate react with polyhydroxy aldehydes or ketones yielding osazones or diphenylhydrazones, yellow solids, of definite melting point and utilized in identification of sugars, e.g., phenyl-d-glucosazone ($CH_2OH(CHOH)_3C{:}(NNHC_6H_5)CH{:}(NNHC_6H_5)$) plus aniline ($C_6H_5NH_2$) plus ammonia. Glucose and fructose yield identical osazones, melting point 205° C. decom. The specific rotatory power of the osazone is also an important consideration.

Osazone of	Melting Point, °C.
Glucose	205
Fructose	205
Mannose	205
Galactose	214
Maltose	205
Lactose	200
Arabinose	107
Xylose	115–158
Sucrose (none)	
Raffinose (none)	

Attention should be directed to the difference between osazones and osones. An osone is formed by reaction of an osazone with hydrochloric acid, e.g., glucosone ($CH_2OH(CHOH)_3CO\cdot CHO$).

Phenylhydrazine is made by reduction of benzene diazonium chloride ($C_6H_5N_2Cl$) by **stannous** chloride ($SnCl_2$) plus **hydrochloric acid,** the **diazonium** chloride being formed by reaction of **aniline** and **nitrous acid** cold.

1,1-Diphenylhydrazine is a white solid, slightly soluble in water, soluble in alcohol or ether, forms salts with acids, is a reducing agent, reacts with aldehydes or ketones yielding 1,1-diphenylhydrazones, and with polyhydroxy aldehydes or ketones yielding osazones, of definite melting point. 1,1-Diphenylhydrazine is made by reduction of diphenylnitrosamine ($(C_6H_5)_2N\cdot NO$) by zinc plus acetic acid, the nitrosamine being formed by reaction of diphenylamine ($(C_6H_5)_2NH$) and nitrous acid.

1,2-Diphenylhydrazine (hydrazobenzene) is a white to pale yellow solid, very slightly soluble in water, soluble in alcohol or ether, upon standing or upon heating changes into azobenzene, red to orange, solid, melting point 68° C., the hydrogens of the amino groups (=NH) are replaceable by acetyl (CH_3CO—) or nitroso (NO—) groups as for secondary **amines.** 1,2-Diphenylhydrazine reacts (1) with oxidizing agents, e.g., **ferric** chloride or air to form azobenzene, (2) with strong reducing agents, e.g., **sodium** amalgam, to form aniline, (3) with strong acids, to form **benzidine** hydrochloride ($(4')H_2N\cdot C_6H_4\cdot C_6H_4\cdot NH_2(4)\cdot HCl$). 1,2-Diphenylhydrazine is formed by reduction of **nitrobenzene** by **zinc** plus **sodium** hydroxide solution.

Tetraphenylhydrazine is a white solid, soluble in chloroform, acetone, benzene, or toluene, and upon standing is changed into triphenylamine plus azobenzene. In solution, tetraphenylhydrazine dissociates into nitrogen **diphenyl** ($(C_6H_5)_2N\cdot$), free **radical**, which in toluene at 90° C. reacts with **nitric** oxide (NO). Tetraphenylhydrazine is formed by oxidation of diphenylamine ($(C_6H_5)_2NH$) by lead dioxide. (R.K.S.)

HYDRAZOATES. **Hydrazoic Acid and Azides.**

HYDRAZO-COMPOUNDS. **Aniline and Azo-, Diazo-, and Related Compounds; Hydrazines.**

HYDRAZOIC ACID AND AZIDES. Hydrazoic acid (HN_3) is a colorless, odorous, poisonous liquid, boiling point 37° C., soluble in water, volatile in steam, made anhydrous by removal of water from 91% hydrazoic acid by **calcium** chloride, explosive. Hydrazoic acid reacts (1) **with** metals, e.g., magnesium, aluminum, zinc, iron, to form azides or hydrazoates (or trinitrides), (2) with heavy metal salt solutions to form insoluble azides, e.g., silver azide (AgN_3), mercurous azide (HgN_3), lead azide (PbN_6). Silver, mercurous, **cuprous** azides decompose in the light to form nitrogen gas plus the metal. Lead azide is used as a detonator for the **explosive** trinitrotoluene (T.N.T.), (3) with **ammonium** hydroxide, to form ammonium azide ($NH_4\cdot N_3$), (4) with **hydrazine,** to form hydrazine azide ($N_2H_4\cdot HN_3$), (5) with **sodium** hypochlorite plus **acetic acid,** to form chlorazide (ClN_3), explosive, (6) with sodium amalgam (sodium dissolved in mercury), to form **ammonia** mainly (and some hydrazine), (7) with **potassium** permanganate, to form **nitrogen** gas plus water.

Hydrazoic acid is formed (1) by reaction of ethyl or amyl **nitrite** in sodium hydroxide solution (sodium azide formed), then acidifying with dilute **sulfuric acid** and distilling. Hydrazoic acid is recovered mainly in the early portion of the condensate, (2) by reaction of ammonia gas and sodium metal heated to about 300° C. (sodamide formed), and then treating the residue with dry nitrous oxide gas at about 200° C. The product is dissolved in water, then acidified and distilled as above.

The azide group ($—N_3$) resembles the halogen groups (—Cl, —Br, —I) in several reactions, and in the properties of several compounds.

Soluble azides react with **ferric** salt solutions to produce a red color, similar to that of ferric **thiocyanate.** Sodium azide is not explosive, even on percussion, and nitrogen may be evolved upon heating. With **iodine** dissolved in ether cold, silver azide forms iodine azide (IN_3), yellow explosive solid.

Ester: methyl azide (CH_3N_3), boiling point 20° C., explosive when heated to about 500° C. (R.K.S.)

HYDRAZONES. **Hydrazines, Hydrozones, and Osazones; Azo-, Diazo-, and Related Compounds.**

HYDRIDES. Hydrides are binary compounds of **hydrogen** and some other element. Sodium hydride (NaH) and calcium hydride (CaH_2) react with water to yield hydrogen gas and the respective hydroxides. When lithium hydride (LiH) is electrolyzed hydrogen is evolved at the *anode* (hydrogen in this case an anion) and lithium metal at the cathode. (R.K.S.)

HYDRIODIC ACID AND IODIDES. Hydriodic acid (HI) is a colorless solution formed when hydrogen iodide gas is dissolved in water, commercially of strength 10% HI, frequently colored brown by **iodine.** There is a maximum constant boiling point 127° C. (774 mm.) at 57% HI (distillate) for mixtures of hydriodic acid and water. Hydriodic acid is used in the preparation of iodides, and as an important reagent in organic chemistry.

All metallic iodides except **silver** iodide, **mercurous** iodide, mercuric iodide, **lead** iodide, **cuprous** iodide, **thallium** iodide, and **palladium** iodide, are soluble. The iodides of **antimony, bismuth, tin** require a little free acid to keep them in solution.

Dilute hydriodic acid reacts with hydroxides, oxides, carbonates, sulfides, metals in a manner chemically analogous to dilute **hydrochloric acid;** with solutions of some salts, e.g., silver nitrate, to yield the corresponding iodide, e.g., silver iodide, precipitate. Higher strengths of hydriodic acid react with oxygen of the air upon standing to yield free iodine, which imparts a brown color to the solution, thus indicating the reducing character of the acid.

Hydriodic acid is made by the reaction (1) of iodine and **hydrosulfuric acid** (or **sulfurous acid**), (2) of **phosphorus** plus iodine plus water, with subsequent distillation in all cases.

Two common tests for iodides are as follows:

1. Silver nitrate produces a yellow precipitate insoluble in **nitric acid,** slightly soluble in **ammonia** and soluble in **potassium** cyanide and in **sodium** thiosulfate.
2. On treatment with **chlorine** water and shaking with **carbon disulfide** a violet color due to free iodine is produced in the carbon disulfide layer. (R.K.S.)

HYDROBIOLOGY. **Limnology.**

HYDROBROMIC ACID AND BROMIDES. Hydrobromic acid (HBr) is a colorless solution formed when hydrogen bromide gas is dissolved in water, commercially of strength 48% HBr. Sometimes colored yellow to red by **bromine.** There is a maximum constant boiling point 126° C. (760 mm.) at 48% HBr (distillate) for mixtures of hydrobromic acid and water. Hydrobromic acid is used in the preparation of bromides, and as an important reagent in organic chemistry.

Dilute hydrobromic acid reacts with hydroxides, oxides, carbonates, sulfides, metals in a manner chemically analogous to dilute **hydrochloric acid;** with solutions of some salts, e.g., silver nitrate, to yield the corresponding bromide, e.g., **silver** bromide, precipitate Higher strengths of hydrobromic acid react with oxygen of the air upon standing to yield free bromine, which imparts a yellow to red color to the solution, thus indicating the reducing character of the acid.

Hydrobromic acid is made by the reaction (1) of **phosphorus** tribromide and water, (2) of bromine and **sulfurous acid** (or hydrosulfuric acid), with subsequent distillation in all cases.

Metallic bromides except silver bromide and mercurous bromide are soluble in water, but **lead** bromide, **cuprous bromide** and thallium bromide are only slightly soluble.

Two common tests for bromides are as follows:

1. Silver nitrate produces a yellow precipitate insoluble in nitric acid and soluble in **ammonia,** in **potassium** cyanide, and in **sodium** thiosulfate.
2. On treatment with **chlorine** water and shaking with **carbon disulfide** a brown coloration due to free bromine appears in the carbon disulfide layer. (R.K.S.)

HYDROCARBONS. Hydrocarbons are compounds of **carbon** and **hydrogen** only. (See **Gasoline, Lubrication, Petroleum Products.**) Hydrocarbons possess, as a whole, a considerable range of properties. This is illustrated by the following selections:

SELECTED REPRESENTATIVE HYDROCARBONS

Hydrocarbon	Physical State	Density	Melting Point, °C.	Boiling Point, °C.	Solubility in		
					Water	Alcohol	Ether
1. Methane	Gas	Air = 1.00 0.56	−184	−161	Slight	Solub.	Solub.
2. Ethane	Gas	1.36	−172	−88	Slight	Solub.	Solub.
3. Ethylene	Gas	0.98	−169	−104	Mod. Slight	Solub.	Solub.
4. Acetylene	Gas	0.91	−82	−84	Very Slight	Solub.	Solub.
5. Normal-hexane	Liquid	Water = 1.000 0.661	−94	69	Insol.	Solub.	Infin.
6. Cyclohexane	Liquid	0.779	6.5	81	Insol.	Infin.	Infin.
7. Benzene	Liquid	0.878	5.5	79.6	Insol.	Infin.	Infin.
8. Toluene	Liquid	0.866	−95	110.5	Insol.	Infin.	Infin.
9. Cymene	Liquid	0.857	−73.5	176	Insol.	Solub.	Solub.
10. Limonene	Liquid	0.842	−97	177	Insol.	Infin.	Infin.
11. Pinene	Liquid	0.878	−55	154	Very Slight	Infin.	Infin.
12. Biphenyl	Solid	1.041	69	255	Insol.	Mod. Solub.	Solub.
13. Diphenylmethane	Solid	1.006	27	262	Very Slight	Solub.	Solub.
14. Naphthalene	Solid	1.145	80	218	Insol.	Slight	Solub.
15. Anthracene	Solid	1.25	218	342	Insol.	Insol.	Very Slight

These particular hydrocarbons (in the foregoing table) are characterized as to:

1. Density: The four gases, from 0.56 (methane) to 1.36 (ethane) (air = 1.00) and other hydrocarbon gases above 1.36, e.g., normal-butane 2.05.
   The seven liquids, from 0.661 (normal-hexane) to 0.878 (benzene; pinene) (water = 1.000).
   The four solids from 1.006 (diphenylmethane) to 1 25 (anthracene) (water = 1.000).
2. Melting point: From −184° (methane) to 218° C. (anthracene).
3. Boiling point: From −161° (methane) to 342° C. (anthracene).
4. Solubility in water: Practically insoluble, except ethylene.
5. Solubility in alcohol: Soluble, except naphthalene, anthracene.
6. Solubility in ether: Soluble, except anthracene.

Further remarks on solubility: In **acetone, acetylene** is very soluble. In **chloroform,** cymene is very soluble. Other solvents of note are **carbon tetrachloride, carbon disulfide.** Hydrocarbons, speaking generally, are soluble in each other.

BEHAVIOR ON TREATMENT WITH BROMINE (IN CCl_4)

Hydrocarbon	No Gas Evolved But Red Color Disappears	Hydrogen Bromide Evolved and Red Color Disappears (White Fog When Breathed Upon)	No Change
1. Methane			√
2. Ethane			√
3. Ethylene	√		
4. Acetylene	√		
5. Normal-hexane			√
6. Cyclohexane			√
7. Benzene		√	
8. Toluene		√	
9. Cymene		√	
10. Limonene	√		
11. Pinene	√		
12. Biphenyl		√	
13. Diphenylmethane		√	
14. Naphthalene		√	
15. Anthracene		√	

In general, on treatment with **bromine in carbon tetrachloride,** and warming:

1. Unsaturated hydrocarbons cause disappearance of the red color and no gas evolved. Reaction is addition, e.g., ethylene forms ethylene dibromide, acetylene forms acetylene tetrabromide.
2. Benzenoid hydrocarbons cause disappearance of the red color and white fog, when breathed upon, of **hydrogen bromide.** Reaction is substitution—bromination, e.g., toluene forms chlorotoluene (ortho or para, or both).
3. Saturated hydrocarbons, chain or cyclic, cause no change, e.g, normal-hexane, cyclohexane.
4. Chlorine behaves similarly to bromine.

BEHAVIOR ON TREATMENT WITH FUMING SULFURIC ACID (AT ROOM TEMPERATURE)

Hydrocarbon	Soluble, Heat Evolved	No Change
1. Methane		√
2. Ethane		√
3. Ethylene	√	
4. Acetylene	√	
5. Normal-hexane		√
6. Cyclohexane		√
7. Benzene	√	
8. Toluene	√	
9. Cymene	√	
10. Limonene	√	
11. Pinene	√	
12. Biphenyl	√	
13. Diphenylmethane	√	
14. Naphthalene	√	
15. Anthracene	√	

With **sulfuric acid** fuming:

1. Unsaturated hydrocarbons react. Reaction is addition, e.g., **ethylene** forms **ethyl hydrogen sulfate**; or reaction is **polymerization,** e.g., pinene.
2. Benzenoid hydrocarbons react. Reaction is substitution—sulfonation, e.g., **naphthalene** forms naph-

thalene sulfonic acid (alpha or beta, or both, or disulfonic acid).

3. Saturated hydrocarbons, chain or cyclic, cause no change, e.g., normal-hexane, cyclohexane.

stitution—nitration, e.g., toluene forms nitrotoluene (mono-, 1,2 or 1,4; or di- 1,2,4 or 1,2,6; or tri- 1,2,4,6); **oxidation** frequently occurs, e.g., **anthracene** forms anthraquinone.

BEHAVIOR ON TREATMENT WITH FUMING NITRIC ACID (AT ROOM TEMPERATURE)

Hydrocarbon	Soluble, Heat Evolved	No Change
1. Methane		√
2. Ethane		√
3. Ethylene	√	
4. Acetylene	√	
5. Normal-hexane		√
6. Cyclohexane		√
7. Benzene	√	
8. Toluene	√	
9. Cymene	√	
10. Limonene	√	
11. Pinene	√	
12. Biphenyl	√	
13. Diphenylmethane	√	
14. Naphthalene	√	
15. Anthracene	√	

With **nitric acid** fuming:

1. Unsaturated hydrocarbons react. Reaction is addition, e.g., pinene and limonene to form nitrosites and nitrosates; cleavage frequently occurs at the unsaturated bond accompanied by violent reaction.
2. Benzenoid hydrocarbons react. Reaction is substitution—nitration, e.g., toluene forms nitrotoluene
3. Saturated hydrocarbons, chain or cyclic, cause no change, e.g., normal-hexane, cyclohexane; secondary and tertiary hydrocarbons moderately easily oxidized to **ketones** and tertiary **alcohols**, respectively.

The most important hydrocarbons are classified in accordance with their composition as follows:

CLASSIFICATION OF HYDROCARBONS

(Upon Basis of Composition)

Class	Examples	Individual Formula	Structural Formula	Class Formula
1. Paraffin	Methane	CH_4		C_nH_{2n+2}
	Ethane	C_2H_6	$H_3C \cdot CH_3$	
	Normal-hexane	C_6H_{14}	$CH_3(CH_2)_4CH_3$	
2. Cycloparaffin	Cyclohexane	C_6H_{12}		C_nH_{2n}
3. Olefin (one double bond)	Ethylene	C_2H_4		C_nH_{2n}
4. Cyclo-diolefin	Limonene	$C_{10}H_{16}$		C_nH_{2n-4}
5. Acetylene (one triple bond)	Acetylene	C_2H_2	HC . CH	C_nH_{2n-2}
6. Benzenoid	Benzene	C_6H_6		C_nH_{2n-6}
(a) one ring	Toluene	C_7H_8		
	Cymene	$C_{10}H_{14}$		
(b) two rings or more, not doubly adjacently interlocked	Biphenyl	$C_{12}H_{10}$		C_nH_{2n-14}
	Diphenyl methane	$C_{13}H_{12}$		
(c) two rings or more, doubly adjacently interlocked	Naphthalene	$C_{10}H_8$		C_nH_{2n-12}
	Anthracene	$C_{14}H_{10}$		C_nH_{2n-18}

The most fundamental classification on the basis of reactivity appears to be into benzenoid and non-benzenoid (and mixed, e.g., toluene, which in many reactions behaves as a benzenoid, but in some others as a non-benzenoid hydrocarbon.)

CLASSIFICATION OF HYDROCARBONS
(Upon Basis of Reactivity)

			Melting Point, °C.	Boiling Point, °C.
Paraffin Class				
1. Methane..	CH_4			−161
2. Ethane..	C_2H_6	$H_3C \cdot CH_3$		−88
3. Propane........ .. .	C_3H_8	$CH_3 \cdot CH_2 \cdot CH_3$		−45
4. Normal-butane....	C_4H_{10}	$CH_3(CH_2)_2CH_3$	−135	0.6
5. Iso-butane................ .. . (2-Methylpropane) (Trimethylmethane)	C_4H_{10}	$(CH_3)_3CH$	−145	-10
6. Normal-pentane.............	C_5H_{12}	$CH_3(CH_2)_3CH_3$		36
7. Tetramethylmethane....... . .. (2,2-Dimethylpropane)	C_5H_{12}	$(CH_3)_4C$		9.5
8. Normal-hexane..	C_6H_{14}	$CH_3(CH_2)_4CH_3$		69
9. Normal-heptane. . .	C_7H_{16}	$CH_3(CH_2)_5CH_3$		98
10. Normal-octane..	C_8H_{18}	$CH_3(CH_2)_6CH_3$		125
11. Normal-nonane.	C_9H_{20}	$CH_3(CH_2)_7CH_3$		150
12. Normal-decane.	$C_{10}H_{22}$	$CH_3(CH_2)_8CH_3$		174

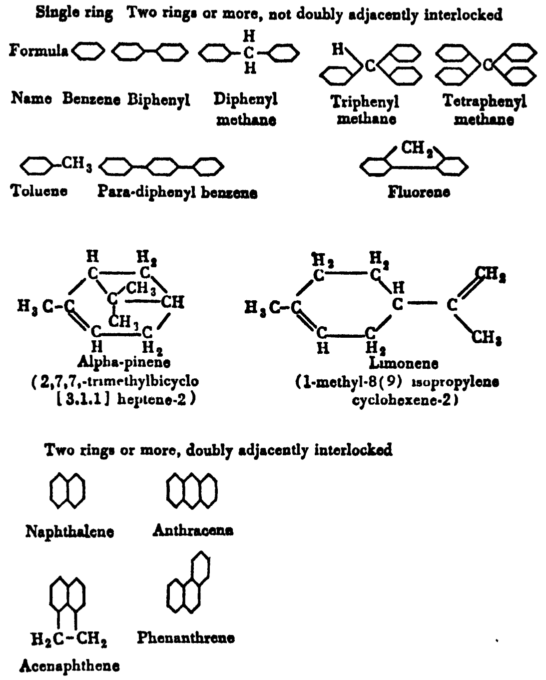
93. Carotene (yellow) (Dicyclic and olefin linkages)	$C_{40}H_{56}$			

Class of Hydrocarbons		Characteristics of the Carbon Linkages	
Paraffin	No ring	Saturated	All single linkages
Cycloparaffin	One closed ring	Saturated	All single linkages
Olefin	No ring	Unsaturated	One or more double linkage
Cycloölefin	One or more closed ring	Unsaturated	One or more double linkage
Acetylene	No ring	Unsaturated	One or more triple linkage
Benzenoid	One or more closed ring	Unsaturated	Oscillating double linkages in groups of three

In hydrocarbons of no ring, the chain of carbons may be single or branched, the limit of branching of the chain being two branch carbons to any one chain carbon.

Formula	$\begin{matrix}H & & H\\ & C & \\ H & & H\end{matrix}$	$\begin{matrix}H & & H\\ & C & \\ H & & CH_3\end{matrix}$	$\begin{matrix}H & & CH_3\\ & C & \\ H & & CH_3\end{matrix}$	$\begin{matrix}H & & CH_3\\ & C & \\ CH_3 & & CH_3\end{matrix}$	$\begin{matrix}CH_3 & & CH_3\\ & C & \\ CH_3 & & CH_3\end{matrix}$
Name	Methane	Methyl methane Ethane	Dimethyl methane Propane	Trimethyl methane	Tetramethyl methane
Boiling Point, °C.	−161	−88	−45	−10	9.5
Designation		Primary Normal	Secondary Iso	Tertiary	Quaternary

In hydrocarbons having more than one closed ring, the attachments may be of various types.



All hydrocarbons are combustible, and many of them have preferred uses as fuels, e.g., methane, ethylene, acetylene, paraffins, benzene, and as solvents, e.g., benzene, toluene, xylenes, paraffins, terpenes. These and others have special importance individually.

PARAFFIN HYDROCARBONS. Paraffin hydrocarbons are characterized in general by lack of marked chemical reactivity, and by having the lowest specific gravity of the liquid hydrocarbons (paraffin range about 0.62 to 0.77). Paraffin hydrocarbons occur in natural gas and petroleum, and are the predominant constituents in the hydrocarbon portion when coal is destructively distilled at low temperatures. By the fractional distillation of petroleum there is obtained a wide range of mixtures of paraffins, illustrated by the following table.

Distillate	Typical Yields by Distillation of Crude Petroleum from		
	Pennsylvania	Texas	California
Gasoline.......	28%	22%	22%
Naphtha.......	10	9	9
Kerosene	8	12	12
Gas or stove oil	7	42	42

From the remaining portion other distillates are obtained by further distillation at atmospheric pressure and by the use of vacuum.

By means of the comparatively recent perfection of processes, any type of petroleum oil, kerosene distillate, gas oil, fuel oil residue, or crude oil may be converted into gasoline with yields of 50% to 75%. These so-called cracking processes, which are of both thermal and catalytic types, result in the decomposition, upon heating under high pressure, without or with catalysts of the raw material into gases, gasoline distillate, and carbon.

Gasoline is a liquid hydrocarbon mixture obtained from three main sources: 1. Straight-run gasoline, by the fractional distillation of crude petroleum. 2. Cracked gasoline, by heat-pressure decomposition without or with catalysts of crude petroleum or any distillate fraction. 3. Natural gas or casing-head gasoline, by condensation under pressure or by absorption of the liquefiable constituents of natural gas. The production of each in the United States is of the order of 55%, 35%, 10%, respectively, and the percentage of cracked gasoline shows rapid increase, with accompanying economy in the utilization of crude petroleum for gasoline production.

Federal Specification for United States Government Lubricating Oil, class D, for Internal Combustion Engines other than Aircraft and Diesel.

Viscosity. A.S.T.M.*[2] method D88–30. The Saybolt universal viscosities of the six grades (S A.E.*[3] numbers 20 to 70) shall lie within the limits:

S.A.E.*[3] Number	Seconds at 130° F. Not Less Than	Seconds at 130° F. Less Than	Seconds at 210° F. Not Less Than	Seconds at 210° F. Less Than
20	120	185		
30	185	255		
40	255	...	...	75
50	...	...	75	105
60	...	...	105	125
70	...	. .	125	150

Flash point. F.S.B.*[1] method 110.32. The flash point shall not be lower than the minimum for each grade:

S.A.E.*[3] Number	Flash Point Minimum for Passing
20	340° F.
30	350
40	370
50	395
60	425
70	460

Pour point. F.S.B.*[1] method 20.12. The pour point shall not be higher than 40° F. In the case of S.A.E.*[3] 20 and S.A.E.*[3] 30 oils, the Government reserves the right to require a pour point of not higher than 15° F., or under adverse climatic conditions, a pour point of not higher than 0° F.

Color. F.S.B.*[1] method 10.2. The color shall not be darker than the darkest for each grade:

S.A.E.*[3]	Darkest A S.T.M.*[2] Color Number
20	7.5
30	8
40	6 dil
50	7 dil
60	8 dil
70	8 dil

Carbon residue. A.S.T.M.*[2] method D189–30. The carbon residue shall not be higher than the maximum for each grade:

S.A.E.*[3]	Maximum A.S.T.M.*[2] Carbon Residue
20	0.60%
30	0.80
40	1.00
50	1.70
60	2.00

Oxidation number. F.S.B.*[1] method 340.1. The Sligh oxidation number shall not be higher than 50. The oxidation number is the number of milligrams of precipitate from 10.0 grams of oil after subjection to the specified treatment with oxygen.

Neutralization number. F.S B.*[1] method 510.31. The neutralization number shall not be higher than 0.30. The

*1 Federal Specifications Board.
*2 American Society for Testing Materials.
*3 Society of Automotive Engineers.

neutralization number is the number of milligrams of potassium hydroxide required for neutralization of 1 gram of oil.

Corrosion. F.S.B.*[1] method 530.31. A clean, freshly polished copper strip shall not show more than extremely slight discoloration when submerged in the oil for three hours at 212° F.

CYCLOPARAFFIN HYDROCARBONS. Cycloparaffin hydrocarbons are characterized in general by lack of marked chemical reactivity, and by moderately low **specific gravity** of the liquid hydrocarbons (cyclohexane 0.78). Cycloparaffins resemble paraffins, except that in the former the ratio of **carbon** to **hydrogen** is slightly less than in the latter, and there is one or more closed rings of carbon atoms in the former and none in the latter. Cycloparaffin hydrocarbons occur in certain petroleum fields, notably Baku, Russia. When the **calcium** salt of a higher dibasic **acid** in the oxalic acid series is subjected to dry **distillation,** a cyclic **ketone** is formed by the separation of calcium carbonate, and this ketone can be reduced to the corresponding cycloparaffin hydrocarbon. By the action of **sodium** on dichloro (or dibromo) paraffins (**chlorine** or **bromine** not attached to the same or adjacent carbon atoms), sodium chloride separates upon heating and cycloparaffin hydrocarbon is also formed.

OLEFIN HYDROCARBONS. Olefin hydrocarbons are characterized by marked chemical reactivity, as shown by the behavior of such reagents as (1) **bromine** in carbon tetrachloride. The red-colored solution is decolorized by olefins by addition of bromine at the olefin linkage (>C:C<), (2) **sulfuric acid,** fuming. Olefins react, generating heat, by addition or polymerization, (3) **nitric acid,** fuming. Olefins react violently, (4) **potassium** permanganate in sodium carbonate solution. The purple-colored solution is decolorized by olefins, (5) **hydrogen,** in the presence of finely divided nickel at 150° C. Olefins form paraffins by addition of hydrogen at the olefin linkage, finally, (6) olefins react, by addition at the olefin linkage, with **hydrogen iodide, hydrogen bromide, hypochlorous acid, hypobromous acid, ozone.**

The olefin hydrocarbon ethylene is a constituent of coal gas (up to 8%), and in larger percentage (up to 30%) in the gases from petroleum subjected to the cracking process. Cracking process gas contains propylene (up to 20%), and butylenes (up to 9%).

Olefin hydrocarbons are formed (1) by the **destructive distillation** of coal, and the cracking of petroleum, (2) by the removal of water from **alcohols,** by passing the alcohol vapor over heated **bauxite,** or by heating with concentrated sulfuric or **phosphoric acid,** (3) by heating paraffin chlorides, bromides, or iodides with **sodium** hydroxide in alcoholic solution, (4) by heating dihalogen saturated hydrocarbons with **zinc,** (5) by **electrolysis** of the **sodium** salts of dibasic acids, which in the case of **succinic acid** ($COOH \cdot CH_2 \cdot CH_2 \cdot COOH$) yields **ethylene** plus **carbon dioxide** (2 volumes) and **hydrogen** (1 volume).

CYCLOÖLEFIN AND TERPENE HYDROCARBONS. Cycloölefin hydrocarbons are characterized by marked chemical reactivity, as shown by the behavior of such reagents as (1) **bromine in carbon tetrachloride.** The red-colored solution is decolorized by cycloölefins by addition of bromine at the olefin linkage (>C:C<), (2) sulfuric acid, fuming. Cycloölefins polymerize and dissolve in the reagent, (3) nitric acid, fuming. Cycloölefins react violently, sometimes with explosive violence, (4) **potassium** permanganate in **sodium** carbonate solution. The purple-colored solution is decolorized by cycloölefins, (5) hydrogen, in the presence of finely divided nickel at 150° C. Cycloölefins form cycloparaffins by addition of hydrogen at the olefin linkage.

Cycloölefin hydrocarbons predominate in the hydrocarbon secretions of plants known as essential or **volatile oils,** the terpenes ($C_{10}H_{16}$). These are found in **coniferous** trees, especially pine, from which **turpentine** is obtained, and in the skin of **citrus fruits,** which yield limonene. Terpenes, especially turpentine, are desirable solvents of many organic materials such as **resins** and **gums** and find application as such in preparing **paints,** varnishes, **lacquers.**

Cymene, para-methylisopropyl benzene ($C_{10}H_{14}$) or (1) $CH_3 \cdot C_6H_4 \cdot C_3H_7$(4) contains the carbon skeleton of the terpenes, limonene ($C_{10}H_{16}$, which is a monocyclo-1(2),8(9)-diene and alpha-phellandrene ($C_{10}H_{16}$), which is a monocyclo-1(2),5(6)-diene. Completely hydrogenated cymene is known as menthane ($C_{10}H_{20}$).

The terpene, alpha-pinene ($C_{10}H_{16}$) is a dicyclo-monoene compound having three methyl groups (2,7,7) attached to two (2,7) of its seven carbon atoms. The three bridges of the dicyclo heptene nucleus (between the two carbon atoms common to each ring) contain respectively 3,1,1 carbon atoms (expressed [3.1.1]).

ACETYLENE HYDROCARBONS. Acetylene hydrocarbons are characterized by marked chemical reactivity, as shown by the behavior of such reagents as (1) **bromine in carbon tetrachloride.** The red-colored solution is decolorized by acetylenes by addition of bromine at the acetylene linkage (—C⋮C—), (2) **sulfuric acid,** concentrated. Acetylenes dissolve in the reagent, (3) **nitric acid,** fuming. Acetylenes react violently, (4) **hydrogen** in the presence of finely divided nickel at 150° C. Acetylenes form olefins or paraffins by addition of hydrogen at the acetylene linkage, (5) ammonio-**cuprous** (or **silver**) salt solution. Acetylene having the group —C⋮CH yield precipitates, explosive when dry.

Acetylene hydrocarbons are formed (1) by reaction of metallic acetylides or certain metallic carbides with acids or water. **Calcium** carbide and water yields acetylene plus calcium hydroxide, (2) by heating dihalogen saturated hydrocarbons with sodium ethoxide, (3) by **electrolysis** of the sodium salts of the **fumaric acid** type, which in the case of fumaric acid (COOHCH:CHCOOH) yields acetylene plus **carbon dioxide** (2 volumes) and **hydrogen** (1 volume).

BENZENOID HYDROCARBONS. Benzenoid hydrocarbons are characterized by moderate reactivity, as shown by the behavior of such reagents as (1) **bromine in carbon tetrachloride,** usually on warming. The red-colored solution is decolorized by benzenoids by substitution of bromine for **hydrogen** of the benzenoid with the simultaneous separation of **hydrogen bromide,** which is evolved as a colorless gas and recognized by the fog formed when breathed upon, (2) **sulfuric acid,** fuming, usually on warming. Benzenoids react by substitution of the sulfonic acid group ($—SO_3H$) for hydrogen of the benzenoid with the simultaneous formation of water (not visible), (3) **nitric acid,** fuming, frequently on warming. Benzenoids react by substitution of the nitro group ($—NO_2$) for hydrogen of the benzenoid with the simultaneous formation of water (not visible), (4) with methyl (or other) chloride, bromide, iodide, in the presence of **aluminum** chloride anhydrous. Benzenoids react by substitution of the methyl (or other) group for hydrogen of the benzenoid with the simultaneous separation of hydrogen chloride, bromide, iodide, (5) with **acetyl** (or other) **chloride,** bromide, in the presence of **aluminum** chloride anhydrous. Benzenoids react by substitution of the acetyl (or other) group for hydrogen of the benzenoid with the formation of a ketone and the simultaneous separation of hydrogen chloride, bromide.

Benzenoid hydrocarbons are the predominant constituents in the hydrocarbon portion when **coal** is **destructively distilled** at high temperatures. This sources furnishes **benzene, toluene, xylenes, naphthalene, anthracene** of commerce. Since 1941, however, more toluene and xylenes have been produced in this country from petroleum sources by catalytic cyclization of paraffins and dehydrogenation of cycloparaffins than from all the coal distillation sources. (R.K.S.)

*[1] Federal Specifications Board.

HYDROCAULUS. The common stalk bearing the individuals of a colony in the **hydrozoan** coelenterates. (A.W.L.)

HYDROCELE. A localized collection of fluid about the **testicle** within the membrane (*tunica vaginalis*) enveloping the testicle. It is cured by surgery. (R.S.M.)

HYDROCEPHALUS. A disorder of the normal circulation and absorption of fluid within the cavities (ventricles) of the **brain.** There are blocking and increased accumulation of cerebrospinal fluid in the ventricles. This may be caused by tumors, congenital deformities, infection, or injury.

Hydrocephalus usually occurs early in childhood. It is characterized by progressive and extreme enlargement of the skull, atrophy of the brain through pressure, mental impairment, and convulsions. Unless the process is arrested, imbecility, blindness, and eventual death from malnutrition or some intercurrent infection results.

The treatment is unsatisfactory and the outlook is usually hopeless. If the obstruction is caused by infection, recovery may take place. Surgical procedures may relieve the block, but the child will still be a mental defective if pressure atrophy of the brain has already begun. (D.M.H.)

HYDROCHLORIC ACID AND CHLORIDES. Hydrochloric acid, "muriatic acid" (HCl), is a colorless solution formed when hydrogen chloride gas is dissolved in water, commercially of strength 18° Baumé (specific gravity at 60° F., water at 60° F., 1.1417, 27-92% HCl); 20° Baumé (specific gravity at 60° F., water at 60° F., 1.1600, 31 45% HCl); specific gravity 1.19 (approximately 36% HCl). Sometimes colored yellow by ferric iron. There is a maximum constant boiling point 108.58° C. (760 mm.), at 20.22% HCl (distillate) for mixtures of hydrochloric acid and water.

A commonly used strength for dilute hydrochloric acid is 18.25 grams HCl per 100 milliliters of solution (5 normal). Dilute hydrochloric acid reacts (1) with many hydroxides, e.g., **sodium** hydroxide, to yield the corresponding chloride, e.g., sodium chloride, solution, (2) with many ordinary oxides, e.g., **magnesium** oxide, to yield the corresponding chloride, e.g., magnesium chloride, solution, (3) with many carbonates, e.g., **calcium** carbonate, to yield the corresponding chloride, e.g., calcium chloride solution plus carbon dioxide gas, (4) with many sulfides, e.g., **ferrous** sulfide, to yield the corresponding chloride, e.g., ferrous chloride, solution plus **hydrogen sulfide** gas, (5) with many metals, e.g., **zinc** (but not copper) to yield the corresponding chloride, e.g., **zinc** chloride, solution plus hydrogen gas, (6) with some special oxides, e.g., lead or manganese dioxide, to yield **lead** or **manganese** chloride plus chlorine gas, (7) with solution of some salts, e.g., silver nitrate, to yield the corresponding chloride, **silver** chloride, precipitate. Higher strengths of hydrochloric acid usually react similarly to the dilute. Hydrochloric acid sometimes reacts as a reducing acid, e.g., (6) above.

The uses of hydrochloric acid have been suggested by the chemical reactions previously cited, and the largest quantities are used for reaction with metals, e.g., zinc recovery from galvanized iron scrap; in the production of chlorides; and, previous to the electrolytic production of **chlorine,** for chlorine.

All metallic chlorides, except **silver** chloride and mercurous chloride, are soluble in water, but **lead** chloride, **cuprous** chloride and **thallium** chloride are only slightly soluble. Metallic chlorides when heated melt, and volatilize or decompose, e.g., **sodium** chloride, melting point 804° C.; **calcium, strontium, barium** chloride volatilize at red heat; **magnesium** chloride crystals yield magnesium oxide residue and hydrogen chloride; **cupric** chloride yields cuprous chloride and chlorine.

Two common tests for chlorides are as follows:

1. An aqueous solution gives a precipitate with **silver** nitrate which is insoluble in **nitric acid** but soluble in **ammonia, sodium** thiosulfate, or **potassium** cyanide.
2. On treatment with **chlorine** water and shaking with **carbon disulfide** no dark coloration is produced as is the case for the bromides and the iodides. (R.K.S.)

HYDROCLADIUM. Small branches bearing sessile polyps in **hydrozoan** coelenterates of the family Plumulariidae. (A.W.L.)

HYDROCORALLINAE. Hydrozoa.

HYDROCYANIC ACID AND CYANIDES. Hydrocyanic acid, prussic acid (HCN), is a solution of hydrogen cyanide gas in water of characteristic odor and very poisonous, is soluble in all proportions in water, alcohol, or ether, and anhydrous liquid hydrogen cyanide is a solvent for many salts and organic substances. Hydrogen cyanide reacts with **hydrogen** at 140° C. in the presence of a **catalyzer,** e.g., **platinum** black, to form methyl **amine** (CH_3NH_2); when burned in air, produces a pale violet flame; when heated with dilute **sulfuric acid** forms formamide ($HCONH_2$) and ammonium formate ($HCOONH_4$); when exposed to sunlight with **chlorine** forms cyanogen chloride (CNCl), plus **hydrogen chloride.** An important reaction of hydrogen cyanide is that with **aldehydes** or **ketones,** whereby cyanhydrins are formed, e.g., acetaldehyde cyanhydrin (CH_3 $CHOH \cdot CH$), and the resulting cyanhydrins are readily converted into alpha-hydroxy acids, e.g., alpha-hydroxypropionic acid ($CH_3 \cdot CHOH \cdot COOH$).

Metallic cyanides are (1) soluble, e.g., **sodium** cyanide (NaCN), **potassium** cyanide (KCN), **calcium** cyanide ($Ca(CN)_2$), **mercuric** cyanide ($Hg(CN)_2$), **aurous** cyanide (AuCN), (2) insoluble, e.g., **silver** cyanide (AgCN), **cuprous** cyanide (CuCN), (3) complex, (a) decomposed by dilute **sulfuric acid** and not affected by dilute **sodium** hydroxide, e g., sodium silver cyanide ($NaAg(CN)_2$) solution, sodium cuprous cyanide ($NaCu(CN)_2$) colorless solution, (b) changed only to the acid by dilute sulfuric acid and reactive with dilute sodium hydroxide, e.g., **potassium** ferrocyanide ($K_4Fe(CN)_6$) yields, with dilute sulfuric acid, **hydroferrocyanic acid, cupric** ferrocyanide ($Cu_2(Fe(CN)_6)$) yields, with dilute sodium hydroxide, cupric hydroxide.

Sodium cyanide solution dissolves certain metals (1) with absorption of oxygen, e.g., gold, silver, mercury, lead, (2) with evolution of hydrogen, e g., copper, nickel, iron, zinc, aluminum, magnesium; and solid sodium cyanide, when heated with certain oxides, e.g., **lead** monoxide (PbO), **stannic** oxide (SnO_2), yields the metal of the oxide, e g., lead, tin, respectively, and sodium **cyanate** (NaCNO). Two classes of **esters** are known, cyanides or nitriles, and iso-cyanides, iso-nitriles or carbylamines, the latter being very poisonous and of marked nauseating odor.

Methyl cyanide (CH_3CN), boiling point 82° C., formed by reaction of (1) methyl iodide and **potassium** cyanide, (2) acetamide and phosphorus pentoxide. Methyl iso-cyanide (CH_3NC), boiling point 60° C., formed by reaction (1) of methyl iodide and **silver** cyanide, (2) of methyl **amine, chloroform** and **sodium** hydroxide solution warmed. Ethyl iso-cyanide (C_2H_5NC), boiling point 78° C. Phenyl iso-cyanide (C_6H_5NC), boiling point 78° C. at 40 mm. pressure.

Hydrogen cyanide is made by reaction of **sodium** cyanide and dilute **sulfuric acid.** Its uses are for fumigation of ships, cars, rooms, and fruit trees. Sodium cyanide is used for recovering gold and silver from ores (cyanide process). The detection of hydrogen cyanide is accomplished (1) by evaporation to dryness with yellow **ammonium** sulfide, whereby **thiocyanate** is formed, which yields red-colored solution upon addition of **ferric**

salt solution. It is said that 1 part of cyanide may thus be detected in 4,000,000 parts of solution, (2) by boiling with ferrous plus ferric salt solution to which sodium hydroxide has been added. Upon addition of excess dilute sulfuric acid to the product, a blue precipitate forms, if cyanide was present, or a blue solution if the amount was small. Cyanides are also detected by the formation, with **silver** nitrate solution, of a white precipitate that is soluble in excess of cyanide. On treatment of cyanides with dilute sulfuric acid, the characteristic almond-like smell of hydrogen cyanide (poisonous) is produced. (R.K.S.)

HYDRODYNAMICS. **Hydraulics.**

HYDROELECTRIC POWER. This is electric power derived from generators, driven by **hydraulic turbines** or water wheels. The principal elements of this kind of power plant are a site to provide flow and head of water, a turbine-generator machine, and a discharge channel.

The desirability of a hydro site rests not only upon its topography and stream flow, but also upon the cost of fuel, the trend of fuel cost, and the load factor to be expected. When coal prices are rising rapidly more attention will be given to the hydro projects than when coal prices are on the decline. The length and cost of transmission lines from plant to load also present problems of some moment in any consideration of hydroelectric development. On the other hand, it can be said for hydro developments that many of them serve more than one purpose and sometimes the power development is of secondary importance. Construction of impounding areas for flood control or for irrigation frequently offers the possibility of producing electrical energy as a by-product. Another feature commending hydro development is the ability to store energy, in the hydraulic form, over long periods of time in a reservoir; also the adjustment, through correct impounded volumes, of a variable stream flow to meet a variable load demand.

Hydroelectric plants can be classified as follows:

1. Extent of impounded volume.
   a. Storage plants.
   b. Run-of-river plants.
2. Status in the power system.
   a. Peak load plant.
   b. Base load plant.
   c. Isolated plant.
3. Head.
   a. High-head development.
   b. Medium-head development.
   c. Low-head development.

The low-head plant has a characteristic design differing in all essentials from the high-head plant. The medium-head plant may partake of the characteristics of either the high- or low-head plants as its working head approaches either the high- or low-head range. There is no definite line of demarcation between high, medium, and low heads; however, a head of more than 500′ can be considered a high-head development, and one lower than 50′ a low-head development. Briefly, the characteristics of the low-head plant are: vertical, reaction type, runners using large volumes of water and requiring large water passages. Substructure is both extensive and expensive, and intake works are large and complicated. Large diameter generators are made necessary by the low rotational speeds. Characteristics of the high-head plant are: horizontal impulse turbines, small volumes of water at high pressures, plant at some distance from the dam. The advantage of smaller and simpler substructure is offset by the presence of a long water conduit, or penstock, between dam and plant. The turbines are high-speed and allow smaller generator diameter. The high speed is accounted for by the high heads used. Inherently, the impulse turbine has a low characteristic speed.

The possible hydroelectric development sites along the flow of a stream are of two types, namely, those suitable for run-of-the-river plants and those offering natural impounding basins for storage plants. In general, the run-of-the-river plant is cheaper than the storage plant of equal capacity, but it suffers seasonal variation of output more or less proportional to the variation of stream flow.

Storage plants give a greater proportion of firm power which can be delivered day by day on a regular schedule. This firm power is in more or less direct ratio to the degree of regulation of the flow of the stream and this in turn is a function of the impounded volume. Complete regulation of stream flow is rarely possible or practical although 80–90% regulation is not infrequent.

In any storage plant the theoretical energy or power available over and beyond the firm power developed is known as flash power or flood peak power. Firm power commands, commercially, a considerably higher rate than flash power.

When integrated with steam generating plants, hydroplants are frequently used to give peak power outputs to take care of peak load conditions and thus avoid the expensive standby service of additional steam generating equipment. Such service, of course, may still permit the delivery of a certain amount of firm power.

If all the run-of-river plants were located upstream from the storage plants they would be operated continuously on a base load plan, because, were they idle, their small reservoirs would quickly overflow and water would be wasted over the crest gates. If, however, they are located between storage plants, the run of the river, as far as they are concerned, is just what the storage plants are passing on to them. So, located downstream from a storage plant, a run-of-river plant will produce an increase in output when the storage plant increases its output.

In the hydroelectric plant the turbines and generators are the main items of equipment. The hydroelectric superstructure, as usually laid out, has one large building housing the main units and an electrical bay, or wing, of one or more stories in which are located the switching equipment, offices, storerooms, and most of the auxiliary equipment.

Hydro sites that are developed to use but part of the normal stream flow are exceptions to the general rule. Only rarely is a development made where conservation of the water and its use in the most efficient manner are not paramount features of operation. Failure to give due cognizance to this feature may wipe out the net operating profit; hence a continuous, watchful scrutiny of all natural factors which can affect the station operation is a duty of the operating personnel.

A **hydraulic turbine** suffers loss of efficiency at heads above or below the designed value because of shock losses. At the correct head there will be one point of best efficiency, somewhere between 80–95% of full load. When a number of units are installed in a plant, and when steam reserve is available, it is generally possible to operate the units near the point of best efficiency. There are four faults of operation and maintenance which can reduce the maximum energy production of a plant. They are:

1. Waste of water over spillways.
2. Improper distribution of the load between the station units.
3. Water leakage through valves, gates, dam or flow line.
4. Wear on moving parts, especially corrosion or erosion of the runner.

The relative simplicity of hydroelectric equipment makes hydraulic efficiency of the turbine the principal consideration. (F.T.M.)

HYDROFERRICYANIC ACID AND FERRICYANIDES. Hydroferricyanic acid ($H_3Fe(CN)_6$) is a brownish-green non-volatile solid, soluble in water to form a strongly acidic brown-colored solution, which decomposes in the light. **Potassium** ferricyanide ("red prussiate of potash," ($K_3Fe(CN)_6$), red soluble solid, the ordinary source of ferricyanide, is made by reaction of potassium ferrocyanide ($K_4Fe(CN)_6$), obtained as a by-product of coal gas works, and **chlorine** in solution, and then crystallization. **Potassium** ferricyanide, unlike potassium ferrocyanide, is soluble in alcohol. From potassium ferricyanide concentrated solution, by treatment with **sulfuric acid,** solid hydroferricyanic acid may be obtained, and then dried in vacuum. When potassium ferricyanide and dilute sulfuric acid are warmed, **hydrogen cyanide** is evolved, but, with concentrated sulfuric acid warmed, **carbon monoxide** is evolved. When potassium, sodium, or ammonium ferricyanide solution is added to certain metallic salt solutions, characteristic results are obtained:

With **silver** nitrate, silver ferricyanide ($Ag_3Fe(CN)_6$), brick red precipitate; with **cadmium** nitrate, cadmium ferricyanide ($Cd_3(Fe(CN)_6)_2$), orange precipitate; with **cupric** sulfate, cupric ferricyanide ($Cu_3(Fe(CN)_6)_2$), yellowish-green precipitate; with **ferrous** sulfate, ferrous ferricyanide ("Turnbull's blue," $Fe_3(Fe(CN)_6)_2$), deep blue precipitate or colloidal solution (this is a common test for ferricyanides); with **ferric** sulfate, no precipitate but brown to green solution. With **nitric acid** or acidified solution of **sodium** nitrite, potassium or sodium ferricyanide solution is changed to nitroferricyanide ("Nitroprusside," $Na_2Fe(NO)(CN)_5$), recoverable by crystallization. (R.K.S.)

HYDROFERROCYANIC ACID AND FERROCYANIDES. Hydroferrocyanic acid ($H_4Fe(CN)_6$) is a white, non-volatile soluble solid. **Sodium** or **potassium** ferrocyanide ("yellow prussiate of potash," $Na_4Fe(CN)_6$) is obtained as a by-product of coal gas works by fixing the **cyanogen** compounds of the gas by reaction with **ferrous** compounds and then boiling with **calcium** hydroxide suspension. Soluble calcium ferrocyanide is converted to soluble sodium or potassium ferrocyanide by reaction with sodium or potassium carbonate, and then filtering off calcium carbonate precipitate and evaporating the filtrate. From sodium ferrocyanide solution, by treatment with **sulfuric acid,** hydroferrocyanic acid may be obtained by extraction with ether, and then evaporating the ether solution. When sodium ferrocyanide and dilute sulfuric acid are warmed, **hydrogen cyanide** is evolved, but, with concentrated sulfuric acid warmed, **carbon monoxide** is evolved. When sodium, potassium, or ammonium ferrocyanide solution is added to certain metallic salt solutions, characteristic results are obtained: with **silver** nitrate, silver ferrocyanide ($Ag_4Fe(CN)_6$), white precipitate slowly turning blue; with **cadmium** nitrate, cadmium ferrocyanide ($Cd_2Fe(CN)_6$), white precipitate; with **cupric** fulfate ($Cu_2Fe(CN)_6$), reddish-brown precipitate; with **ferrous** sulfate, ferrous ferrocyanide ($Fe_2Fe(CN)_6$), white precipitate when pure ferrous but usually pale blue precipitate; with ferric sulfate, ferric ferrocyanide ($Fe_4(Fe(CN)_6)_3$) or $Fe_3(Fe(CN)_6)_2$), deep blue precipitate ("Prussian blue") (this is a common test for ferrocyanides). Sodium and other soluble ferrocyanides are oxidized to ferricyanides, when in acid solution, by **chlorine, nitric acid, nitrous acid, hydrogen peroxide,** dichromate, **permanganate, lead** dioxide, **manganese** dioxide. (R.K.S.)

HYDROFLUORIC ACID AND FLUORIDES. Hydrofluoric acid (HF or H_2F_2) is a colorless solution formed when hydrogen fluoride gas is dissolved in water, commercially of strengths 30% HF, and 60% HF. There is a maximum constant boiling point 111° C. (750 mm.) at 43% HF (distillate) for mixtures of hydrofluoric acid and water. Since hydrofluoric acid attacks glass, the container must be resistant, e.g., of lead or ceresine.

Hydrofluoric acid is used (1) to etch and frost glass, (2) to volatilize **silicon** oxide, (3) in the preparation of fluorides, fluosilicates, fluoborates. (See **Boron.**)

Metallic fluorides are soluble as follows: **sodium, potassium, ammonium, silver, mercurous, mercuric, thalum;** the remaining fluorides are insoluble.

A common test for fluorides is treatment (of the dry sample) with hot concentrated sulfuric acid. This produces hydrogen fluoride, which can be identified by its property of etching glass. (R.K.S.)

HYDROGEN. Symbol: H. Atomic number: 1. Atomic weight: 1.0080. Density: 0.0899 gram per liter. 0° C., 760 mm., or 0.070 when air equals 1.000. Formula of hydrogen gas: H_2. Melting point: −259.1° C. Boiling point: −252.7° C. Critical temperature: −239.9° C. Critical pressure: 12.8 atmospheres.

Hydrogen is a colorless, odorless, tasteless gas, suffocating but not toxic. **Palladium,** finely divided, adsorbs 1000 to 3000 times its own volume of hydrogen, and most of the gas is retained at a temperature as high as 100° C. Also, when finely divided as by reduction of the oxide powder, the following metals adsorb appreciable quantities of hydrogen: **cobalt, gold, nickel, iron.** Hydrogen was recognized as a distinct substance by Cavendish in 1766, who called it "inflammable air." Isotopes (1) (99.98%), (2) (0.02%) (deuterium), (3) (small percentage) (tritium). Used (1) in the oxyhydrogen and atomic hydrogen flames for high-temperature **welding,** cutting and melting of metals, (2) in the fixation of **nitrogen** as **ammonia,** (3) in the **hydrogenation** of fatty oils, unsaturated hydrocarbons, coal tar, coal, (4) in the formation of methyl **alcohol** by reaction with **carbon monoxide** in the presence of a **catalyzer.** In **fuel** gas mixtures, such as coal gas, water gas, and producer gas, hydrogen is a fuel constituent of low fuel value, namely, 320 B.T.U. per cu. ft.

Hydrogen occurs chiefly combined with **oxygen** in water, with **carbon** in hydrocarbons, with carbon and oxygen (without and with nitrogen) in a vast variety of organic substances, and with other elements in acids and bases.

When ignited, hydrogen burns in air with a pale blue to colorless, non-luminous flame; when mixed with air or oxygen and ignited, is explosive; combines violently with **chlorine** in sunlight or magnesium light to form **hydrogen chloride** (HCl); when heated with **sodium, calcium,** or related metals, yields the corresponding hydride; reacts with **nitrogen** to form **ammonia** (NH_3) in the presence of a **catalyzer;** with **sulfur,** to form **hydrogen sulfide** (H_2S) upon heating; with **cupric** oxide, cuprous oxide, ferric oxide, ferroferric oxide, ferrous oxide to form copper metal in the cases of the first two and iron metal in the cases of the last three plus water in all cases. Similar reactions take place with oxides of **nickel, tin, lead,** but not with oxides of zinc, aluminum, magnesium; with unsaturated organic compounds, to form corresponding saturated compounds, e.g., **oleic acid** ($C_{17}H_{33}COOH$) to form **stearic acid** ($C_{17}H_{35}COOH$), in the presence of a catalyzer.

Hydrogen is prepared (1) by the **electrolysis** of water solutions of salts, e.g., sodium chloride, of bases, e.g., sodium hydroxide, of acids, e.g., sulfuric acid, (2) by the reaction of dilute hydrochloric or sulfuric acid and a metal, such as **zinc** or **iron,** but not copper or mercury, (3) by the reaction of heated steam and a metal, such as zinc or iron, forming zinc oxide and ferroferric oxide, respectively, but not copper or mercury, (4) by reaction of **silicon** or **aluminum** with **sodium** hydroxide solution heated, forming sodium silicate and sodium aluminate, respectively, (5) from water gas, by separation from **carbon monoxide** by fractional liquefaction, (6) in the cracking of natural gas for carbon black, (7) from water gas and steam by catalytic conversion, (8) from

methane and steam on catalysts at high temperatures, in the last instance generally accompanied by nitrogen for ammonia synthesis.

"Heavy hydrogen," **deuterium,** hydrogen isotope 2 (0.02%), symbol D, atomic weight 2.01363, is ultimately obtainable by prolonged electrolysis of the residual water of electrolytic cells from which ordinary hydrogen (isotope 1, 99.98%) has been largely removed. Approximately one part by weight of isotope 2 is present in ordinary water along with 5000 parts by weight of isotope 1. The discovery of deuterium made possible in electron bombardment studies the use of a projectile of atomic mass 2, intermediate between hydrogen of atomic mass 1 and helium of atomic mass 4. By means of its compounds, deuterium makes possible the extended study of chemical structure and reactions.

Below −220° C. the specific heat of hydrogen is that of a monatomic gas like **helium** (He). Practically pure para-hydrogen may be obtained by adsorption of ordinary hydrogen, which is three-fourths ortho and one-fourth para, on charcoal at about −225° C. The melting point of para-hydrogen is 0.13° C. lower (ortho-hydrogen 0.04° C. higher) than ordinary hydrogen, and the boiling point at 60 mm. pressure is 0.13° C. lower (ortho-hydrogen 0.04° C. higher) than ordinary hydrogen. Para-hydrogen reverts slowly to ordinary hydrogen, but immediately in the presence of platinized asbestos.

At high temperatures the loss of heat from a glowing wire in hydrogen is larger than expected on regular assumptions. This is believed to be due to dissociation of ordinary hydrogen into atomic hydrogen (H).

Temperature, °C	Dissociation of Hydrogen At 760 mm.	At 1 mm.
1730	0.33%	8.7%
2230	3.1	57.5
2730	34	99.3

When hydrogen is passed through an electric arc between tungsten poles, a considerable transformation into atomic hydrogen occurs, and when a stream of this gas strikes a surface a large evolution of heat takes place through recombination to ordinary hydrogen. This atomic hydrogen flame is of temperature sufficiently high to melt **tungsten** (melting point 3370° C.). The half-life period of the hydrogen atom is one-third second at 0.5 mm. pressure.

Acids: Hydrogen is present in all solutions of acids. (See **Acids,** general.)

Hydrocarbons: (See **Hydrocarbons.**)

Hydrogenation: (See **Hydrogenation.**)

Hydrides: Of oxygen—H_2O, water; H_2O_2, hydrogen peroxide.

HYDROGEN IONS. **Reactions Involving Recombination of Ions.**

HYDROGEN PEROXIDE. Hydrogen peroxide, hydrogen dioxide (H_2O_2), is a colorless (blue in thick layers), odorless liquid, melting point −2° C., boiling point 152° C., decomposition 84° C. at 68 mm. pressure (68° C. at 26 mm.), soluble in water in all proportions, usually encountered as a dilute solution (3% H_2O_2, "10-volume solution," that is, one volume of solution yields 10 volumes of oxygen) although available up to 30% strength. Acetanilide is frequently added in small amount (0.002%) to decrease the decomposition on storage. Hydrogen peroxide is formed in 90 to 100% concentration when atomic hydrogen reacts with oxygen gas at ordinary temperature.

Hydrogen peroxide is used (1) as a bleaching agent as stated, (2) as an antiseptic and disinfectant, (3) as an oxidizing agent.

Hydrogen peroxide reacts (1) with **alkalis** to form peroxides, (2) with **potassium** iodide solution, in presence of ferrous sulfate, to liberate **iodine.** This reaction serves to indicate the presence of as small an amount as 1 part by weight of hydrogen peroxide in 25,000,000 parts of water, (3) with **lead** sulfide (PbS), brown solid, to form lead sulfate ($PbSO_4$), white solid, and sometimes used to brighten the lead pigment of darkened oil paintings, (4) with lead dioxide to form lead oxide, (5) with **sulfites,** especially in alkaline solution, to form **sulfates,** (6) with **nitrites** to form **nitrates,** (7) with **arsenites** to form arsenates, (8) with **ferrous** compounds to form ferric, (9) with chromic compounds to form chromates (see **Chromium**), (10) with permanganates (see **Manganese**), in acid solution to form manganous plus oxygen gas of twice the volume available from the hydrogen peroxide used, (11) with dichromates in acid solution cold to form perchromic acid, blue solution, more soluble in ether than in acid, (12) with titanic salt solutions to form pertitanic acid, yellow solution (see **Titanium**), (13) with colored organic materials, e.g., litmus, indigo, to destroy the color, and thus used for **bleaching** hair, silk, feathers, straw, ivory, teeth, bones, gelatin, flour. When hydrogen peroxide solution is treated with finely divided **platinum** or other substances, or comes in contact with rough surfaces, e.g., ground glass, **oxygen** is evolved (water also formed).

Hydrogen peroxide is prepared from **barium** peroxide by treatment with ice-cold dilute acid; when **sulfuric acid** is used barium sulfate insoluble may be separated by filtration. Other peroxides, e.g., sodium peroxide, react similarly with acids to form hydrogen peroxide plus the salt corresponding to the peroxide and acid used. Hydrogen peroxide is formed when ether is exposed to sunlight, when a hydrogen-oxygen flame impinges on ice, and when water in a quartz vessel is exposed to **ultra-violet light.** (R.K.S.)

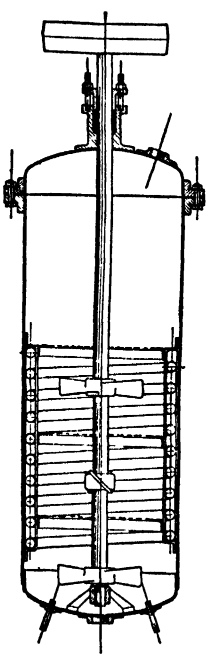
HYDROGEN SCALE. **Thermometry.**

HYDROGEN SULFIDE AND SULFIDES. **Hydrosulfuric Acid and Sulfides.**

HYDROGENATION. **Nickel,** prepared in finely divided form by reduction of nickel oxide in a stream of hydrogen gas at about 300° C., was introduced by Sabatier (1897) as a **catalyzer** for the reaction of **hydrogen** with unsaturated organic substances to be conducted at about 175° C. Nickel, while not the only catalyst, has proved one of the most successful in such reactions. **Platinum** black or **palladium** black is sometimes used at lower temperatures, and finely divided **copper** metal or nickel oxide at higher temperatures. The unsaturated organic substances that are hydro-

genated are usually those containing the olefin linkage (C:C), but those containing a triple bond (—C —) and (—C⋮N) may also be hydrogenated.

Ethylene (or **acetylene**) with hydrogen—all properly purified, as the catalyzer is easily poisoned—reacts in the presence of properly prepared nickel at the properly controlled temperature to form **ethane; benzene** (C_6H_6) to form cyclohexane (C_6H_{12}); styrolene ($C_6H_5CH:CH_2$) or phenylacetylene ($C_6H_5C⋮CH$) to form ethyl cyclohexane ($C_6H_{11} \cdot CH_2CH_3$); phenol (C_6H_5OH) and di- and trihydroxylphenols to form the respective hydroxycyclohexanes with change of properties from those of **phenols** to those of tertiary **alcohols; naphhthalene** ($C_{10}H_8$) to form tetra- or decahydronaphthalene; **anthracene** ($C_{14}H_{10}$) to form di- or hexahydroanthracene; **aniline** ($C_6H_5NH_2$) to form cyclohexylamine (C_6H_{11}-NH_2) a strong base; methyl cyanide (CH_3CN) to form ethyl amine ($CH_3CH_2NH_2$); oximes to corresponding amines; nitrobenzene ($C_6H_5NO_2$) to aniline ($C_6H_5NH_2$).



Apparatus used in the hydrogenation of oils under pressure.

The reaction is applied on a large scale to the hydrogenation of oleate ester fats under the influence of pressure, advantage thereby being taken of the decrease in volume upon the fixation of hydrogen by the fat. (See **Equilibrium.**) **Oleate** ester fats are hydrogenated to **stearate** ester fats of lower melting point and the product may be obtained of intermediate hydrogenation—and consequently of intermediate melting point—as desired. Artificial shortenings are thus prepared from liquid fatty oils such as cottonseed, peanut, corn oil. Oleic acid behaves similarly.

The catalyzer may be supported on such a material as kieselguhr. The method of preparation of the catalyzer and the avoidance of impurities are the two greatest difficulties of the process. Nickel is more active when reduced at 320–350° C. unsupported and at 500° C. on a support than when higher temperatures are used; nickel reduced at 700° C. is almost inactive.

Great interest has attached to the extension of the hydrogenation reaction to the technical field of unsaturated liquid hydrocarbons such as petroleum and coal tar fractions, and also to the hydrogenation of coal. (See **Catalysis.**) Temperatures of the order of 450° C. and pressures of the order of a hundred atmospheres are utilized. A British report states that 100 tons of dry ash-free coal will yield 62 tons of "petrol," 28 tons of gas, and a residue containing ash and 6 tons of solid carbonaceous matter, and then an additional equal weight of coal is requisite to operate the process. (See **Methyl Alcohol** and **Ammonia.**) (R.K.S.)

HYDROGRAPH. By graphing the discharge of a stream as ordinate against time sequence as the abscissa, a hydrograph of the stream flow is obtained. The hydrograph proves to be an important source of information in **hydroelectric power** design. The reliability of the information it contains increases as the period of time over which the hydrograph extends is lengthened. Hydrographs extending over periods of less than 10 years are liable to be deceptive in the information they convey regarding maximum and minimum flows. The **United States Geological Survey** water supply papers form a valuable and important reference source for data upon which hydrographs are constructed. (F.T.M.)

HYDROGRAPHIC MAP. Map.

HYDROGRAPHIC SURVEYING. Surveying.

HYDROID. One of the two forms of individuals in the **coelenterates.** The **polyp.** This form is a tubular or sac-like individual whose body wall is composed of two cellular layers separated by a thin mesogloea. The latter contains some cells derived from the other layers but is not developed as a third cellular layer. The hydroid is usually attached to the stalk of a colony or directly to a supporting surface. Its cavity opens at the free end of the body, and the mouth is surrounded by a circlet of slender tentacles except in specialized individuals found in some colonial species. The other form of coelenterate individual is the **medusa.** (A.W.L.)

HYDROKINETICS. The flowing of liquids is due to three principal causes: pressure difference, gravity, and inertia. **Bernoulli's law** expresses an ideal condition fulfilled by the three components of "head" corresponding to these three causes. The value of this head (whether constant or not) is, at a given point (x, y, z) of the liquid,

$$e + \frac{p}{\rho g} + \frac{v^2}{2g} = F(x, y, z). \tag{1}$$

The terms of this expression represent lengths, usually given in cm. or ft. The assumption of constant density requires that the product of the speed of flow by the cross-section of any conserved portion of the stream shall be constant and that the streamlines (paths of the moving particles) therefore converge as the speed increases. If one could assume that the function F is really constant, or if it were possible to obtain F as a known function of the coordinates of the moving particle, then all hydrokinetic problems could be solved by applying suitable mathematics to the equation which would thus develop from (1).

Various attempts have been made to do this. Useful formulae result from assuming F constant (Bernoulli's law) and applying the equation to special cases. But when such formulae are tested, the calculated results are found to be in error, in every case indicating that appreciable energy has been lost in friction. While some improvement is obtained by introducing a friction factor, it has on the whole been found more satisfactory to employ empirical formulae adapted to each type of problem. Thus we have the Darcy formula

$$v = D\sqrt{\frac{d(F_1 - F_2)}{l}}, \tag{2}$$

for the speed of flow in a pipe of length l and diameter d, running full, and with a difference of total head $F_1 - F_2$ at the two ends; D being a constant to be determined by experiment. Also the Chezy formula

$$v = C\sqrt{\frac{as}{u}}, \tag{3}$$

giving the speed of flow in an inclined channel, like a ditch or a sewer; a being the cross-section of the flow, u the length of channel perimeter covered by the liquid, s the fall per unit length, and C an experimental constant.

The "hydraulic grade line" is a convenient concept in connection with flow through pipes. This is an imaginary line so drawn that each point of it lies vertically above (or below) the pipe at a distance equal to the pressure head $p/\rho g$ at the corresponding point of the pipe. In the case of a **siphon,** part, at least, of the

conduit rises above this line, which means that the pressure in this portion is less than atmospheric.

Among the more difficult problems are those of vortex motion (like a whirlpool) and turbulent flow; and the general treatment of flow through a cavity of given shape under given boundary conditions, which presents some analogies to the electric current and the conduction of heat. (L.D.W.)

HYDROLITE. Sinter.

HYDROLOGIC CYCLE. Hydrology.

HYDROLOGY. The science, or study, of water, especially in relation to its occurrence in streams, lakes, underground structures, and as snow. The study of glaciers, their origin and geological effects is usually included under the heading of Glaciology. The term hydrology is derived from the Greek meaning water, and reason, hence the science of water, including its discovery, uses, control and conservation. Since water ranks first of all the natural resources, the science of hydrology is of great practical importance. The basis of hydrology is the hydrologic cycle. All terrestrial (fresh) waters are derived from the great oceanic reservoirs through evaporation and precipitation as rain or snow, hail or sleet.

The basis of rainfall data is the rainfall records collected by the United States Weather Bureau from its 106 climatological divisions. Rainfall is expressed in inches per year, and the volume that has fallen in a given time is expressed in acre feet, meaning the volume which would cover an acre to the depth of one foot. Most of the moisture that falls on the ground eventually returns to the sea by means of rivers. This is called the run-off. Stream flow past a stated point is measured in cu. ft. per sec., a term that is universally shortened to "second-feet." The difference between precipitation and run-off represents the amount of rain water which is, (1) temporarily caught in local depressions, such as lakes and swamps, (2) added to the **ground water** reservoir, (3) returned to the atmosphere by evaporation, or the transpiration of plants.

A great variation in rainfall in different parts of the country is to be noted, as is also the variation of precipitation at one point from year to year. This might be expected on the basis of the physical factors which cause rainfall.

The data of most importance to the study of water supply are the average annual precipitation, the minimum annual precipitation, and the frequency of occurrence of dry years. There exists only an indirect, and sometimes unrecognizable, connection between rainfall and run-off. Much depends on the topography of the watershed, its extent, and its geology. Of the volume precipitated in a rainfall, a large amount is evaporated from the watershed surfaces, more is absorbed by plants and trees, some goes into natural ground storage, and that which remains after these demands of nature have been satisfied will appear as run-off in the streams draining the watershed. The effect of a rainfall on stream flow must be interpreted in the light of the following conditions:

1. The character of the rainfall. If it is alternated with sunny periods, the evaporation will be large.
2. Temperature. The warmer the atmosphere, the more evaporated moisture it is able to contain.
3. Porosity of the soil. This governs the rate of percolation of the water from the surface to the depths.
4. Inclination, depth, and character of the underlying rock strata. This affects the amount of ground storage and its rate of flow to run-off.

It has been estimated that nearly half of the people of the United States obtain their water from wells (underground water). Within recent years the shallow, hand-dug wells have been supplemented by deeper, drilled wells, each one of which penetrates one or more water-bearing strata called aquifiers. When the water in a drilled well rises to the surface under its own pressure, it is called an **artesian well.** Due to the acts of Man, as well as Nature, water contributes to such catastrophes as floods and epidemics. A deficiency of water results in droughts. It should be fairly obvious that a careful and continuous study of the hydrology of a country is highly essential to the general welfare of its people. (R.M.F., F.T.M.)

HYDROLYMPH. The watery body fluid or blood of lower invertebrates. (A.W.L.)

HYDROLYSIS. Reactions Involving Water.

HYDROMETEORS. Condensation products of atmospheric processes often appear as hydrometeors or bodies of falling liquid and solid water:

1. Rain is liquid water drops ranging in diameter from 0.5 mm. to approximately 5.0 mm. and usually falls with a velocity ranging from 3 meters per sec. to 8 meters per sec. Rain is the most common type of precipitation.
2. Snow is solid water in the form of branched hexagonal crystals sometimes mixed with simple ice crystals.
3. Drizzle is numerous very small liquid droplets whose diameter is less than 0.5 mm. and whose rate of fall is usually less than 3 meters per sec. Normally the drops seem to float downward.
4. Sleet is frozen rain drops (or drizzle) which fall as particles of ice. (International usage defines sleet as a mixture of rain and snow.)
5. Freezing rain and drizzle are liquid hydrometers that freeze upon impact with the ground or surface objects, glazing such surfaces with a film of ice.
6. Hail is stones of ice ranging from about 1/16" in diameter to as much as 4 or 5". Hail stones are often transparent, but more frequently translucent, being formed of alternate layers of clear and opaque ice. Hail usually falls from thunderstorms.
7. Snow pellets are whitish, opaque, usually round pellets with a structure something like snow. They are compressible and often burst when striking a hard surface. They are a shower type of hydrometeor.
8. Small hail is small ice particles consisting of a nucleus of soft hail with a shell of ice about it. They do not rebound when striking a hard surface, are not compressible or crisp. Usually small hail is wet and falls at a temperature near or slightly above 32° F. (P.E.K.)

HYDROMETER. A well-known device for making quick, approximate measurements of the **densities** or **specific gravities** of liquids. It consists essentially of a long, slender glass float weighted at the lower end, and provided with a scale so graduated that the depth to which the instrument sinks in the liquid indicates the specific gravity by direct reading on the scale. The numbering of the scale necessarily increases from the top downward. The instrument is sometimes so proportioned that the numbering begins with unity at the top, being applicable only to liquids of the density of water or heavier; in others it increases from the top to unity at the lower end and is thus for use with light liquids only; in some cases it has unity at the middle and applies to both light and heavy liquids. To be very sensitive, the stem carrying the scale must be slender. Obviously the scale intervals corresponding to equal increments of density cannot be equal if the stem is of uniform diameter; in fact, they are inversely proportional to the square of the density, being much smaller at the lower than at the upper end of the scale. To avoid this, some hydrometers are graduated with an arbitrary scale having uniform spacing, like that of Baumé, the readings of which may be converted into true density by means

of a table. Nicholson devised a hydrometer for measuring the densities of small solids, the specimen being placed on the hydrometer first above and then below the

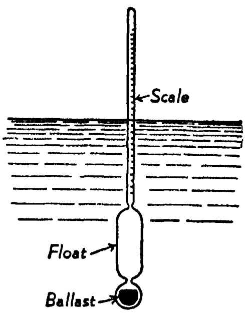


Fig. 1. Ordinary hydrometer for liquids.

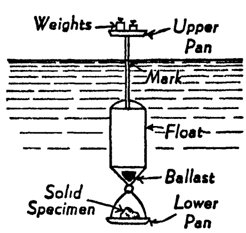

Fig. 2. Nicholson's hydrometer for small solids.

surface of the water in which the instrument floats, and its volume deduced from the resulting change in buoyant force. (L.D.W.)

HYDROPHYTES OR WATER PLANTS. These plants, which can grow only where there is an abundance of water, form an interesting and very distinct group of plants. Those hydrophytes which are members of the **Spermatophyta** are probably all plants which have reverted to an aquatic habitat, since it is assumed that all land plants originally evolved from plants growing in water. The reverting land plants may first have become marsh plants and then gradually developed into definite hydrophytes.

An aqueous environment presents conditions far more constant than an aerial one does. In the tropics such conditions permit the plants to grow throughout the year. In colder regions there is a definite winter period when growth must cease. Many hydrophytes of temperate regions merely sink to the bottom and remain dormant during the winter. Others accumulate food reserves in **rhizomes,** which remain rooted in the bottom and renew growth in the spring. Still others form winter buds, consisting of large apical buds surrounded by many closely packed leaves containing much reserve food material. A few hydrophytes form small tubers.

The stems of hydrophytes contain a very small amount of **vascular** tissue, since support is largely afforded by the water and conduction is not a great problem. In many of these plants the stem is very porous so that the plant floats in the water. The leaves of hydrophytes are of two types. Submerged leaves are thin and of various shapes; some, like **eel grass** leaves, are long and ribbon-like; others, like **bladderworts,** are finely dissected; while others are reduced to awl-shaped structures of small size. Floating leaves are usually large, undivided, and with **stomata** on the upper surface. Many hydrophytes show interesting leaf changes as the plant grows; leaves formed under water are finely dissected; when the stem emerges from the water it bears entire leaves. By changing the water level as the stem grows it is possible to cause repeated alternation of dissected and entire leaves. Once formed, the nature of the leaf cannot be changed.

The submerged surface of most hydrophytes is slimy with a secretion of a mucilaginous substance which probably protects the plant against excessive diffusion of substances present in the cell-sap and also against external enemies.

Reproduction in hydrophytes occurs both asexually and sexually. The flowers of nearly all hydrophytes are wind and insect pollinated, apparently a hangover from the time when they lived on land. A few have become modified to such an extent that **pollination** takes place on the surface of the water, the pollen floating about thereon and eventually reaching the stigma. A small number of hydrophytes are pollinated under water.

Nearly all **Algae** and many **Fungi** are hydrophytes, so also are several **Bryophytes** and a few **Pteridophytes.** In the flowering plants there are many water plants, such as the water lilies, bladderworts, eel grass and pond-weeds. Many are very interesting plants; several are aquarium plants serving to oxygenate the water; few are of any economic value. (R.M.W.)

HYDROPONICS. The term hydroponics has been suggested as a technical designation for the soilless culture of plants. The possibilities of such a method of growing plants have received considerable attention in recent years. The practice of the soilless culture of plants is an outgrowth of the laboratory techniques of sand cultures and solution cultures, long used by plant physiologists. In these techniques plants are grown with their roots immersed in a solution containing certain necessary mineral salts or rooted in a sand medium which is kept moistened with such a solution. The soilless culture of plants is similar in principle but larger in scale. In one version of the method the plants are supported in a matrix of peat, excelsior or some similar material on a wire screen with their roots dipping into the solution below. Aeration of the solution must also be provided if the best results are to be obtained. In another method the plants are rooted in a medium of sand, gravel, or some similar material contained in a shallow tank into which the solution is automatically pumped at suitable intervals. Between pumpings the solution gradually drains back into a reservoir tank.

The elements known to be necessary in chemically detectable amounts for the development of plants are carbon, oxygen, hydrogen, nitrogen, phosphorus, sulfur, potassium, magnesium, calcium, iron, manganese, boron, copper, zinc, and perhaps molybdenum. The first three of these elements are obtained by the plant from atmospheric gases or from water absorbed from the soil. The others are all absorbed in the form of mineral salts from the soil. Of the elements absorbed as salts the iron, manganese, boron, copper, zinc, and molybdenum are required in relatively minute quantities and are often called micronutrient elements. The principal elements which must be provided in the form of dissolved salts in hydroponic techniques, therefore, are nitrogen, phosphorus, sulfur, potassium, calcium, and magnesium.

Numerous solutions have been devised for use in the solution or sand culture of plants on both large and small scales. One solution which has been widely and successfully used for such purposes is made as follows: To each liter of water (preferably distilled or rain) add 1 molar solution of the following salts as indicated: 1 cc. KH_2PO_4, 5 cc. KNO_3, 5 cc. $Ca(NO_3)_2$, and 2 cc. $MgSO_4$. To this solution then add 1 cc. per liter of a solution of micronutrients made as follows: 2.5 g. H_3BO_3, 1.8 g. $MnCl_2 \cdot 4H_2O$, 0.1 g. $ZnCl_2$, 0.05 g. $CuCl_2 \cdot 2H_2O$, and 0.075 g. MoO_3 per liter of distilled water. Also add to each liter of the solution made as described above, 1 cc. of a 0.5% solution of iron tartrate. The solution must be replaced with a fresh one at suitable intervals, and it is often necessary to add more of the iron solution between replacements.

Crop yields of at least some kinds of plants fully equal to those obtained on fertile soils can be obtained by hydroponic methods. The raising of crops by this method, however, probably will prove to be economically sound only for certain intensive types of agriculture or under certain special conditions. Some greenhouse floricultural and horticultural crops are now being grown successfully by this method. In regions where there is no soil, or the soil is extremely infertile, but in which the climate is suitable to the development of plants, it seems likely that hydroponic techniques may prove useful. They have

been used with some success, for example, on some of the coral islands of the Pacific Ocean. (B.S.M.)

HYDROQUININE. Alkaloids.

HYDRORHIZAE. The root-like processes by which colonies of **hydrozoan** coelenterates are attached to a supporting surface. This term is in the plural. The singular is hydrorhiza. (A.W.L.)

HYDROSPHERE. The discontinuous envelope of **water,** both fresh and salt, which covers a major portion of the **lithosphere.** The bulk of the hydrosphere is contained within the deeper depressions of the surface of the earth. These depressions are termed ocean basins, and the water within them, oceans. Since the ocean basins are not large enough to hold the entire hydrosphere, seas are formed by the overflow of the oceanic waters on the continents. Geologists classify seas as epicontinental (epeiric) or relict. Technically, lakes, rivers and underground waters are also part of the hydrosphere. In general therefore, the term hydrosphere is used mainly to distinguish the watery covering of the earth from the lithosphere on which, and in which, in part, it rests. (R.M.F.)

HYDROSTATIC EQUATION. Atmospheric Structure.

HYDROSTATIC PRESSURE. The pressure created by a superimposed layer of a liquid is hydrostatic pressure. As the science of **hydraulics** is commonly understood, the fluid is water, and hydrostatic pressure is considered as pressure due to the existence above the point of measurement of the pressure of a head of water. The intensity of hydrostatic pressure is commonly expressed as lbs. per sq. in. A head of 2.31′ of fresh water creates a hydrostatic pressure of 1 lb. per sq. in. At a given depth of immersion in water, the pressure acts with equal intensity in all directions, that is, hydrostatic pressure is not directional in effect Hydrostatic pressures are measured by means of **pressure gauges** of the Bourden tube type, or **manometers** of the U-tube type. (F.T.M.)

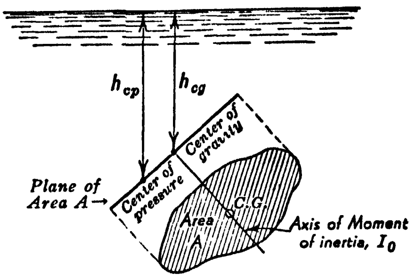
HYDROSTATICS. This branch of physics has to do with the **equilibrium** of liquids and the laws relating to liquid **pressure.** A study of these laws makes it clear that the components of pressure in a liquid fall naturally into two classes, according to the way in which they are produced; namely, (1) pressures due to forces applied externally, as by the atmosphere or by the piston of a pump, and (2) those due to causes operating throughout the body of liquid, such as gravity or inertia.

Pascal's law applies only to the first class, and states that any pressure in an enclosed liquid, originating in forces applied at its boundary, is communicated with unaltered intensity to all parts of the liquid. A familiar illustration of this fundamental law is the hydraulic press, which consists of two communicating cylinders, usually of different diameter, fitted with pistons, the force acting upon one piston and the force exerted by the other being in proportion to their areas.

The pressure in an enclosed liquid due to its own weight, on the other hand, increases uniformly with the depth below its highest point, and is equal to the product of the depth by the weight per unit volume. For fresh water, the pressure at depth h ft. is 62.4 h lbs. per sq. ft. The pressure of water against a submerged plane area is equal to the average intensity of pressure times that area. (See **Center of Pressure.**)

$$h_{cp} = \frac{I_0}{Ah_{cg}}.$$

Problems of flotation, draft, and buoyant stability always involve the density of the liquid and the volume and shape of the floating object. A floating body of



Center of pressure on a submerged plane.

mass m in a liquid of density ρ, will float with a volume v submerged, v determined by the relationship $v = \frac{m}{\rho}$. The buoyancy may be said to be the force which is equivalent to the weight of the liquid displaced by the submerged portion of the floating object. Buoyancy and weight do not, in general, act in the same vertical line. The weight acts at the **center of gravity** of the floating object, the buoyancy at the center of gravity of the displaced liquid, called the center of buoyancy. The relative positions of the buoyancy and the weight when a floating object is disturbed from an upright floating position, determines whether it is stable or unstable flotation. If the vertical drawn through the center of buoyancy passes above the center of gravity of the body, there is a righting moment, and the body is stable, whereas if it passes below the center of gravity, it is unstable in that the buoyancy tends to tip the object still further. The intersection of the line of buoyancy with the axis of symmetry of the floating body is the metacenter, and the distance from the metacenter to the center of gravity is the metacentric height. The latter is used to measure the stability of a hull. Another case of flotation is illustrated by the balance of the **hydrometer.** It is apparent from the above that with a given weight, the volume of immersion varies inversely with the density of the liquid In other words, a floating body rides higher in a denser liquid. This fact is put to use in the hydrometer, which has a given weight and which is immersed in fluids to measure their density. The hydrometer is calibrated to read the volume submerged directly in terms of density of the liquid.

An important general principle of hydrostatics is that which determines the free liquid surface in equilibrium. The direction of the surface at any point is perpendicular to the resultant of all forces acting upon a particle at that point. Thus, if only gravity is acting, the surface is horizontal or "level"; but if there are capillary forces, or if the external pressure is not uniform, the surface is inclined. An interesting case is that of a liquid rotating uniformly in a cylindrical tub; the surface then assumes the form of a paraboloid of revolution, symmetrical about the vertical axis. (See **Capillarity, Barometer, Pumps, Pressure Gauges,** etc.). (F.T.M.)

HYDROSULFURIC ACID AND SULFIDES. Hydrosulfuric acid (H_2S) is a colorless solution formed when hydrogen sulfide is dissolved in water, decomposes slowly in the presence of air forming sulfur. Hydrogen sulfide is removed completely from solution by boiling. A strong reducing agent, usually with the separation of **sulfur,** e.g., with **nitric acid** (nitric oxide formed), with concentrated **sulfuric acid (sulfur dioxide** formed), with **chlorine (hydrochloric acid** formed), with permanganate (**manganous** formed in the presence of acid), dichromate (**chromic** formed **in** the presence of acid).

Sulfides. (See **Sulfur.**) (R.K.S.)

HYDROSULFUROUS ACID AND HYDROSULFITES. Commercial names far hyposulfurous acid and hyposulfites. Not to be confused with thiosulfate, e.g., sodium thiosulfate, $Na_2S_2O_3$, photographers' "hypo." (R.K.S.)

HYDROTHERMAL METAMORPHISM. **Metamorphism.**

HYDROTROPISM. **Movement in Plants.**

HYDROXYAZO COMPOUNDS. **Azo-, Diazo-, and Related Compounds.**

HYDROXYL IONS. **Reactions Involving Recombinations of Ions.**

HYDROXYLAMINES AND OXIMES. Hydroxylamine (H_2NOH) is a white, odorless solid, melting point 33° C., boiling point 56° C. at 22 mm., explosive, soluble in all proportions in water or alcohol. Hydroxylamine is: 1. A weak **base** forming with **acids** soluble salts that decompose more or less violently when heated, e.g., hydroxylamine hydrochloride (hydroxylammonium chloride, $H_2NOH \cdot HCl$), melting point 151° C., nitrate ($H_2NOH \cdot HNO_3$), hemisulfate $H_2NOH \cdot \frac{1}{2}H_2SO_4$. Dihydroxylamine oxalate and trihydroxylamine phosphate are insoluble in water. Hydroxylamine hydrochloride is soluble in alcohol. 2. A weak acid forming with bases soluble salts, e.g., sodium hydroxylamite (H_2NONa). Hydroxylamine salt solution is a powerful reducing agent, more especially in alkaline than in acid solution, for example, **cupric** salt solutions changed to cuprous oxide, **silver** salt solutions to silver, **mercuric** chloride solution to mercurous chloride, ferric salt solutions (in acid) to ferrous. **Ferrous** hydroxide in sodium hydroxide is, however, oxidized by hydroxylamine to ferric hydroxide plus ammonia.

Phloroglucinol (phloroglucinol-1,3,5-trioxime)	155 expl.	
Quinonemonoxime	125	144 dec.
Quinone-1,4-dioxime	240 appr. dec.	
Anthraquinone-9-oxime	224 dec.	

Hydroxylamine hydrochloride may be made by reduction of **nitric oxide** gas when the latter is passed into tin plus hydrochloric acid heated, then evaporating and dissolving hydrochloride in alcohol, which may be distilled off. All the oxides and oxygen acids of **nitrogen**, except nitrous oxide, may be reduced to yield detectable amounts of hydroxylamine, ethyl nitrate (CH_3ONO_2) being used to advantage. Better yields of hydroxylamine are reported as having been obtained by electrolytic reduction of nitrites or nitric acid.

Beta-phenylhydroxylamine, N-phenylhydroxylamine, is a white solid, slightly soluble in water, very soluble in alcohol or ether, forms salts with acids, e.g., beta-phenylhydroxylamine hydrochloride ($C_6H_5CHNOH \cdot HCl$), upon exposure to air the water solution forms azobenzene ($C_6H_5N{:}NC_6H_5$). Beta-phenylhydroxylamine reacts (1) with oxidizing agents, such as **chromic** acid or ferric chloride, to form nitrosobenzene (C_6H_5NO), (2) with reducing agents, such as tin plus hydrochloric acid, to form **aniline** ($C_6H_5NH_2$), (3) with alkaline **cupric** salt solution (Fehling's solution) at room temperature to form cuprous oxide, (4) with **ammonio-silver** salt solution (Tollen's solution) at room temperature to form silver, (5) in the presence of **hydrochloric** acid to form para-aminophenol ($HO \cdot C_6H_4 \cdot NH_2(1,4)$). (See **Azo-, Diazo-, and Related Compounds.**)

Beta-phenylhydroxlamine is formed by reduction of nitrobenzene (1) by zinc and calcium chloride or ammonium chloride solution, (2) by electrolysis in acetic acid plus sodium acetate solution.

Diphenylhydroxylamine is prepared by reaction of nitrosobenzene and phenylmagnesium bromide in anhydrous ether, followed by treatment with water (magnesium hydroxybromide also formed.) (R.K.S.)

HYDROZOA. A class of the phylum **Coelenterata** composed chiefly of small animals without common

names. Many species are colonial and the colonies of a few, such as the Portuguese man-of-war, are quite large.

The class differs from the other coelenterates in the occurrence of both **hydroid polyps** and **medusae** in the same species, usually in alternating generations. In many colonies additional specialization occurs among the polyps for the performance of different functions; the **gonozooids, gastrozooids,** and **dactylozooids** of the siphonophores are such individuals. Hydrozoan medusae differ from the jellyfishes and are called **medusoids.** In some cases they are specialized forms which remain attached to the colony and show no resemblance to medusae, but the free-swimming forms differ from medusae only in details of structure. The medusoids are sexual reproductive individuals.

Relatively few species of hydrozoans live in fresh water. **Hydra,** the most widely known genus, includes a number of species without a medusa stage. The polyps are solitary and carry on both asexual and sexual reproduction. Several fresh-water medusae for which no polyp stage has been discovered are also known from lakes in Europe, Africa, and the Americas. The marine species are numerous.

The following orders are recognized:

Order Hydrariae. Small cylindrical polyps. Solitary. Mostly in fresh water.

Order hydrocorallinae. Marine colonial forms with a calcareous covering which sometimes resembles coral.

Order tubulariae. Mostly colonial forms. Polyps without a protective sheath (hydrotheca). Medusae free or sessile, often ovoid or bell-shaped.

Order Campanulariae. Colonial species with polyps of two kinds, **hydranths** and **blastostyles.** A sheath called the perisarc invests the colony and extends about each individual polyp.

Order Trachomedusae. Polyps minute where known, in some species never discovered. Medusae free-swimming. Marine and fresh-water.

Order Narcomedusae. Marine species without known polyps. Medusae with lobed margin.

Order Siphonophora. Free-swimming colonial species. Polyps of several specialized types, in many species borne by a stalk which is expanded at one end to form a hollow float, the **pneumatophore. Portuguese man-of-war** and others. (A.W.L.)

HYENA. Mammalia, Carnivora. *Hyaena.* Large animals slightly resembling wolves but more closely related to the civets. They live in Africa, India, and the eastern Mediterranean countries. They are heavily built, with massive heads and disproportionately long front legs. Hyenas are said to be cowardly and skulking but at times vicious. (A.W.L.)

HYGROGRAPH. Meteorological Instruments.

HYGROMETERS. Any apparatus for measuring atmospheric **humidity,** either absolute or relative, is called a hygrometer. The most common relative humidity instrument is the so-called wet-and-dry-bulb thermometer, or psychrometer. Two exactly similar mercury thermometers are mounted side by side. The bulb of one is wrapped in a wick dipping into water, and is thereby kept wet. This bulb is cooled by the evaporation, the rate of which, and hence the resultant cooling, depends in a definite manner upon the relative humidity of the air. A table accompanies the instrument, giving the humidity in terms of the actual air temperature as indicated by the dry-bulb thermometer, and the difference of temperature between the wet bulb and the dry bulb.

The dew point hygrometer is an apparatus for indicating the **dew point,** from which the relative humidity can be calculated when the air temperature is known. It usually consists of a small metallic cup or thimble, the outside of which is polished like a mirror. The cup contains a small quantity of ether, into which dips a thermometer. Air is bubbled through the ether, whose rapid evaporation lowers the temperature of the cup; when it reaches the dew point of the surrounding air, a film of moisture suddenly appears upon its surface.

Various hygrometers have been designed which depend for their operation upon the longitudinal shrinkage of organic fibers or hairs in damp air, being arranged so that the shrinkage causes a pointer to move over a dial. These instruments, called absorption hygrometers, have not, however, proved reliable and do not give consistent readings. (L.D.W.)

HYGROSCOPE. Meteorological Instruments.

HYMEN. A layer of membranous tissue which almost completely closes the outer opening of the **vagina** during virginity. It may be quite tough or very delicate in structure. In rare cases it completely closes the opening. This latter condition requires surgical interference when menstruation begins. (R.S.M.)

HYMENOPTERA. One of the large orders of **insects,** including **ants, bees, wasps, saw flies,** and many species without common names. The mouth is formed for biting or for biting and sucking and the wings, when present, are four in number and membranous. Metamorphosis is complete. The order includes plant-eating, parasitic, and predacious species, and in the ants and bees displays some of the finest examples of social organization. The order includes about 70,000 species.

Owing to its extent and diversity this division of the insects includes many species of economic importance. Some of the **saw flies** and **gall wasps** are harmful to plants and on the other hand the fig insects are beneficial and the galls produced by some gall wasps are of commercial value. Many parasitic species are of undoubted value in holding in check important insect pests. Ants are sometimes very troublesome and the large carpenter bee sometimes damages wood in construction. The most important single species is the honey-bee, which is of great value as a producer of honey and wax and in the cross pollination of fruit trees. (A.W.L.)

HYOCYAMUS. Potato Family.

HYOSCINE. Alkaloids.

HYOSCYAMINE. Alkaloids.

HYPABYSSAL. A general term sometimes used by structural geologists and petrologists to designate those igneous rocks such as **sills** and **dikes** which have congealed under less pressure than the **plutonic** or deep-seated rocks, but under greater pressure than the effusive rocks (lavas). (R.M.F.)

HYPERBOLA. The hyperbola is one of the conic sections, and may be cut from a right circular cone by a plane which cuts both nappes of the cone.

The hyperbola is the **locus** of a point which moves so that the difference of its distances from two fixed points is **constant.**

The fixed points are called the foci. The curve consists of two open branches. It is symmetric about the line through the foci, and about a line through the center perpendicular to the preceding line; the center is the point midway between the foci. It is also symmetric about the center. (Fig. 1.)

The segment (or length) between the vertices is called the transverse axis; the vertices are the points where the curve is cut by the line through the foci. The constant in the definition of the hyperbola is equal to the transverse axis length. If this transverse axis is $2a$, and the distance between the foci is $2c$, then if $b^2 = c^2 - a^2$, $2b$ is called the conjugate axis (or sometimes the segment

of this length symmetric about the center, and along the line through the center perpendicular to the line through the foci).

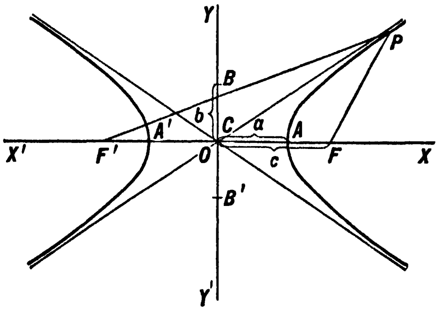

Fig. 1. Hyperbola.

The latus rectum (or focal width) is the chord through the focus perpendicular to the transverse axis.

The eccentricity of the hyperbola is the ratio c/a; it is >1.

If the origin of a system of **rectangular coordinates** is taken at the center of a hyperbola, and the X-axis along the transverse axis, the equation of the curve is

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1,$$

where a and b are the semi-transverse and semi-conjugate axes.

The equation $\frac{x^2}{b^2} - \frac{y^2}{a^2} = 1$ $(a > b)$ represents a hyperbola with foci on the Y-axis.

The lines $x = \pm\frac{a}{e}$ are called the directrices of the hyperbola $\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1$. They have the property that the ratio of the distance of any point of the hyperbola from a focus to the perpendicular distance of the point from the corresponding directrix is equal to the eccentricity.

The equation $\frac{(x-h)^2}{a^2} - \frac{(y-k)^2}{b^2} = 1$ represents a hyperbola with center at (h, k) and axes of symmetry $x = h$, $y = k$.

The hyperbola $\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1$ has the lines $\frac{x}{a} + \frac{y}{b} = 0$ and $\frac{x}{a} - \frac{y}{b} = 0$ as **asymptotes.** (Fig. 2.)

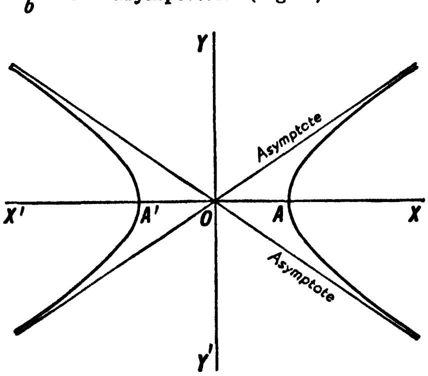

Fig. 2. Hyperbola.

The branches of the hyperbola approach indefinitley near its asymptotes as the tracing point recedes to infinity.

The asymptotes serve as a convenient guide in drawing the hyperbola.

Two hyperbolas are called conjugate hyperbolas if the transverse and conjugate axes of one are, respectively, the conjugate and transverse axes of the other. If $\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1$ is one hyperbola, the conjugate is $\frac{y^2}{b^2} - \frac{x^2}{a^2} = 1$.

Two conjugate hyperbolas have the same asymptotes.

A construction (by continuous motion) based on the definition is the following (Fig. 3): Fasten thumb

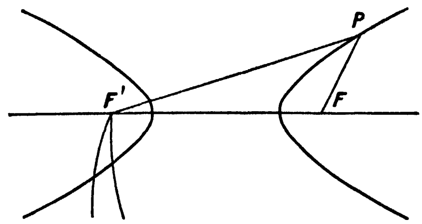

Fig. 3. Construction of hyperbola.

tacks at the foci. Pass over F' and around F a string whose ends are held together. If a pencil is tied to the string at P, and both strings are pulled in or let out the same length, the point P will describe a hyperbola. If the transverse axis is to be $2a$, the strings must be adjusted at the start so that the difference between PF' and PF is $2a$.

An equilateral or rectangular hyperbola is one in which the transverse and conjugate axes are equal. If its center is at the origin and its transverse axis is along the X-axis, its equation is $x^2 - y^2 = a^2$, where a equals the semi-transverse or conjugate axis.

Its asymptotes bisect the quadrants and are therefore perpendicular.

If the hyperbola be referred to its asymptotes as rectangular coordinate axes, its equation becomes $2xy = a^2$. (Fig. 4.)

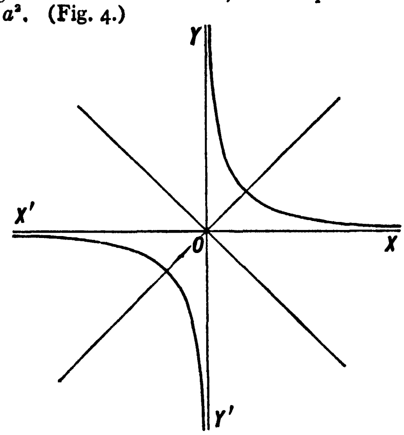

Fig. 4. Hyperbola.

A construction often used for an equilateral hyperbola when the asymptotes and one point A on the curve are given is as follows (Fig. 5):

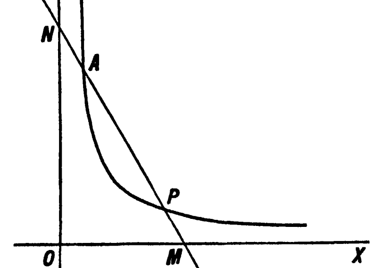

Fig. 5. Construction of hyperbola.

Let OX and OY be the asymptotes and A the given point. Draw any line through A to meet OX at M and OY at N. Lay off $MP = AN$. Then P is a point on the required hyperbola.

The simplest **parametric equations** of a hyperbola are:

$$x = a \sec\phi, \quad y = b \tan\phi,$$

where a and b are the semi-axes, and ϕ is an auxiliary angle.

The equation of the **tangent** to the hyperbola $\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1$ at the point (x_1, y_1) is $\frac{x_1x}{a^2} - \frac{y_1y}{b^2} = 1$.

The equation of the **tangent of slope** m to the hyperbola $\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1$ is

$$y = mx \pm \sqrt{a^2m^2 - b^2}.$$

Applications of the hyperbola are: Boyle's law in physics, and sound ranging. (L.L.S.)

HYPERBOLIC FUNCTIONS. In many applications the **exponential functions** e^x and e^{-x} occur in certain combinations which have many analogies to the **trigonometric functions.** Their geometric representation is related to a **rectangular hyperbola** in a way similar to that in which the trigonometric functions are related to a **circle.** These combinations are therefore called hyperbolic functions.

The hyperbolic functions are defined as follows:

$$\sinh x = \tfrac{1}{2}(e^x - e^{-x}),$$
$$\cosh x = \tfrac{1}{2}(e^x + e^{-x}),$$
$$\tanh x = \frac{\sinh x}{\cosh x} = \frac{e^x - e^{-x}}{e^x + e^{-x}},$$
$$\coth x = \frac{\cosh x}{\sinh x} = \frac{1}{\tanh x} = \frac{e^x + e^{-x}}{e^x - e^{-x}},$$
$$\operatorname{sech} x = \frac{1}{\cosh x} = \frac{2}{e^x + e^{-x}},$$
$$\operatorname{csch} x = \frac{1}{\sinh x} = \frac{2}{e^x - e^{-x}}.$$

From these definitions follows at once:

$$\cosh x + \sinh x = e^x,$$
$$\cosh x - \sinh x = e^{-x}$$

Fundamental relations between these functions are:

$$\cosh^2 x - \sinh^2 x = 1,$$
$$\tanh^2 x + \operatorname{sech}^2 x = 1,$$
$$\coth^2 x - \operatorname{csch}^2 x = 1.$$

For the negative of the variable we have:

$$\sinh(-x) = -\sinh x,$$
$$\cosh(-x) = \cosh x,$$
$$\tanh(-x) = -\tanh x, \text{ etc.}$$

For the hyperbolic functions of the sum of two variables and of double and half the variable, we have the formulae:

$$\sinh(x \pm y) = \sinh x \cosh y \pm \cosh x \sinh y,$$
$$\cosh(x \pm y) = \cosh x \cosh y \pm \sinh x \sinh y,$$
$$\tanh(x \pm y) = \frac{\tanh x \pm \tanh y}{1 \pm \tanh x \tanh y};$$
$$\sinh u + \sinh v = 2 \sinh \tfrac{1}{2}(u + v) \cosh \tfrac{1}{2}(u - v),$$
$$\sinh u - \sinh v = 2 \cosh \tfrac{1}{2}(u + v) \sinh \tfrac{1}{2}(u - v),$$
$$\cosh u + \cosh v = 2 \cosh \tfrac{1}{2}(u + v) \cosh \tfrac{1}{2}(u - v),$$
$$\cosh u - \cosh v = 2 \sinh \tfrac{1}{2}(u + v) \sinh \tfrac{1}{2}(u - v);$$
$$\sinh 2x = 2 \sinh x \cosh x,$$
$$\cosh 2x = \cosh^2 x + \sinh^2 x = 2\cosh^2 x - 1 = 2\sinh^2 x + 1.$$
$$\tanh 2x = \frac{2 \tanh x}{1 + \tanh^2 x};$$
$$\sinh \tfrac{1}{2}x = \pm\sqrt{\frac{\cosh x - 1}{2}},$$
$$\cosh \tfrac{1}{2}x = \sqrt{\frac{\cosh x + 1}{2}},$$
$$\tanh \tfrac{1}{2}x = \pm\sqrt{\frac{\cosh x - 1}{\cosh x + 1}}.$$

The inverse hyperbolic functions are defined as are all **inverse functions.** Thus, if $x = \sinh y$, then we write $y = \sinh^{-1} x$.

We find that the inverse hyperbolic functions can be expressed in terms of **natural logarithms,** as follows:

$$\sinh^{-1} x = \log(x + \sqrt{1 + x^2}),$$
$$\cosh^{-1} x = \log(x \pm \sqrt{x^2 - 1}), \quad x \geqq 1,$$
$$\tanh^{-1} x = \tfrac{1}{2} \log \frac{1 + x}{1 - x}, \quad -1 < x < 1,$$
$$\coth^{-1} x = \tfrac{1}{2} \log \frac{x + 1}{x - 1}, \quad x < -1, \quad x > 1,$$
$$\operatorname{sech}^{-1} x = \log \frac{1 \pm \sqrt{1 - x^2}}{x}, \quad 0 < x < 1,$$
$$\operatorname{csch}^{-1} x = \log \frac{1 + \sqrt{1 + x^2}}{x}.$$

The **derivatives** of the hyperbolic functions and of the inverse hyperbolic functions are:

$$\frac{d}{dx}(\sinh u) = \cosh u \frac{du}{dx}, \quad \frac{d}{dx}(\cosh u) = \sinh u \frac{du}{dx},$$
$$\frac{d}{dx}(\tanh u) = \operatorname{sech}^2 u \frac{du}{dx}, \quad \frac{d}{dx}(\coth u) = -\operatorname{csch}^2 u \frac{du}{dx}$$
$$\frac{d}{dx}(\operatorname{sech} u) = -\operatorname{sech} u \tanh u \frac{du}{dx},$$
$$\frac{d}{dx}(\operatorname{csch} u) = -\operatorname{csch} u \coth u \frac{du}{dx};$$
$$\frac{d}{dx}(\sinh^{-1} u) = \frac{1}{\sqrt{u^2 + 1}} \frac{du}{dx},$$
$$\frac{d}{dx}(\cosh^{-1} u) = \pm \frac{1}{\sqrt{u^2 - 1}} \frac{du}{dx}, \quad |u| > 1$$
$$\frac{d}{dx}(\tanh^{-1} u) = \frac{1}{1 - u^2} \frac{du}{dx}, \quad |u| < 1$$
$$\frac{d}{dx}(\coth^{-1} u) = \frac{1}{1 - u^2} \frac{du}{dx}, \quad |u| > 1$$
$$\frac{d}{dx}(\operatorname{sech}^{-1} u) = \pm \frac{1}{u\sqrt{1 - u^2}} \frac{du}{dx}, \quad 0 < u < 1$$
$$\frac{d}{dx}(\operatorname{csch}^{-1} u) = -\frac{1}{u\sqrt{1 + u^2}} \frac{du}{dx}, \quad u \neq 0.$$

Certain standard **indefinite integral** forms are conveniently expressed in terms of hyperbolic functions, thus:

$$\int \frac{du}{\sqrt{u^2 + a^2}} = \sinh^{-1} \frac{u}{a} + C, \quad a > 0$$
$$\int \frac{du}{\sqrt{u^2 - a^2}} = \pm \cosh^{-1} \frac{u}{a} + C, \quad u > a > 0$$
$$\int \frac{du}{a^2 - u^2} = \frac{1}{a} \tanh^{-1} \frac{u}{a} + C, \quad |u| < a, \quad a > 0$$

$$\int \frac{du}{a^2 - u^2} = \frac{1}{a} \coth^{-1} \frac{u}{a} + C, \quad |u| > a.$$

Expansion of the hyperbolic functions into **series** gives:

$$\sinh x = x + \frac{x^3}{3!} + \frac{x^5}{5!} + \frac{x^7}{7!} + \cdots,$$

$$\cosh x = 1 + \frac{x^2}{2!} + \frac{x^4}{4!} + \frac{x^6}{6!} + \cdots$$

The hyperbolic functions are related to the trigonometric functions by the following formulae, in which $i = \sqrt{-1}$;

$$\sin(ix) = i \sinh x, \quad \cos(ix) = \cosh x,$$

$$\sinh(ix) = i \sin x, \quad \cosh(ix) = \cos x.$$

The graphs of the hyperbolic functions are shown in Figs. 1–3.

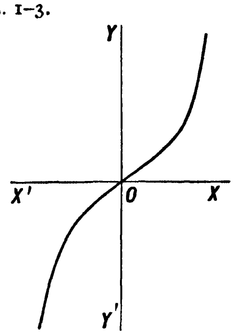

Fig. 1. $y = \sinh x$.

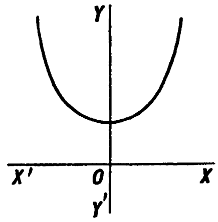

Fig. 2. $y = \cosh x$.

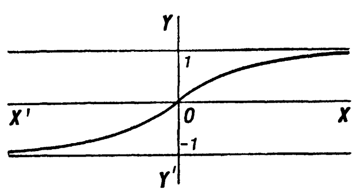

Fig. 3. $y = \tanh x$.

The hyperbolic functions are related to the hyperbola as follows (Fig. 4): Take the rectangular hyperbola

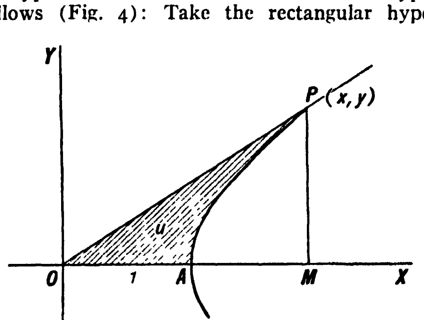

Fig. 4. Hyperbolic sector.

$x^2 - y^2 = 1$, let $P(x, y)$ be any point on the hyperbola, and let u be the area of the sector OAP between the curve, the X-axis and OP. Then

$$x = \cosh 2u, \quad y = \sinh 2u.$$

The function $\tan^{-1}(\sinh x)$ is called the gudermannian of x and is denoted by $\operatorname{gd} x$. Then

$$\frac{d}{dx}(\operatorname{gd} x) = \operatorname{sech} x, \quad \int \operatorname{sech} x \, dx = \operatorname{gd} x.$$

(L.L.S.)

HYPERBOLIC GEOMETRY. **Non-Euclidean Geometry.**

HYPERBOLIC LOGARITHMS. **Logarithms.**

HYPERBOLIC NAVIGATION. The term hyperbolic **navigation** is used to describe the general method for determining a **line of position** by measuring the difference in distance of the navigator from 2 stations of known position.

The difference in distance is determined by measuring the difference in time of arrival of signals transmitted from the 2 stations. Although a great variety of signaling methods are theoretically possible, at the present time only **radio** waves are used in hyperbolic navigation. One system, which uses continuous-wave signals, is known as **Decca.** **Loran** and **GEE** are systems using signals transmitted as pulses.

Since **electro-magnetic** waves travel with a speed of about 186,000 miles per sec., the difference of arrival times of the signals will be very small. The unit of time, which is used in all systems at present, is the microsecond (0.000001 sec.); and a difference of arrival of one of these units indicates a distance difference of 0.186 miles from the 2 transmitters.

From the very nature of the problem the transmission must be made from 2 stations, separated by distances ranging from 75 to 1200 miles, and the synchronization of the two signals is of fundamental importance. One station of each pair is known as the master, and the other as the slave. In some systems, e.g., GEE, 2 or more slave stations may be used with a single master The cycle of transmission always begins at the master station and the signal travels out in all directions. The arrival of the master signal at the slave "triggers off" the slave. This signal in turn travels out in all directions. Operators are continually on watch at both stations, each monitering the signals for the other to detect the slightest variations of frequency of carrier waves, interval between pulse, characteristics of the signals, etc. At the slave station adjustable delay circuits are available so that, once the cycle has been started, the slave station may transmit simultaneously with the master, or be delayed by any desired amount.

Points of constant difference of time of arrival of the 2 signals will fall on spherical hyperbolas with the transmitters at the foci. For navigational purposes we need only to consider the lines of intersection of these surfaces with the surface of the earth. The total number of distinguishable lines in any system is equal to the time required for the signal to travel from the master to the slave and back again, divided by the smallest time interval that can be measured by the receiving equipment. This number is different for the various systems in use, being about a thousand for GEE and eight or ten thousand for Loran and Decca. Certain fundamental lines, representing integral multiples of distance or time difference, are superimposed on regular navigational charts. Such a family of curves is shown in Fig. 1. Tables are also published which contain the data for determining the fundamental lines. By graphical interpolation on the chart, or mathematical interpolation from the tables, the navigator can determine a hyperbolic line of position, using the observed difference in time of arrival of the signals, and the particular stations being used. The accuracy of this line varies from about 200 yards up to 2 miles, depending upon the distance of the observer from the base line between stations, and upon the type of equipment and system being used.

Although the navigator's equipment differs in details for GEE, Decca, and Loran, nevertheless the fundamental characteristics of all are the same. For all systems a simple single wire antenna is sufficient. The receiver is a good quality radio receiver which contains amplifiers of high fidelity. The indicating system must contain a timing system employing a crystal oscillator and this must

be capable of maintaining stability to within a few parts in a million for periods of a few minutes. Manual controls are provided for adjusting the timing equipment

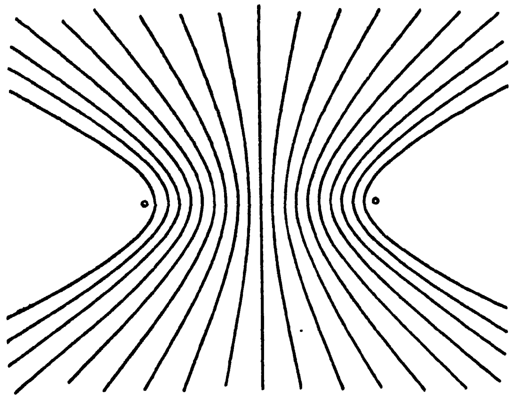

Fig. 1.

into exact step with the received signals. The signals themselves are "seen" on the viewing plate of a **cathode ray tube,** known as an oscilloscope or "view scope." Sweep generators, controlled by the oscillator, send traces across the face of the cathode tube The time required for these traces to cross the viewing disk may be adjusted to various specified values for various stages in the process of measuring the difference of arrival time of the signals. The signals themselves appear as "pips" on the sweep traces. At low sweep speed these "pips" appear as short lines standing above or below the horizontal sweep line. With high sweep speed the pips are drawn out to indicate the actual characteristics of the received signals. Time indicators, governed by the oscillator, may be set up along the sweep lines and the time differences seen directly. For more accurate readings calibrated delay circuits may be used to bring the pips, magnified by high-speed sweeping, into coincidence. More detailed discussion of the methods of time measurement will be found in the articles dealing with the individual systems (see GEE, Decca, Loran).

Fig. 2 indicates a **fix** as determined by a hyperbolic navigation system employing 1 master station, M, and

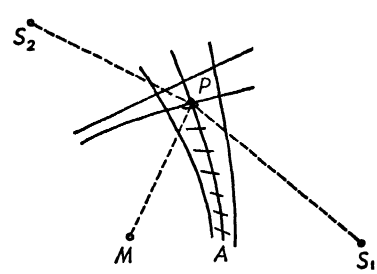

Fig. 2.

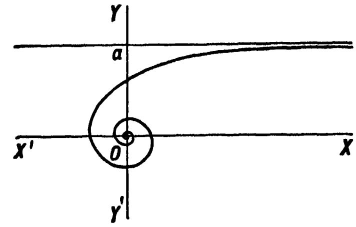
2 slaves, S_1 and S_2, as in GEE navigation. The diagram also indicates the value of hyperbolic navigation for "homing" on a point A. The navigator obtains a fix at P and then sets his indicating equipment so that the pips from M and S_1 are in coincidence on the view scope. He then heads his plane or ship so that these pips remain in coincidence and he must be following the hyperbola PA. By taking observations on the M S_2 pair at intervals he can determine the rate at which he is approaching his objective. (W.K.G.)

HYPERBOLIC PARABOLOID. **Paraboloids.**

HYPERBOLIC SPIRAL. The plane curve whose polar coordinate equation is $r\theta = a$ is called a hyperbolic spiral. It is shown in the accompanying figure. (L.L.S.)



Hyperbolic spiral.

HYPERBOLOIDS. The hyperboloids are certain types of mathematical surfaces in which certain characteristic sections are hyperbolic curves.

The **surface** represented in **rectangular coordinates** by the equation

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} - \frac{z^2}{c^2} = 1$$

is called an (elliptic) hyperboloid of one sheet; its sections parallel to the coordinate planes are: one set elliptic and two sets **hyperbolic.** (Fig. 1.)

If $a = b$, one set of sections becomes circular and we have a hyperboloid of revolution (of one sheet), which may be obtained by revolving a **hyperbola** about its conjugate axis.

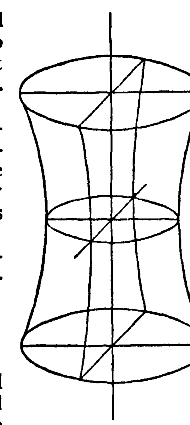


Fig. 1. Hyperboloid of one sheet.

The surface represented in rectangular coordinates by the equation.

$$\frac{x^2}{a^2} - \frac{y^2}{b^2} - \frac{z^2}{c^2} = 1$$

is called an (elliptic) hyperboloid of two sheets; its sections parallel to the coordinate planes are: one set elliptic and two sets hyperbolic. (Fig. 2.)

If $b = c$, one set of sections becomes circular, and we have an hyperboloid of revolution (of two sheets), which

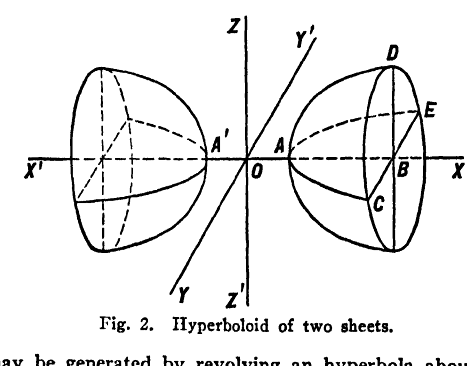

Fig. 2. Hyperboloid of two sheets.

may be generated by revolving an hyperbola about its transverse axis. (L.L.S.)

HYPERBOLOIDS OF REVOLUTION. **Hyperboloids.**

HYPERCOMPLEX NUMBERS. A hypercomplex number is a number represented by a form $x = x_1e_1 + x_2e_2 + \cdots + x_ne_n$, in which $x_1, x_2, \cdots, x_n$ are ordinary

real or complex numbers, and $e_1, e_2, \cdots, e_n$ are n independent units. (L.L.S.)

HYPERFINE STRUCTURE. Many spectrum lines, when examined under high resolution, turn out to be "multiplets," i.e., to be composed of two, three, four, or more, closely packed, fine lines. (See **Atomic Spectra.**) This multiplicity is attributed to a quantization (successive, finite differences) in the energy of rotation of the atomic nucleus. Abrupt changes in this energy take place simultaneously with the much larger electronic transitions which determine the location of the multiplet as a whole. The rotational quantization thus results in slight differences in the total energy of the emitted quanta, and hence in a group of different frequencies. Atomic spectra often have series of multiplets. For example, the two D lines of sodium belong to a series of doublets. Hartley (1883) found that all the multiplets of a given series have the same frequency separations between their components. Kossel and Sommerfeld pointed out that the arc spectra of elements of even **atomic number** have odd multiplets and vice versa. Thus sodium (atomic number 11) exhibits doublets, and zinc (30), triplets. (See also **Zeeman Effect and Stark Effect.**) (L.D.W.)

HYPERGEOMETRIC PROBABILITY FUNCTION. Let

$$P_x = \frac{{}_{Tp}C_x \cdot {}_{Tq}C_{N-x}}{{}_{T}C_N},$$

$x = 0, 1, 2, \cdots N$ or T_p whichever is smaller, N is the number of **variates** in the **sample** chosen from a **population** of T variates consisting of Tp variates of one kind termed "success" and Tq items of another kind termed "failure." We may interpret P_x as the **probability** of obtaining x successes when sampling from such a population as described above. The mean of the hypergeometric probability function is Np, the variance is $Npq\left(\frac{T-N}{T-1}\right)$. The hypergeometric function reduces to the **Bernoulli probability function** when T approaches infinity, and when $N = 1$. In case T is large and p is small, the **Poisson probability function** may be used as an approximation to the hypergeometric probability function. The hypergeometric function has applications in **industrial statistics**, in sampling from a finite population, and has served as a basis of the **Pearson system** of **probability functions.** (L.A.A.)

HYPERHARMONIC SERIES. The infinite series $\sum_{1}^{\infty} 1/n^p$ is called the hyperharmonic series; it is **convergent** when $p > 1$ and is **divergent** when $p \leqq 1$. (L.L.S.)

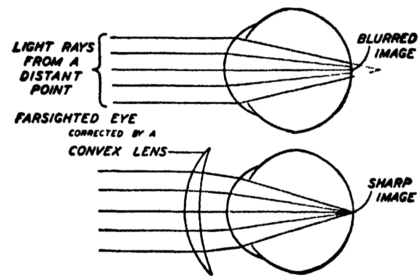
HYPERMASTIGIDA. **Mastigophora.**

HYPERMETROPIA. **Vision.**

HYPERNASTY. **Movement in Plants.**

HYPEROARTIA. **Cyclostoma.**

HYPEROPIA (Farsightedness). A decrease in the refractive power of the eye so that rays of light coming from nearby objects cannot be focused on the retina, but those coming from distant objects can be properly refracted. As a result, close images are blurred while distant ones are clear. The cause may be too shallow an eyeball, or not a great enough convexity of the lens (see **Eye, Vision**). The defect is corrected by means of glasses having convex lenses. (D.M.H.)



(Carlson and Johnson's The Machinery of the Body, University of Chicago Press.)

HYPEROTRETA. **Cyclostoma.**

HYPERSENSITIZING OF EMULSIONS. The sensitiveness of photographic emulsions may be increased, i.e., the time of exposure reduced, (1) by bathing in ammonia or hydrogen peroxide before exposure, (2) by prolonged exposure to a weak source of light, (3) by exposure, either before or after exposure in the camera, to mercury, or to acetic acid. The increase in sensitivity in all cases varies greatly with different emulsions, some showing no appreciable increase.

Hypersensitizing with ammonia is generally unsatisfactory because of the increased fog and the necessity of using the material immediately after treatment to avoid heavy fog and loss in speed. Hydrogen peroxide is too unreliable for practical use as a hypersensitizer.

The effective speed of some medium-speed panchromatic materials is increased from 2–4 times when exposed from 30–60 minutes to light of such intensity as to produce a **fog density** of about 0.2. The increase in speed is obtained only if the general exposure is given *after* exposure in the camera.

Exposure of either the exposed or unexposed emulsion in a sealed container to a small quantity of mercury for 36–72 hours at room temperature increases the speed by as much as 100% in some cases. While convenient, the utility of the method is limited as high-speed films show an appreciable increase in fog.

Muller and Bates of the Ansco Research Laboratories have discovered that many modern high-speed emulsions are increased in speed if exposed to 1% acetic acid and formic acid in equal quantities for 1–2 hours directly before development. The degree of hypersensitizing increases with the time up to a maximum which varies with the emulsion and the temperature. Prolonged exposure results in softening of the gelatin and an actual loss in speed.

The increase in speed is confined principally to the lower densities, becoming progressively less as the density increases. (C.B.N.)

HYPERSTHENE. The mineral hypersthene is an **orthorhombic pyroxene,** chemically a ferro-magnesian silicate, differing from enstatite in that the **iron** content is considerable (FeO being greater than 15%). It is usually found as a massive mineral, whose crystals tend to be prismatic or tabular in habit. It has a distinct prismatic **cleavage; fracture,** uneven; brittle; hardness, 5–6; specific gravity, 3.4–3.5; luster, pearly to somewhat metallic; color, brownish-green, brown, greenish-black to grayish-black; streak, grayish-brown; translucent to opaque. Hypersthene is often associated with **labradorite in gabbro** and **norite** and in extrusive rocks like **andesite.** It is occasionally encountered in **meteorites.** Hypersthene is associated with **pyrrhotite** in Bavaria, with labradorite on the Isle St. Paul, Labrador. It is also found in Montmorency County, Quebec; and in the United States in the rocks of the **Cortlandt series in the Hudson River Valley,** and the **andesites** of Colorado and northern California. The

word hypersthene comes from the Greek words meaning *strong* or *tough*. (E.S.C.S.)

HYPERTENSION. Hypertension means high blood pressure. It is a common sign and may have many causes. The chief types of hypertension are those associated with (1) kidney disease; (2) arteriosclerosis; and (3) essential hypertension, which is not secondary to any of the known conditions causing elevation of the blood pressure. These three forms can, and often do, overlap one another, which accounts for the difficulty and confusion in classification. The end picture of hypertension from any cause is much the same: the heart is enlarged and the vascular system almost invariably shows some arteriosclerosis; the kidneys are always involved, with damage to the glomeruli, and degenerative changes in the kidney vessels.

1. Kidney disease, inflammatory, obstructive and vascular, is accompanied by hypertension. It is a transient feature of acute nephritis and a constant one in chronic nephritis. Chronic **pyelonephritis** of bacterial origin eventually leads to hypertension. The vascular type of nephritis, nephrosclerosis, is characterized pathologically by degenerative changes in the small vessels of the kidney, the arterioles, and clinically by the various manifestations of hypertension.

2. Arteriosclerosis, as is seen almost uniformly in old age, is often accompanied by mild elevation of the blood pressure, usually unassociated with symptoms.

3. Essential hypertension is a clinical term which covers a variety of types of cases not included in (1) and (2). Benign essential hypertension is a chronic, slowly progressing disease, while the so-called malignant form may occur early in life and run an extremely rapid and severe course. The benign form after a number of years of mild severity may suddenly change and run the course of malignant hypertension. Both forms eventually lead to death from heart disease in 60% of cases, from cerebral hemorrhage or thrombosis (stroke) in 20%, and from uremia in 10%. Nevertheless, long life, even in the face of very high blood pressure, is not uncommon.

The signs and symptoms of hypertension are the same regardless of cause, and vary with the degree of elevation of pressure. Headaches, dizziness, and loss of a sense of well being are early symptoms. Cardiac symptoms eventually occur as enlargement of the heart and strain on its capacities develop: **dyspnoea**, cough, paroxysms of shortness of breath, and finally congestive heart failure appear. Renal failure and uremia are often terminal. In malignant hypertension, particularly, hemorrhages into the retina of the eye and white spots or scars in the eye grounds are common.

The treatment of hypertension is symptomatic. If the patient is a hard-driving, overactive individual, helping him adjust to a slower pace is one of the most important aspects of therapy. Rest, sedation and reduction in weight if the patient is obese are useful. When congestive failure develops, **digitalis** is given, as well as **diuretics**, and other measures to regulate fluid balance. (D.M.H.)

HYPERTHYROIDISM. **Thyroid Gland.**

HYPERTROPHY. This is the excessive growth or development of any part of an organ or organism. (R.M.W.)

HYPHA. **Basidomycetes.**

HYPIDIUM. **Pleistocene.**

HYPNOSIS. The induction by psychical means of a state resembling sleep. The subject to be hypnotized usually lies in the recumbent position and is directed to fix his attention on some object. The psychiatrist repeats over and over in a monotonous manner that the individual is growing tired, drowsy, sleepy. By this means a trancelike state of varying depth is induced; the conscious mind of the individual is in abeyance, and he is in complete obedience to the commands of the hypnotist. The value of this state therapeutically is that it is the most effective way of employing suggestion. The patient is highly receptive; since his critical faculties are not operating he cannot reject the statements and suggestions made by the hypnotist.

Hypnosis is particularly useful in the treatment of hysteria (see **psychoneurosis**). An hysterical paralysis, or hysterical blindness, often clears completely under the influence of suggestion while the patient is under hypnosis; this is accomplished by the therapist's repeating over and over that the limb is well, or the eyes see. The connotation of mysticism and an evil spell that shrouded the practice of hypnosis in the early days is unjustified. Hypnotism is now recognized as a useful psychotherapeutic measure although its application is limited to the treatment of very few conditions. (D.M.H.)

HYPNOTIC. Any remedy or **drug** used to induce or maintain sleep. Drugs of this order produce their effect by depressing the higher centers of the **brain,** the excitability of which often prevents sleep. Because of the nervous factors involved in insomnia the taking of hypnotic drugs may lead to a drug habit. The commonly employed hypnotics are chloral hydrate, paraldehyde, the bromides, barbital and its derivatives. (D.M.H.)

HYPO. **Sodium Thiosulfate.**

HYPO ELIMINATORS. Hypo is removed readily from films and plates by washing in water and, consequently, there is little need for a hypo eliminator. Where water is scarce, or the time of washing must be short, a 3% solution of ammonium hydroxide may be useful in removing the last traces of hypo. After washing for 10 minutes, the negatives are placed in the hypo eliminator for 3 minutes and then washed for 3 minutes.

The investigations of Crabtree, Eaton and Muehler have shown that the last traces of hypo cannot be removed from photographic papers by washing in water and the use of a hypo eliminator is necessary if the highest degree of permanency is desired.

The hypo eliminator recommended is as follows:

Water	400 cc.	16 oz.
Hydrogen peroxide (3% sol) . . .	125 cc.	4 oz.
Ammonia (3% sol)	100 cc.	3¼ oz.
Water to make	1 liter	32 oz.

One gallon (4 liters) of this solution, *which should be used but once,* is sufficient for 50 8 x 10″-prints or their equivalent.

The prints should first be washed for 30 minutes, then placed in the hypo eliminator for 6 minutes and washed again for 10 to 15 minutes.

The slight yellowing of the highlights which occurs on some papers may be removed by placing the prints in a 1% solution of sodium sulfite upon their removal from the eliminator. (C.B.N.)

HYPOBROMITE. **Hypobromous Acid and Hypobromites.**

HYPOBROMOUS ACID AND HYPOBROMITES. Hypobromous acid (HOBr) is a yellow solution, of characteristic odor. It is unstable and when distilled under reduced pressure solutions containing only less than 1% can be obtained; decomposes into **bromine** and **bromic acid,** completely at 60° C. into bromine (and water).

Prepared by reaction (1) of bromine and mercuric oxide suspension in water, mercuric bromide being simultaneously formed, (2) of sodium hypobromite and an acid, excess acid yielding bromine.

Sodium hydroxide solution reacts with bromine to form bromide and hypobromite.

Sodium hypobromite solution reacts with ammonium salts or urea yielding nitrogen gas quantitatively. (R.K.S.)

HYPOCHLORITE. **Hypochlorous Acid and Hypochlorites.**

HYPOCHLOROUS ACID AND HYPOCHLORITES. Hypochlorous acid (HOCl) is a yellow solution of characteristic odor. It decomposes upon standing, the rate depending upon the concentration; the exposure to light; upon the presence of a **catalyst,** such as cobaltous hydroxide (see **Cobalt**), which promotes the evolution of oxygen; and upon the acidity or alkalinity. A powerful oxidizing agent, e.g., manganous chloride solution changed to **manganese** dioxide, insoluble, by calcium or sodium **hypochlorite,** and prolonged boiling yields green manganate solution or pink permanganate solution; and bleaching agent for many organic colors.

Prepared by the reaction (1) of **chlorine** monoxide (Cl_2O) and water, (2) of sodium hypochlorite and an acid, excess acid yielding **chlorine** and oxygen, (3) of chlorine and mercuric (see **Mercury**) oxide suspension in water, mercuric chloride being simultaneously formed.

All hypochlorites are soluble in water, and the solutions are decomposed at 100° C. to form the corresponding chlorate and chloride. The most important hypochlorites are those of sodium, calcium, and silver, which last substance decomposes quickly to form silver chloride, white precipitate, and silver chlorate in solution. Sodium hydroxide solution reacts with chlorine to form chloride and hypochlorite. Sodium hypochlorite solution reacts with ammonium salts or urea yielding nitrogen gas quantitatively. A common means of detecting hypochlorites is the production of a blue color (caused by free **iodine**) with starch iodide paper by hypochlorites in weakly alkaline solution. Again, **silver** nitrate solution precipitates part of the hypochlorite as white silver chloride. (R.K.S.)

HYPOCHONDRIA. Undue anxiety about one's own health, often accompanied by simulated symptoms of disease. Hypochondria is common in the psychoneurotic. (D.M.H.)

HYPOCOTYL. **Seed.**

HYPOCYCLOID. A hypocycloid is a type of mathematical plane curve defined as follows:

If a circle of radius b rolls upon the interior of a fixed circle of radius a, a point on the first circle describes a hypocycloid (Fig. 1). Its **parametric equations** are:

$$x = (a - b)\cos\theta + b\cos\left(\frac{a-b}{b}\theta\right),$$

$$y = (a - b)\sin\theta - b\sin\left(\frac{a-b}{b}\theta\right).$$

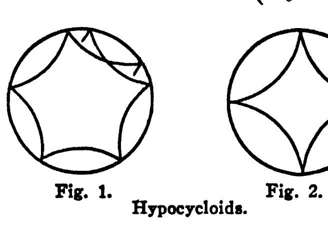


Fig. 1. Fig. 2.
Hypocycloids.

When $a = 4b$, we get the hypocycloid of four cusps, also called the astroid (Fig. 2). Its equation in **rectangular coordinates** is

$$x^{2/3} + y^{2/3} = a^{2/3}.$$

It has **parametric equations** of the form $x = a\cos^3\phi$, $y = a\sin^3\phi$. (L.L.S.)

HYPODERMIS. The cellular layer of the integument (**integumentary system**) in the invertebrates, which secretes the outer **cuticula.** (A.W.L.)

HYPOGENE. Originated by the geologist Charles Lyell for all **igneous** rocks which assumed their **form, fabric** and **texture** at great depths beneath the surface of the **lithosphere.** (See also **Plutonic.** Contrast with **Hypabyssal.**) (R.M.F.)

HYPOGYNY. **Fruit.**

HYPOID GEARING. **Bevel Gearing.**

HYPOIODITE. **Hypoiodous Acid and Hypoiodites.**

HYPOIODOUS ACID AND HYPOIODITES. Hypoiodous acid (HOI) is a greenish yellow solution, of characteristic odor. It is unstable, and cannot be distilled unchanged.

Prepared by reaction (1) of **iodine** and mercuric oxide (see **Mercury**) suspension in water, mercuric iodide being simultaneously formed, (2) of sodium hypoiodite and an acid, excess acid yielding iodine.

Sodium hydroxide solution reacts with iodine to form iodide and hypoiodite, the latter decomposing in a few hours at ordinary temperatures to form iodide and iodate. (R.K.S.)

HYPONITROUS ACID AND HYPONITRITES. Hyponitrous acid ($H_2N_2O_2$) is a white solid, explosive even at as low a temperature as 0° C., soluble in water, more soluble in ether, can thus be extracted from water solution by ether and the latter evaporated, water solution decomposes quickly into nitrous oxide plus water. Hyponitrous acid is non-reactive with **hydriodic acid** (a strong reducing agent), but reactive with permanganic (see **Manganese**) acid (a strong oxidizing agent) to form **nitrous** or **nitric acid.**

Prepared (1) by reaction of **silver** hyponitrite ($Ag_2N_2O_2$) and **hydrogen chloride** in anhydrous ether, and evaporation of the resulting solution, (2) by reaction of **hydroxylamine** (H_2NOH) plus **nitrous acid** (HONO).

Sodium hyponitrite ($Na_2N_2O_2$) is formed (1) by reaction of **sodium** nitrate or nitrite solution with sodium amalgam (sodium dissolved in mercury), after which **acetic acid** is added to neutralize the alkali. Sodium stannite (see **Tin**), **ferrous** hydroxide, or **electrolytic** reduction with mercury cathode may also be utilized, (2) by reaction of hydroxylamine sulfonic acid and sodium hydroxide. Silver hyponitrite is formed by reaction of silver nitrate solution and sodium hyponitrite. (R.K.S.)

HYPOPHARYNX. A protuberance on the floor of the mouth of **insects.** It is somewhat similar to the tongue of vertebrates and is sometimes called the lingua. (A.W.L.)

HYPOPHOSPHORIC ACID AND HYPOPHOSPHATES. Hypophosphoric acid (H_2PO_3 or $H_4P_2O_6$) is a solid, melting point 55° C., decomposing in solution to form **phosphorus** plus **phosphoric acids.** Hypophosphoric acid is used in solution and is a reducing agent, but only with strong oxidizing agents, such as **potassium** permanganate; and the acid is unaffected by zinc and dilute **sulfuric acid** (distinction from phosphorous acid). Dehydration of hypophosphoric acid **does not yield phosphorous tetroxide; hydration of**

phosphorous tetroxide does not yield hypophosphoric acid but phosphorous plus phosphoric acids.

Hypophosphoric acid is formed by reaction (1) of yellow phosphorus and potassium permanganate in sodium hydroxide medium, (2) of red phosphorus and calcium hypochlorite solution, (3) also one of the products of slow oxidation at ordinary temperatures of phosphorus in moist air.

There are recorded the following sodium hypophosphates: Na_2PO_3 (or $Na_4P_2O_6$), $NaHPO_3$ (or $Na_2H_2P_2O_6$), $Na_3H(PO_3)_2$ (or $Na_3HP_2O_6$), $NaH_3(PO_3)_2$ (or $NaH_3P_2O_6$); and the dimethyl ester of hypophosphoric acid: $(CH_3O)_2PO$. There is evidence in support of each of the formulas H_2PO_3, $H_4P_2O_6$ for hypophosphoric acid.

Ester: Dimethyl hypophosphate ($(CH_3)_2PO_3$ or $(CH_3O)_2PO$). (R.K.S.)

HYPOPHOSPHOROUS ACID AND HYPOPHOSPHITES. Hypophosphorous acid (H_3PO_2, or $H \cdot PO_2H_2$) is a colorless liquid, melting point 26.5° C., density 1.493.

Hypophosphorous acid is miscible with water in all proportions and a commercial strength is 30% H_3PO_2. Hypophosphites are used in medicine.

Hypophosphorous acid is a powerful reducing agent, e.g., with **copper** sulfate forms cuprous hydride (Cu_2H_2), brown precipitate, which evolves hydrogen gas and leaves copper on warming; with **silver** nitrate yields finely divided silver; with **sulfurous acid** yields sulfur and some hydrogen sulfide; with **sulfuric acid** yields sulfurous acid, which reacts as above; forms **manganous** immediately with permanganate.

Hypophosphorous acid is formed by reaction of **barium** hypophosphite and sulfuric acid, and filtering off barium sulfate. By evaporation of the solution in vacuum at 80° C., and then cooling to 0° C., hypophosphorous acid crystallizes.

Sodium hypophosphite ($NaPO_2H_2$), the only sodium hypophosphite, is formed (1) by reaction of yellow **phosphorus** and sodium hydroxide solution (phosphine simultaneously formed), (2) by reaction of hypophosphorous acid and sodium hydroxide, and evaporating. Sodium hypophosphite, upon heating, yields sodium phosphate and sodium phosphide. Common tests for the hypophosphites are as follows:

1. Zinc reduces dilute **sulfuric acid** solution of hypophosphites to **phosphine** recognizable by odor (difference from phosphates).
2. **Barium** chloride produces no precipitate (difference from phosphites). (R.K.S.)

HYPOPHYSIS. An **endocrine gland** attached to the ventral surface of the brain, also called the **pituitary gland.** (A.W.L.)

HYPOPUS. A larval form of certain **mites.** It has eight legs but no mouth. Ventral suckers enable it to attach itself to another animal for transportation. (A.W.L.)

HYPOPYGIUM. The protruding male genital organs of some flies. In some species they form a conspicuous appendage at the tip of the abdomen, much like an additional segment. (A.W.L.)

HYPOSTOME. A projection at the free end of the body of a **hydroid** polyp in which the mouth opens. (A.W.L.)

HYPOSULFUROUS ACID AND HYPOSULFITES. Hyposulfurous acid ($H_2S_2O_4$) is a yellow solution rapidly oxidized in air to sulfurous acid and then to sulfuric acid. Commercially known as hydrosulfurous acid and its salts as hydrosulfites (but not to be confused with "hypo" which is sodium thiosulfate).

Hyposulfurous acid is a powerful reducing agent, e.g., with **copper** sulfate forms cuprous hydride (Cu_2H_2), brown precipitate, which evolves hydrogen gas and leaves copper on warming, with **silver** nitrate yields finely divided silver, with permanganate yields **manganous.** Hyposulfurous acid is formed by reaction of sodium hyposulfite and an acid.

Sodium hyposulfite, sodium hydrosulfite ($Na_2S_2O_4 \cdot 2H_2O$) is formed (1) by reaction of **zinc** and **sulfurous acid** (or sodium hydrogen sulfite), yielding zinc hyposulfite and then converted by sodium chloride into sodium hyposulfite, (2) by **electrolysis** of sodium hydrogen **sulfite** and then addition of sodium chloride.

Sodium hyposulfite is used to bleach sugar, indigo, wood pulp. With moist **hydrogen sulfide, sulfur** is precipitated and sodium thiosulfate simultaneously formed. (R.K.S.)

HYPOTHYROIDISM. Thyroid Gland.

HYPOTRICHIDA. Ciliata.

HYPOTYPE. A species identified in print as belonging to the species in question. (R.M.F.)

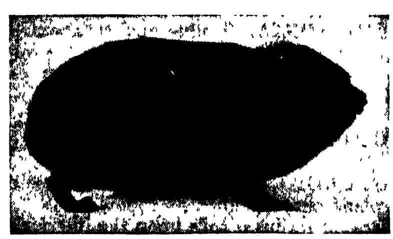
HYPOXANTHINE. Alkaloids.

HYRACODON. Oligocene.

HYRACOIDEA. The hyraces, less properly called the coneys. They are small animals, superficially resembling rodents. The fore feet have four toes and the hind feet three, part of them with nails instead of claws. The several species live throughout Africa and some extend north to Syria. An order of **mammals.** (A.W.L.)

HYRACOTHERIUM (Eophippus). Fossil Mammals.

HYRAX. Mammalia, Hyracoidea. Any of the small animals of this order. There are two genera, *Procavia,* which includes the **cony,** and *Dendrohyrax.* (A.W.L.)



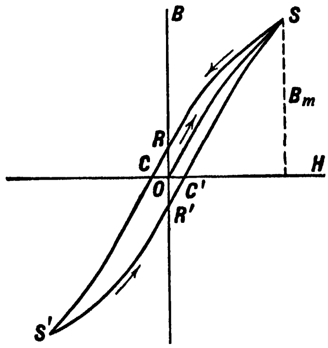
Hyrax. (*N. Y. Zool. Soc.*)

HYSTERECTOMY. The operation of removing the **uterus.** This is usually done by a lower abdominal incision, although in certain instances it has been removed by the vaginal route. Hysterectomy is usually performed for **cancer** or **fibroid tumors of the uterus.** (R.S.M.)

HYSTERESIS. This term usually refers to magnetic hysteresis, of importance in **alternating-current** machinery. When a ferromagnetic material such as iron is placed in a magnetic field, a certain amount of energy is involved in bringing about its magnetization. If the field is a rapidly alternating one, the material may become noticeably warm. It appears that the repeated changes of orientation in whatever it is within the substance that responds to the reversals of field are opposed by something like viscous friction.

A quantitative study of the process indicates that, as the field intensity H increases, the magnetic induction B

also increases in a manner characteristic of the substance. This is conveniently represented by a graph, such as *OS* (see figure). Upon reducing the intensity *H*, the induc-



Typical *B-H* hysteresis curve for a ferromagnetic material.

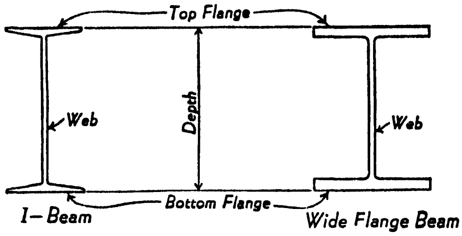
tion *B* does not fall off as it was built up, but follows a different course, *SRC*, so that there is some residual induction *OR* even when *H* has fallen to zero. A reverse intensity *OC*, called the coercive force, must be applied to demagnetize the material completely. From this point the cycle proceeds over the path *CS'R'C'S*, thus completing a closed curve called a hysteresis loop The initial graph *OS* is not retraced. The amount of energy converted into heat during the cycle is proportional to the area of the loop. Steinmetz found that this energy is represented by the formula $aB_m^{1.6}$ in which B_m is the maximum induction during the cycle, and *a* is a constant for the given material, called the Steinmetz coefficient. An instrument known as a hysteresigraph has been devised to trace hysteresis loops automatically for any specimen of magnetic material under test.

Electric hysteresis is a somewhat analogous phenomenon exhibited by **dielectrics** in the electric field and gives rise to heating in a-c condensers.

Some solids exhibit what is called elastic hysteresis, in which the variables corresponding to *H* and *B* in the magnetic case are the stress and the strain or deformation. Elastic bodies such as metals operating at stresses below the **proportional limit** also undergo hysteresis. If *B* represents positive or tensile stress and *H* represents positive strain or elongation, the action of an elastic metal under cyclic or reversed stress can be represented by *OSC'S'CS*. By definition of the proportional limit the line *OS* should be straight; however, highly sensitive measurements show a slight curvature, leading to the development of a loop of appreciable thickness. The area within the loop is proportional to the loss of energy in a complete cycle of reversed stress. If it were not for this loss in energy even in the most perfect elastic bodies, **perpetual motion** might be possible in a tuning fork or spring vibrating in a vacuum. (See also **Damping.**)
(L.D W., R.H.H.)

HYSTERIA. **Psychoneurosis.**

I-BEAM. An I-beam is a structural shape whose cross-section resembles the capital letter I. The I-beam is rolled from **steel** for ordinary use. **Aluminum** is sometimes used where the structure must be exceptionally light as in the case of bridge floors. Brass and other materials are also used. The size is designated by its over-all depth from the top of the top **flange** to the bottom of the lower flange, and by its weight per ft. of length. A beam of this shape has a disposition of material such as to allow the material to be stressed most efficiently, thus reducing waste due to inclusion of



slightly stressed material. A beam, carrying **load,** deflects slightly, which puts part of the beam in compression and part in tension. The farther a given amount of beam material is from the **neutral axis,** the more effective it is in resisting load. (See **Flexure** theory.) The I-beam with its two flanges, connected by a thin vertical web, provides the proper resistance to load with a minimum of material. When the proportions of width to depth are nearly equal the beam is known as an H beam. Another type of I-shape beam is called the wide flange beam. This is a popular shape for building columns and floor beams. (C.W.C., F.T.M.)

IBEX. Mammalia, Artiodactyla. **Goats** of several species, all with very large horns in the male sex. The species found in the Alps is also called the steinbok or

Asiatic ibex. (*Field Museum of Natural History.*)

bouquetin, ***Capra ibex,*** and the Arabian species is called the beden. Others live in Egypt and the Himalayas. (A.W.L.)

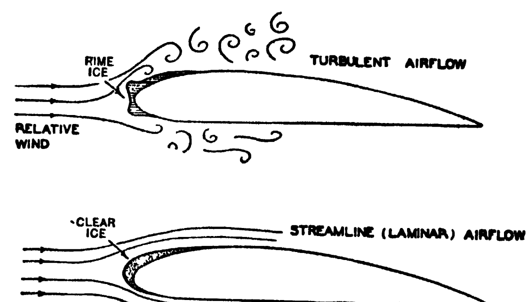
IBIS. Aves, Ciconiiformes. *Ibis.* Long-legged wading birds (**Aves**) with long curved beaks. Related to the storks. The numerous species occur in all continents. (A.W.L.)

ICE. A natural (mineral) form of water, H_2O. Crystallizes in the hexagonal system as snow flakes, or hail. (See **Glaciation.**) (R.M.F.)

ICE CALORIMETER. Calorimetry.

ICE CRYSTAL CLOUDS. At temperatures below about 15° F. water vapor changes to solid water directly without the intermediate liquid water stage. Cloud particles form directly on sublimation nuclei as ice crystals, and such clouds are then composed of ice crystal particles. Cirro-form clouds are of the ice crystal group. (P.E.K.)

ICE FORMATION ON AIRCRAFT. Liquid droplets can remain liquid at temperatures well below 32° F. but, when such supercooled droplets are disturbed, they freeze almost instantly. Both cloud droplets and rain drops appear in the atmosphere at temperatures below 32° F. and both present considerable hazard to aircraft in flight because the drops and droplets impinging on the craft freeze to it and form a layer of glaze which not only weights the plane but alters the leading edge of the wings to destroy lift. Very small cloud droplets



Ice formation on an airfoil.

tend to flow around the surface of an aircraft with the **airstream** and therefore present no great hazard. Small cloud droplets are found primarily in stratus clouds and in stable air.

Intermediate-size drops penetrate the friction layer and impinge on the aircraft surfaces but may not break upon impact. They freeze where they strike and form a rough, irregular, opaque rime ice coating which usually is not too difficult to break with de-icer boots.

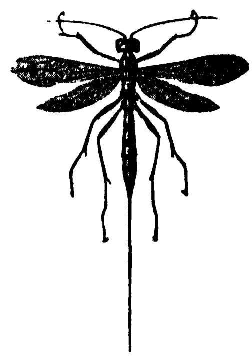
On initial impact, large drops break and freeze but, in freezing, release enough heat of fusion to warm remaining parts of the drops somewhat. At temperatures usually encountered, the warmed part of a drop actually reaches a temperature of 32° F. and then tends to flow along the surface of the craft in a thin film which freezes rapidly due to exposure to the air, as well as evaporation. This conversion process takes place quite quickly but it does permit the formation of two different types of ice Ice formed on initial impact is predominately non-crystalline and opaque rime ice; ice formed from the remainder of the drop is usually crystalline and clear. The temperature of the droplets or drops, therefore, determines primarily the type of ice that will be predominant, although both types form over a wide range of temperatures. At temperatures of 32° F. or less, down

to about 28° F., clear ice is predominant; at temperatures below 15° F. rime is predominant.

Water droplets grow largest in rising currents of air. Cumulus clouds which grow in rising currents, orographically lifted clouds, and frontal clouds, therefore, are the most serious cloud icing hazards, although icing does occur in other types of clouds. Icing in supercooled rain drops is always a serious hazard because the total water (which forms ice) intercepted by the craft is considerable and all that impinging on the craft's surfaces adheres as ice in one form or other. Cold air regions beneath warm frontal surfaces are the most serious icing regions of freezing rain. (P.E.K.)

ICELAND MOSS. **Lichens.**

ICELAND SPAR. Calcite.



Ichneumon fly.

ICHNEUMON. 1. Insecta, Hymenoptera. Any **insect** of a large number of species which live as parasites on other insects in the larval stage. They resemble wasps in appearance. 2. Mammalia, Carnivora. The Egyptian **mongoose**, ***Herpestes ichneumon.*** (A.W.L.)

ICHTHYOLOGY. The science that deals with facts pertaining to fishes (**Pisces**). The species of fishes are so numerous that the classification of the group is an important part of this science, and their value as food is so great that the regulation of fisheries and measures for maintaining the supply of food and game fishes make up an important practical field. (A.W.L.)

ICHTHYOPSIDA. **Cyclostomes, fishes,** and **amphibians.** A division of vertebrates characterized by moist skin and by the presence of gills during part or all of the life. The eggs are usually deposited in the water and the embryo develops without an **amnion,** hence the name Anamnia is also applied to the group. (A.W.L.)

ICHTHYORNIS. **Fossil Birds.**

ICHTHYOSAUR. **Fossil Reptiles.**

ICING, AIRCRAFT. For many years the formation of ice on airplanes in flight set considerable limitation on their usefulness. When faced with weather bearing the threat of an icing condition, pilots either had to turn back, or risk the hazard and perhaps have to "bail out " When airlines first began to carry passengers, flights were made only under favorable weather conditions. Many travelers were reluctant to consider air transportation during winter months. To maintain scheduled operation, improved techniques, including methods of combating icing, were developed. Even today, when icing conditions are known to exist, the airlines frequently change their flight plans, even though this may inconvenience passengers. However, this may not always be possible, and, of course, in military operations, the aircraft should be able to complete their missions regardless of the weather.

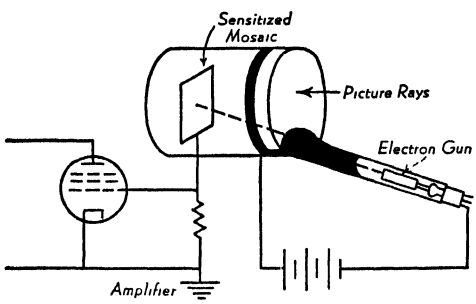
Meteorological conditions which are conducive to the formation of ice on aircraft are the presence of visible moisture and an atmospheric temperature lower than 34° F. These conditions may result in ice formed on wings, control and tail surfaces, propellers, and fuselage. On account of the adiabatic expansion in the Venturi of carburetors, ice may form there when atmospheric temperatures are considerably above 34° F. Visible moisture in the air may take the form of sleet, snow, or water droplets, supercooled below freezing. Water can remain liquid below 32° F. in the atmosphere for several reasons. Sometimes water vapor condenses on microscopic sea-salt particles, thus lowering the freezing temperature of the droplets. Or the droplets may be so small that surface tension prevents freezing. Or again, there may not be sufficient agitation of the droplets to prevent them becoming supercooled water. When these supercooled droplets of water strike the leading surfaces of an airplane, part of each droplet instantly changes into ice, with the rest of it quickly freezing by evaporative cooling. Three forms of ice may be produced, viz., glaze ice, rime ice, and rime frost. Glaze ice is formed from freezing rain near the freezing temperature. It is quite solid and smooth, but covers the most area. Rime ice is formed from droplets of supercooled water and from wet snow or sleet mixed with glaze ice, being porous and opaque, and of irregular rough shapes on the leading edges of the airfoils. It is likely seriously to affect the lifting properties of a wing. It is the most frequently encountered form of icing. Rime frost is formed at very low temperatures from very small droplets. Its chief effect is to alter the landing characteristics of an airplane.

As ice may hold the potential threat of interruptions of flight, making scheduled flights hazardous and landings difficult, great efforts have been made to overcome it. These efforts have been, first, accurately and scientifically to chart the weather, with the purpose of routing flights to avoid icing conditions, and second, to provide devices for freeing the airplane in flight of accumulations of ice. The airplane has high sustained speed. For this reason, ice forms only on its frontal area. The smallness of this area simplifies the problem of keeping the plane free of ice. The problem has been attacked by three general methods—chemical pastes or liquids, heat, or by methods which remove the ice mechanically. Chemical pastes are difficult to apply smoothly. Abrasion and water erosion tend to roughen the surface and make frequent application necessary. Antifreeze materials and heat applied to the leading edge only permit melted ice to run back and re-freeze. In the case of heat, the entire wing must be heated. Consequently, the method of most promise is that of removing the ice mechanically.

Dr. W. C. Geer of Ithaca, New York, was commissioned by the Daniel Guggenheim Foundation to study the ice problem. As the result of considerable experimentation, he found that the most practical method is to allow a little ice to form, and then break it mechanically so the air stream can remove it. Since Dr. Geer's studies, the mechanical **de-icer** has been developed for application to practically all exposed parts of the airplane which have a tendency to pick up ice. In the case of propellers and windshields, however, antifreeze liquids are employed to de-ice. (F.T.M.)

ICONOSCOPE. This is a form of electron **tube** used as a camera tube in **television.** The scene to be transmitted is focused on the mosaic consisting of many very minute photo-electric cells. These are formed by treating a mica sheet with silver oxide and reducing the oxide to metallic silver in such a way that many little globules of silver rather than a continuous sheet result. These silver particles are then photosensitized by treating with caesium as in the conventional **phototube.** The mica is backed by a conducting coating so the silver units form little **condensers** with the backing. The scene focused on this mosaic causes the photosensitive particles to emit electrons proportional to the light falling on each. These emitted electrons are removed by the circuit connections to the tube. Thus the various midget condensers formed by the particles and the

backing of the mica are charged, the amount of charge depending upon the light at the corresponding part of the picture and upon the time during which the charge is allowed to build up. These condensers are periodically discharged by a scanning beam of electrons which is swept back and forth across the picture until every particle has been touched in sequence. This electron beam restores the negative charge which the photoelectric action had removed. This sudden restoration of charge gives a pulse of current in the circuit connected to the other plate of the little condenser, i.e., the backing conductor. This pulse magnitude depends upon how many electrons had to be restored and hence upon the brilliance of the picture at that point. Since the charges are restored in sequence there will be a sequence of pulses



Iconoscope.

in the output circuit which represents the orderly dissection of the picture into minute parts for transmission. (See figure.) (L.R.Q.)

ICW. **Interrupted Continuous Wave.**

IDE. Pisces, Teleostei. A European fish (**Pisces**), *Idus idus,* related to the roach and dace. (A.W.L.)

IDEAL GAS LAW. An "ideal gas" would, if kept at a constant temperature, behave as respects volume and pressure in strict accord with **Boyle's law.** If now the temperature is also allowed to vary, we must combine the **law of Charles** (or of Gay Lussac) with Boyle's law, yielding the **Boyle-Charles law:**

$$pv = p_0v_0(1 + at), \qquad (1)$$

in which p_0v_0 is the value of the pressure-volume product pv when the temperature t is zero, a is the coefficient of expansion of the gas, practically the same for all gases, and in the ideal case equal to the reciprocal of the absolute temperature of the scale zero. If the centigrade scale is used, the value of a is approximately 1/273.2 per degree. Substituting this, Eq. (1) may be written

$$pv = \frac{p_0v_0}{273.2^\circ}(t + 273.2^\circ), \qquad (2)$$

which is one expression for the ideal gas law.

The factor $t + 273.2^\circ$ will be recognized as **the absolute temperature** T of the gas. And since the ideal gas obeys Boyle's law, the product p_0v_0 is constant however p_0 and v_0 may vary between themselves. We may thus denote the coefficient $p_0v_0/273.2^\circ$ by a single constant symbol, say R, and the ideal gas equation then takes the usual form

$$pv = RT. \qquad (3)$$

The value of R depends, of course, upon the quantity of gas used, since at any pressure p_0 it is proportional to the volume v_0. For 1 gram of air, R equals about $2{,}868{,}000 \frac{\text{g cm.}^2}{\text{sec.}^2\,\text{deg.}}$. At the zero of temperature and at any given pressure p_0, the gram molecular weights, or moles, of all pure gases have equal volumes. (This follows from **Avogadro's law.**) Hence if one mole of any pure gas is used, R will always have the same value, in c.g.s. units about $8.314 \times 10^7 \frac{\text{g. cm.}^2}{\text{sec.}^2\,\text{deg.}}$; which is called the "ideal gas constant." Many physical formulae involve a quantity which may be regarded as the ideal gas constant per molecule, that is, the above molar gas constant divided by the number of molecules in a mol, 6.064×10^{23}, giving $1.3805 \times 10^{-16} \frac{\text{g. cm.}^2}{\text{sec.}^2\,\text{deg.}}$. This is the "Boltzmann constant."

Since actual gases, even those with the smallest molecules, hydrogen and helium, do not obey the ideal gas law exactly, various empirical **characteristic equations** have been devised to represent their behavior. (L.D.W.)

IDENTITIES. An identity is an **equality** in which both members are equal for all values of the symbols for which the members are defined.

In an identity, either member can be transformed into the other by use of the fundamental rules of operation. An identity involves a difference of form but not of value.

An identity is frequently indicated by putting the symbol $\equiv$ between the two members. Thus, $(a + b)(a - b) \equiv a^2 - b^2$. (L.L.S.)

IDEOTYPE. Used by paleontologists to designate a specimen collected from some other than the type locality. (R.M.F.)

IDIOBLAST. A term proposed by Becke in 1903 for pseudo-idiomorphic crystals occurring in the **metamorphic** rocks. (R.M.F.)

IDIOCY. Complete congenital imbecility. (See **Mental Deficiency.**) (R.S.M.)

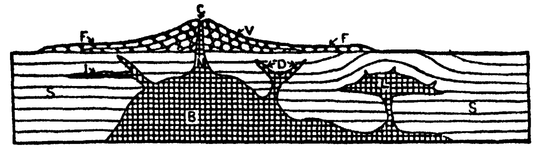
IDIOMORPHIC. The term proposed by Rosenbusch for those minerals in **igneous** rocks which are well crystallized and therefore display their **crystal** form with a high degree of perfection. (See also **Euhedral** and **Automorphic.**) (R.M.F.)

IDIOSYNCRASY. 1. Individual hypersensitivity to the effects of any drug, food, or physical or chemical agent. 2. A habit or temperament peculiar to any individual. (D.M.H.)

IDLER. **Gear Train.**

IDOCRASE. **Vesuvianite.**

IGNEOUS ROCK. Igneous rocks are rocks which have solidified (congealed) with, or without, **crystallization** from hot natural solutions such as **magma** or **lava.** Igneous Rocks are classified by their **texture,** fabric, chemical (mineral) composition, and their field relationship or mode of occurrence. Under mode of occurrence igneous rocks are classified as intrusive (**plutonic**) or extrusive (**effusive**). The intrusive rocks are classified according to the shape and size of the intrusive body



Diagrammatic structure section illustrating modes of occurrence of igneous rocks. S, strata; B, batholith of plutonic rock; L, laccolith; D, dikes; I, intrusive sheet or sill; V, volcano; N, neck of volcano; F, lava flow; C, crater.

and its relation to the other formations which it intrudes. Typical intrusive are **batholiths, laccoliths, sills** and **dikes.** The extrusive types are called **lavas.** Over 700 species of igneous rocks have been described, the bulk of which are intrusives. (R.M.F.)

IGNITER. Ignitron.

IGNITION. Ignition is the initiation of **combustion.** It is necessary for the inception of any flame and is accomplished by raising a mechanical mixture of the combining substances, such as carbon and oxygen, to the "ignition temperature." This temperature may be defined as the lowest temperature which will cause flame to start and spread through a combustible mixture. The ignition temperature varies with the substance. Some typical values are:

	°F.
Carbon	750
Carbon monoxide	1250
Hydrogen	1090
Sulfur	470
Isoöctane	980
Heptane	500
Phosphorus, yellow	93

The most common source of high-temperature energy used for exciting molecular activity to the point of ignition is the ordinary match. On account of its low ignition temperature, yellow phosphorus was at one time employed as the igniting element of matches; however, its use was hazardous, and in modern match manufacture the tip is composed of a mixture of various materials, including phosphorus, glue, ground glass, chlorate, and potash. The common match is composed of a paraffined splint dipped into a combustible compound which, upon hardening, forms the bulb of the match head. The head is redipped, to form an eye, in a compound which will ignite spontaneously by friction against a rough surface. In safety-match manufacture, the phosphorus compound is usually affixed to the side of the box and the head contains the oxidizing agent.

Rays of the sun, properly focused through a lens, are capable of heating some substances to their ignition points. Mechanical (flint and steel) and electrical (spark) energy can be used for the same purpose, as can also compression (of air), and fluid friction (meteors).

In certain apparatus, combustion is not continuous, and ignition must be intermittently and precisely accomplished. The most familiar example is the **internal combustion engine.** Two common variants of this engine are the spark ignition (Otto) and the compression ignition (Diesel) engines. In either case the fuel and air must be mixed and raised to the ignition temperature, or above. Each of these actions is time-consuming, with the result that the crankpin describes a finite arc between the moment of inception of the ignition action and the moment of actual ignition.

An explosive mixture is compressed in the spark ignition engine, but although mixing is reasonably thorough, there is some small but finite elapsed time after appearance of the spark at the **spark plug** of the **ignition system** and the completion of combustion, which leads to the timing of the spark somewhat in advance of dead-center position. Some delay in pressure rise after ignition is desirable to reduce **detonation.**

An engine which employs compression ignition provides the necessary ignition temperature by compression of air to a compression ratio sufficiently high that the polytropic temperature rise will cause the air to equal or exceed the ignition temperature of the fuel employed. In the Diesel engine a liquid fuel is employed, generally a petroleum derivative. It is sprayed into the hot air, mixed, and ignited. Both the mixing process and the rise of temperature of the fuel are time-consuming, and an ignition delay occurs which must be offset by advancing the moment of fuel ignition before dead-center position. The number of degrees of crankpin travel between beginning of injection and the action of ignition is termed the **delay angle.** It is desired to have the delay angle as small as possible so that the cylinder will not be overloaded with fuel when ignition occurs, otherwise detonation may result. Note that ignition delay promotes detonation in the compression ignition engine, and opposes it in the spark ignition engine. (F.T.M.)

IGNITION QUALITY. This characteristic measures the ability of fuel oil to ignite spontaneously in the engine cylinder. It is a quality which assumes increasing importance the higher the rotative speed of the engine. It is believed that combustion knock in a Diesel engine is caused by delay in ignition during the first part of the injection, causing accumulation of fuel which burns simultaneously with the fuel injected during the latter part of the injection. Good ignition quality, as represented by high Cetane Number, minimizes the delay period and the tendency of the engine to knock. Ease of starting and occurrence of a smoky exhaust at light loads are also dependent, to a degree, on ignition quality. The Cetane Number scale is derived from the standard practice of using a test fuel composed of cetane and alpha-methol-napthalene. Of these two, cetane has very good ignition qualities, whereas alpha-methol-naphthalene is very poor. The Cetane Number of a fuel is the percentage of cetane, in a mixture of the two, which will give the same ignition quality as the fuel oil under test. The average high-speed Diesel engine requires a fuel having ignition quality of better than 45 Cetane Number, and will scarcely run at all on fuels rated lower than 25 Cetane. Cracked oils show a considerably lower Cetane Number than straight run oils. (F.T.M.)

IGNITION SYSTEM. The ignition system here described is that used in engines operating on the **Otto cycle.** In this cycle, an inflammable mixture is compressed just before each power impulse. This mixture cannot be compressed until it reaches the spontaneous ignition temperature (as is the case in the **Diesel cycle**) because the presence in the cylinder of the combustible mixture would cause ignition to be uncontrolled and irregular. This engine must, therefore, depend upon some system of ignition which is under control, and which is automatically synchronized with the action of the cycle. Although early engines were operated on hot tubes and open flames, in these days ignition systems are universally electrical in nature. In a **gasoline** engine the gasoline-air mixture has an **ignition temperature** varying somewhere between 650 and 850° F. The ignition system must produce a focal point of heat sufficient to exceed this temperature and to provide it at exactly the right instant. The average time allowable in a gasoline engine operating at about 2000 rpm for ignition and explosion of the mixture following ignition, is only about one one-hundredth of a second. Furthermore, it has been found necessary to vary the timing of ignition with respect to the cycle of operation in such a way that ignition occurs relatively earlier in the cycle the higher the rotative speed. These conditions are well met by the electrical spark system of ignition, in which a high-voltage spark jumps across a stationary spark gap. Due to the high speed of electrical impulses in wires, there is no difficulty in accurately timing the ignition in an electrical system. However, the high-voltage jump spark method of ignition is not the only electrical form in use, and both the low-tension and high-tension ignition systems will be briefly described.

A low-tension ignition system is one in which the voltage at the ignition points is insufficient to cause a spark to jump a static gap. The **electrodes** of the gap are brought together, and then rapidly separated. In this way, a low-voltage supply is able to cause an electric arc

to follow the separation of electrodes. Fig. 1 shows a system of this nature. It consists of a source of voltage (a battery), an induction coil, and ignition points. The

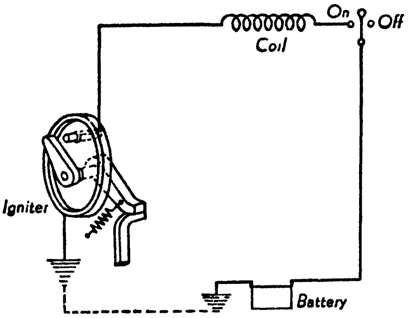


Fig. 1. Low tension system for single cylinder stationary engine.

ignition points and their operating mechanism constitute what is known as the igniter. The igniter is mounted in the **combustion** chamber, and is composed of one stationary, and one moving, electrode. The moving member is mechanically operated from the crankshaft by means of a shaft extending through the cylinder wall, and in this way the igniter is synchronized with the cycle. When the igniter points are pushed together, making contact, an electric current flows through the coil, igniter points, and battery. If, then, the current is suddenly interrupted through rapid opening of the igniter points, the battery voltage, aided by self-induced voltage of the induction coil, will cause an arc to follow the opening of the points. This arc is the source of ignition. This low tension system is only occasionally used on engines, usually on relatively slow-moving, fixed, or semi-portable engines.

The high-tension system, shown by Fig. 2, is the system used on most gasoline and gas engines, and is

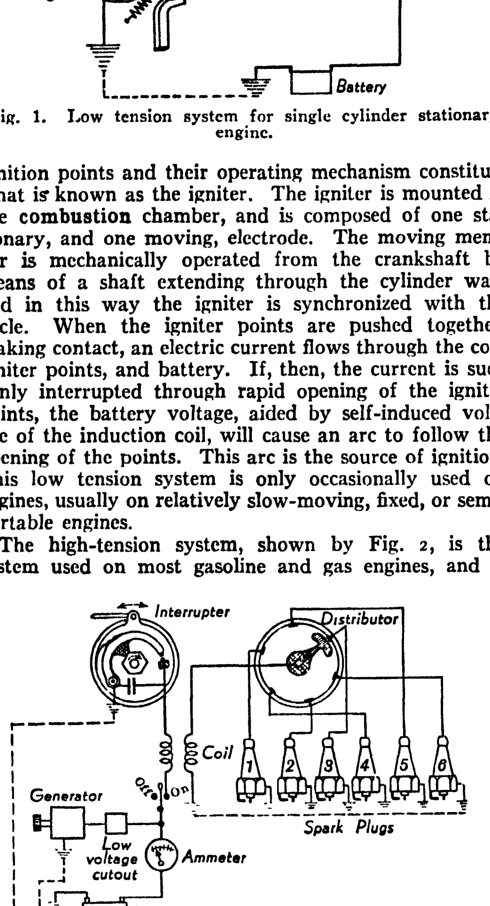

Fig. 2. Typical high tension ignition system for a 6-cylinder automotive engine.

familiar to many persons through its use as the ignition system of the automobile engine. It is well adapted to multi-cylinder engines, and is especially suitable where other electrical services are required; for example, lighting and electric cranking. Two systems of high-tension ignition should be mentioned. One, the battery and coil system, is most popular today on automobiles; the other, the **magneto** system, is the more widely used on aeronautical and fixed or semi-portable engines. The magneto system of ignition operates very much in the same manner as the coil and battery, except that, having all of the separate elements consolidated in one piece of apparatus, it is a much more compact ignition system. On the other hand, an automobile, with its need of a battery for purposes other than ignition, is best serviced with the coil and battery system.

Coil and battery electrical ignition will be explained in connection with the figure. A source of low voltage, i.e., the battery at 6 volts, is connected to the primary of an induction coil through an automatic switch which is opened at regular intervals by the engine itself. This automatic switch is called the interrupter or timer. Whenever the interrupter opens the circuit, the induction coil generates a high voltage which is sufficient to cause a spark momentarily to jump the static spark points which are in the combustion space of the cylinder. At the moment of ignition, the cylinder is filled with a compressed gas, some of which occupies the space between the spark points. The gap extends between .010 and .020", so that it is apparent that the induction coil must generate a very high voltage in order for the secondary current to be able to overcome the resistance of the compressed gas between the points. These points are made part of a spark plug which is screwed into the cylinder, thus providing a way of attaching the points, one of which must be insulated. The use of a single coil to supply high-voltage current to the spark plugs of a multi-cylinder engine, involves the use of another mechanically operated device, the **distributor.** The distributor picks up the high-voltage impulse as it comes from the induction coil, and shunts it to the cylinder ready to receive ignition action. Depending upon the sequence with which high-voltage leads are attached between spark plug and distributor, the engine will operate with a definite sequence of power strokes derived from the different cylinders. There are certain standard arrangements of this sequence for the common multiples of cylinders employed in gasoline engines. These arrangements are called the firing orders. The firing order must be well chosen to prevent rocking or galloping of the engine.

In the common **four-cycle** engine, one ignition impulse serves a cylinder for two complete revolutions. Because of this fact, the distributor rotates at one-half engine speed. Now the interrupter is usually driven by a **cam** which does not necessarily have to rotate at one-half crankshaft speed, but which can conveniently be made to do so, since a one-half speed shaft must be provided for the distributor. If the interrupter is operated by a cam revolving at one-half crankshaft speed, the cam must have as many lobes on it as there are cylinders in the engine. The adjustment of the instant of ignition in a cycle with due regard to the demands of variable speed

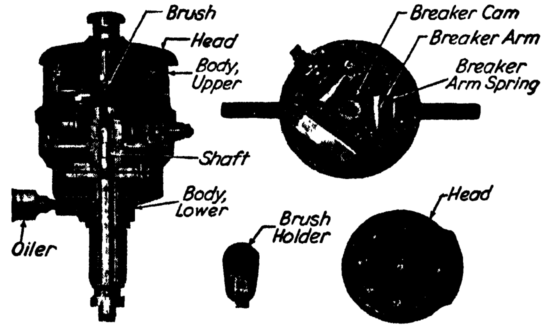

Fig. 3. North-East ignition unit (Packard).

operation, can be done through a slight rotative displacement of the contact-carrying case of the interrupter. Formerly this action was accomplished manually, but at present progress in electrical ignition systems has enabled manufacturers to develop automatic spark advances, where centrifugal weights opposed by springs adjust the interrupter to a position of spark advance which will be best for the speed of the engine. A **condenser** paralleled across the interrupter points absorbs energy which would otherwise be manifested as a small arc following the opening of the points. It is convenient to mount the

condenser, interrupter, and distributor as a unit enclosed in a single case, and driven by a one-half speed shaft. A unit of this type is shown in Fig. 3. (F.T.M.)

IGNITRON. This is an electron **tube** of the **mercury-arc** type having a special starting principle. The tube consists of a mercury pool, to serve as **cathode,** and an **anode** for the main part of the circuit and an auxiliary electrode, the igniter, which dips into the mercury pool. Since all mercury pool tubes are essentially cold cathode devices until the arc is started some means must be provided for initiating the arc. For rectification of a.c. where no provision is made for keeping the arc alive from cycle to cycle or for control purposes where the tube may be alternately turned on and off under the influence of auxiliary equipment, the arc must be restarted at intervals. In the ignitron this is accomplished by the igniter, a rough-surfaced material which will not be "wet" by the mercury. The resultant points of contact between the igniter rod and the mercury will carry very high current densities if a pulse having only a fair current value is passed through it. This high current density, possibly coupled with high fields where the mercury and rod are not actually in contact, cause the creation of a minute cathode spot at the junction of the mercury surface and the rod. This gives the electron emission necessary to start conduction to the main anode if the latter is positive. The current between the spot and the anode then will develop the spot to its normal size. This tube has the advantages of the ordinary mercury-arc tube plus the great advantage of an easily controlled starting mechanism not involving any moving parts. It has rapidly come into extensive use for applications requiring ease of control and high current capacities; especially capacities of short-time duration, such as motor control, welding control, rectifiers in electrochemical processes, etc. (L.R.Q.)

IGUANA. Reptilia, Sauria. Large **lizards** of South America and the West Indies. They eat vegetation and insects and are largely **arboreal,** although they are at home on land or in the water. The eggs and flesh of some species are eaten.

The name is applied to other lizards than the true iguanas, including members of the same family and others less closely related. Among these species are a land lizard of the Galapagos Islands and a marine species of the same archipelago which eats seaweed, and the unrelated monitors of the Old World. The family Iguanidae also includes the **basilisks,** anolis lizards, and **horned toads.** (A.W.L.)

IGUANODON. (Duck-billed dinosaur.) **Fossil Reptiles.**

IJOLITE. Ijolite is a wholly crystalline, granular igneous rock consisting essentially of **nephelite** and **pyroxene.** (E.C.E.S.)

ILLINIUM. Discovery announced by Harris, Yntema, and Hopkins in 1926 and presumably a member of the **cerium** sub-group of the rare earth metals of atomic number 61. See **Chemical Composition,** I. Elements. (R.K.S.)

ILLUMINATION. The illumination of a surface is the luminous flux which it receives per unit area. The three most common units are: the foot-candle, or 1 lumen per sq. ft.; the phot, or 1 lumen per sq. cm.; and the lux, or 1 lumen per sq. meter. (See **Photometry.**) The phot is thus equal to 10,000 luxes and to about 929 foot-candles, and is appropriate to only very intense illuminations; the milliphot (0.001 phot) is usually more convenient.

Illumination obeys a cosine law, like the radiation from a surface and for similar reasons (see **Cosine Emission Law**). That is, if the illumination is I_0 for zero angle of incidence, then for any other angle θ it is $I = I_0 \cos \theta$. Since for perpendicular incidence the illumination from a concentrated source of luminous intensity L at distance r is $I_0 = kL/r^2$, the illumination at incidence angle θ is

$$I = k \frac{L}{r^2} \cos \theta.$$

The value of the constant k depends on the units of I, L, and r; for example, if I is in foot-candles, L in candles, and r in ft., $k = 1$ (lumen per candle).

The illumination desirable at any point varies of course with the circumstances. For reading tables or office desks a typical night-time illumination should be from 6 to 8 foot-candles. Actual illuminations are measured by means of an illumination photometer or **illuminometer.**

The term illumination is also applied to the science of providing and directing light for a specific purpose associated with the activities of mankind. The light itself is radiant energy whose wavelength lies within a band to which the human eye is sensitive. It is produced from an incandescent source such as that furnished by the sun or artificially by lamps. The sources of incandescence employed most frequently are open flames and closed flames, electric arcs, incandescent filaments, and luminescent gas. In point of historical precedence, the flames of open fires were undoubtedly the first artificial illumination employed by man. This method was next improved on by selecting certain sticks of wood which contained resinous parts which provided torches that would remain alight while carried from point to point. Then animal and vegetable fats and waxes were variously employed in candles and lamps, yielding a more portable type of illumination which could be employed for illumination only, and without the necessity of receiving large amounts of heat as well. With the discovery and refining of **petroleum,** the kerosene lamp, which was so much more effective as a source of light than anything previous, came for a short period of time into almost universal use. The kerosene lamp is still used in isolated homes removed from the conveniences of the more efficient kinds of lighting, and where lowest cost lighting is wanted. Defects associated with odor, fire hazard, nuisance of maintenance, and inferiority of illumination, have discouraged the continued use of the kerosene lamp.

A fuel gas may be employed as a means of securing illumination. Among such gases might be mentioned ordinary artificial **illuminating gas, acetylene gas,** air gas (gasoline-air mixture), and natural gas. The use of natural or illuminating gas is confined largely to cities and larger towns wherein is installed a gas distribution system. For isolated homes, acetylene gas, which is generated from the action of water on **calcium** carbide, and air gas lamp units are available. As a gas flame is practically transparent when the gas is completely burned by a suitable burner, illumination from gas can be obtained only by heating to incandescence finely divided particles or objects placed in the flame. An ordinary slit type gas burner having an open flame produces a certain amount of carbon particles which, when heated in the flame, emit a yellowish light. This yields illumination of low intensity which is often unsteady, and is certainly inefficient. The addition to plain open-flame gas burners of a mantle consisting of a mineral which, when subjected to the heat of the burning gas, becomes white hot and emits a strong steady light, greatly improved gas lighting. The standard Welsbach mantle is composed chiefly of thorium oxide supported on a cotton or artificial cellulose base which burns out when the mantle is first lit. The luminous shell of mineral left must be very gently handled in order to prevent its destruction. The fragility of the gas mantle has been its chief defect, as it is an efficient source of illumination, quiet and odorless. Invention of the incandescent lamp, and the building up of electric service distribution networks which reach a

large portion of the population, have made gas lighting an inferior and less desirable form of illumination. Today in the United States most homes that are not illuminated by electricity have retained the kerosene lamp in more or less improved forms. The above statement holds true even though a great many rural homes will be found enjoying acetylene gas illumination. The relatively high illuminating efficiency of electric lighting may be demonstrated by quoting the energy consumption per unit of illumination of a few illuminants. The unit ordinarily employed in this field is the lumen per watt of input. Open-flame gas burners and kerosene lamps yield about ¼ of a lumen per watt of power. The mantle-type gas lamp may provide as much as 1½ lumens per watt, but the modern incandescent lamp can deliver 8 lumens per watt, and the mercury-arc lamps 30 lumens per watt, or over 100 times as much illumination per unit of energy used. (See **Electric Lighting.**)

The merits of an illumination system may be judged by the freedom from fluctuation of light, by color, by intensity of lighting on the working plane, and by diffusion which prevents glare. Glare is due to excessive illumination of surfaces, the light reflected from which reaches the eye. Glare is reduced or eliminated by diffusion, which can be obtained by special designs of lighting units or by special treatment of the walls of an interior. There are three methods of supplying artificial illumination to the region in which the illumination is desired. With specific reference to interior illumination, the region in which the illumination is most desired is the lower part of a room, in which persons live and move. Also, the source of light is usually above, as it has been customary to place lamps near the ceiling, with sufficient clearance so that they will not interfere with freedom of movement of the individual about the room. The direct downward supply of light from the lamp is known as direct lighting. Direct lighting is efficient as measured by **candles** of luminous intensity per watt of energy, but is likely to have some glare, and to illuminate different regions of the interior unequally. Indirect lighting, the second lighting system to be mentioned, avoids glare, and incidentally loses considerable illuminating power by concealing the source of light from view and directing it upon a reflecting surface, usually the ceiling, which reflects it in a diffused state throughout the interior being illuminated. Shadows are softened, the general effect is more pleasing than in direct lighting, but freedom of choice of ceiling surface is somewhat restricted, the installation is more expensive, and high-powered lamps must be provided or portable lamps provided for direct illumination where high lighting intensity is needed. The third system of lighting, known as the semi-indirect, is intermediate between direct and indirect. Semi-indirect lighting is obtained by enclosing the lamp in a translucent bowl having a surface which diffuses the light as it is transmitted.

The **candle power** of a lamp is what primarily determines brightness of the illumination provided by it. The standard candle is the reference source for illumination, and is maintained in most of the national standardizing laboratories. Since a lamp in space may provide illumination in all directions, it can be considered a spherical source of illumination. The average candle power, taken in all directions from the lamp, is known as the mean spherical candle power. Often the shape of a lamp, or of its accessories, interferes with transmission of light equally in all directions. The candle power in a horizontal direction is frequently employed. The average horizontal candle power is expressed in candles, output is expressed in lumens. The luminous flux from a source of one spherical candle power is 12.57 lumens (4π). Recommended intensities of illumination for a number of different interiors are given in the accompanying table.

INTENSITIES OF ILLUMINATION

	Foot-candles
Auditoriums, churches	2–4
Armories, exhibition halls	3–6
Corridors, stairways	1–2
Drafting rooms	10–15
Foundries, forge shops, boiler rooms	3–6
Industrial yards	0.2–0.5
Instrument shops	6–15
Laundries, machine shops	5–10
Offices	6–10
Schools, libraries	6–10
Show windows	10–70
Stores	4–10
Tool rooms, press rooms, textile mills	8–16

The lumens which are actually received upon a working area are fewer in number than those which are emitted by the sources of illumination, because of the absorption by walls, ceiling, drapes, etc. The ratio of the lumens reaching the working area to those emitted from the lamp or lamps is the utilization factor. This factor is determined chiefly by the character of the walls and ceiling, the number of windows and hangings, and the type of reflectors or lighting fixtures in which the lamps are mounted. The utilization factor affords a means for connecting the desired intensity of illumination with the lighting installation. (L.D.W., F.T.M.)

ILLUMINOMETER OR ILLUMINATION PHOTOMETER. An instrument for measuring **illumination.** The older, standard forms of this instrument employ a **photometer** of ordinary type to measure the luminous intensity due to light reflected from a white matt surface or diffused by a white translucent screen exposed to the illumination to be measured. The balance may be secured as usual by the **bench photometer** method, by screening down the comparison lamp, or by turning the diffusing surface through a known angle and relying upon the cosine law (see **Illumination**). A different type, known as a foot-candle meter, utilizes the Bunsen screen principle, there being however a long row of translucent spots lighted from behind by a lamp at one end, hence unequally along the row. At some point in the row this balances the illumination from in front, which is to be measured, and a scale indicates the foot-candles directly. In a still more recent instrument the illuminated element is a copper oxide photovoltaic cell (see **Photovoltaic Effects**) connected to a sensitive current meter reading directly in foot-candles. All of these instruments must, of course, be portable to be of practical use. (L.D.W.)

ILLUSION. A false interpretation of a sensory image. (See **Hallucination.**) (D.M.H.)

ILLUVIATION. A special term in soil nomenclature implying the process by which clay is added to the subsoil horizon. (R.M.F.)

ILMENITE. A mineral in the hematite group. Composition, $FeTiO_3$. (R.M.F.)

IMAGE DISSECTOR. This is an electron tube serving as a camera tube for a television system. The picture to be transmitted is focused on a photosensitive surface, causing electrons to be emitted from each part of the surface in proportion to the amount of light in that particular part of the picture. These electrons are drawn down the tube by a positive anode but are kept focused in an electron reproduction of the picture. This focusing is done by magnetic fields. The focusing fields or auxiliary fields are varied periodically so the electron picture is swept back and forth, up and down, as it moves down the tube. Placed in the path of this electron picture is an aperture opening into an **electron multi-**

plier. Each part of the electron stream is thus swept across this aperture and so the output of the electron multiplier will vary with the various parts of the picture. This output, then, represents the electrical unravelling of the picture into an orderly sequence of parts to be transmitted. (L.R.Q.)

IMAGE FREQUENCY. In the **superheterodyne** receiver the **intermediate frequency** is obtained by beating the incoming radio signal with the locally generated signal and selecting the difference (see **Heterodyne**). Since the intermediate frequency stages are tuned to this particular value of frequency they will respond to it regardless of how it may be generated. If the local oscillator is designed always to be higher in frequency than the incoming signal the normal intermediate frequency signal is obtained by subtracting the incoming frequency from the local one. Exactly the same result is obtained in heterodyning if the oscillator is below the incoming signal by the same amount. Thus, if, for example, a set is tuned to 550 kc. and the intermediate frequency is 450 kc., the local oscillator will be tuned to 1000 kc. (giving a difference between the incoming and local of 450). If at the same time a signal is received from a station at 1450 and this signal gets to the **grid** of the first detector it will give a difference frequency of 450 also and hence will go through the i.f. stages along with the desired one. Once the signals have reached the i.f. stages in this manner there is no way of separating them. Both the station at 550 and the one at 1450 will contribute to the loud-speaker output. The frequency of 1450 is said to be the image frequency of the one of 550. (L.R.Q.)

IMAGES. **Geometrical Optics.**

IMAGINAL DISK. **Histoblast.**

IMAGINARY NUMBERS. **Numbers,** also **Complex Numbers.**

IMAGO. An insect in the adult stage. (A.W.L.)

IMBIBITION. In color photography, the transfer of a dye from a matrix, such as a gelatin-relief image, onto a prepared support. Both surfaces are moist and the dye diffuses from the gelatin relief into the support, which is generally coated with a suitably prepared layer of gelatin. (H.C.C.)

IMBRICATE STRUCTURE. The type of compound, low-angle (almost horizontal) thrust faults which produce mechanical piles similar in arrangement to slates on a roof. This type of compound faulting consists of the lower thrust plane or sole, the intervening multiple thrusts (imbricate) and the overlying thrust plane or thrust proper. Imbricate structure is particularly characteristic of the North West Highlands of Scotland. (R.M.F.)

IMHOFF TANK. The Imhoff tank is a chamber of special design suitable for reception and purification of **sewage.** It may be used for the clarification of sewage by plain sedimentation with digestion of the sludge thereby collected. It consists of an upper chamber in which sedimentation takes place and from which the collected solids slide down inclined bottom slopes to an entrance into a lower chamber in which the collection of sludge and digestion take place. The chambers are otherwise completely separated with normal flow of sewage through the upper sedimentation chamber and no flow of sewage in the lower or digestion chamber. The latter must be provided with separate gas vents and sludge discharge lines for withdrawing the sludge after thorough digestion which takes place progressively for a time interval of 6–9 months. The Imhoff Tank is in effect a 2-story septic tank which by means of this separation retains the advantage of the simplicity of the septic tank without its many disadvantages, most of which accrue from the intimate mixing of fresh sewage and septic sludge in the same chamber.

Imhoff Tanks are being superseded by plain sedimentation tanks with mechanical devices for continuously collecting the sludge which is conveyed to separate sludge digestion tanks. Such an arrangement gives improved sedimentation results and permits, by temperature control, a much more rapid, complete and satisfactory digestion of the sludge in the separate tanks. (E.W.S.)

IMIDES. **Amines and Amides.**

IMINO-COMPOUNDS. Imino-compounds are organic compounds containing the imino-group (<NH), e.g,. dimethylamine ($(CH_3)_2NH$), dibenzamide ($(C_6H_5-CO)_2NH$), succinimide , pyrrole ((CH_4-NH)), uric acid . (R.K.S.)

IMMUNITY. The power of the body to resist or overcome a specific disease: the state of being immune.

Natural immunity is immunity developed by an individual without having the disease or inoculations against it. Congenital immunity is immunity that is present at birth. Acquired immunity is immunity that is acquired during life. Active immunity is immunity produced by the stimulation of antibody formation by one of the following means: 1. Recovery from a specific disease. 2. Cumulative exposures to infection without actually having suffered a noticeable attack of the disease. 3. Treatment with a **vaccine.** 4. Injection of toxins of bacteria. Passive immunity results from the transfer of antibodies from an immune to a non-immune subject by **transfusion of blood or serum.** (D.M.H.)

IMPACT. Impact is the action of two bodies in collision, whereby the velocity of one or both bodies is changed. In the case of direct impact, the velocity of the moving bodies is in the direction of the normal (perpendicular) to the bodies at the point of contact. Otherwise the impact is oblique. The impact is central when the centers of gravity of the two bodies lie on the line of impact (normal to the bodies at the point of contact). The momentum of a body is its mass multiplied by its velocity. A law of impact is that the sum of the momentums of the two masses before and after impact is the same, provided the bodies are perfectly elastic, and no energy is absorbed in permanent plastic deformation.

The impact coefficient (coefficient of restitution) is the ratio between the differences of velocities of the two bodies after impact to the same differences before impact. This coefficient would be unity for impact of perfectly elastic bodies, and zero for fully inelastic bodies. To find the energy lost in an imperfect impact (one in which the impact coefficient is some number less than one), the masses of the two bodies, M_1 and M_2, may be substituted into the following formula. This formula has in it also the differences of velocity of the bodies after collision. Let f be the impact coefficient.

$$\text{Energy lost} = \frac{M_1 M_2(1 - f^2)(v_1 - v_2)^2}{2(M_1 + M_2)}.$$

(F.T.M.)

IMPACT LOAD. **Load.**

IMPACT STRESS. **Load.**

IMPACT TOUGHNESS. In the design of metal structures and machines the static stresses can ordinarily be calculated and a material of suitable strength selected.

The impact loading requirements are usually less definitely known, and the translation of these requirements into a material specification is very difficult.

In testing rails, car wheels, and certain structural parts such as railway draft gears, a simple drop test is used. The weight, height of fall, and number of blows to failure give a relative measure of impact resistance.

In determining the impact toughness of metals as materials rather than as finished structures or machine parts, tests are made in a pendulum-type testing machine which breaks a standard beam-type sample with a single blow. The height of swing of the weighted pendulum past the anvil after fracturing the sample is related inversely to the energy absorbed in breaking the sample. For example, a tough steel will absorb a large proportion of the total energy of the pendulum so that the swing past the anvil will be small. The results are expressed in foot lbs.

While some tests on relatively brittle materials are made on square-sectioned beam samples, in most cases a notch is machined opposite the striking position to localize fracture as in the Izod and Charpy tests. This introduces stress concentration and a state of combined stresses in the vicinity of the notch, which tends to restrict normal plastic deformation and to produce a brittle fracture quite independent of the velocity effect. In fact, some prefer to call this the notched-bar test rather than an impact test because the energy required to break a notched specimen differs little from that required to fracture a similar specimen by slow bending methods. Furthermore, the velocity developed by a free falling pendulum of reasonable length is relatively small compared to the velocities encountered in moving vehicles, in certain machine parts, or in ballistics, therefore the so-called impact test is more nearly a static than a dynamic test.

High-velocity impact testers which break a test specimen in tension have been developed. The interpretation of test results of this type is still somewhat uncertain.

It is known from experience that impact failures are more likely to occur at low temperatures than at normal room temperatures. Of the ferrous alloys, only austenitic **stainless steels** and certain other alloy grades containing nickel retain a large proportion of their normal room temperature toughness at low temperatures. The aluminum, copper, and nickel base non-ferrous alloys do not develop low-temperature brittleness. The Charpy notched-bar impact test is generally used to determine impact toughness at various temperatures. Other tests such as the tension test fail to detect low-temperature brittleness. (R.H.H.)

IMPALA, PALA. Mammalia, Artiodactyla. *Aepyceros.* Moderately large African **antelopes** of several species. They have long slender horns, slightly spiraled and ringed through most of their length. (A.W.L.)

IMPEDANCE. **Alternating-Current Circuits.**

IMPEDANCE, CHARACTERISTIC. **Characteristic Impedance.**

IMPEDANCE MATCHING. Impedance matching is the process of making equal the **impedance** looking both ways from a junction point of two parts of a circuit. This serves two important functions; it gives a condition for maximum power transfer from one circuit to another and also prevents reflection of voltage and current waves. Impedances are usually matched by using the **transformer** which multiplies the value of an impedance connected to its secondary terminals by a factor equal to the square of the primary to secondary turns ratio. Other methods include networks of resistances, networks of reactances, tuned circuits, quarter-wave and half-wave transmission lines, open- and short-circuited transmission line segments in parallel with the circuits at proper matching points, and numerous others. Matching is very important in long smooth transmission lines to prevent reflection from the load. The latter must be equal to the **characteristic impedance** of the line and, if it is not so, must be transformed by one of the methods previously described. (L.R.Q.)

IMPELLER. The impeller is the rotating member of a **centrifugal pump.** It has backwardly curved vanes mounted on a hub attached to the pump shaft. When these vanes are cased with disks on either side, they are known as shrouded impellers. The water is admitted to the pump in such a way that it comes in contact with the impeller first near the central or hub portion. The impeller rotates in its cases with close clearances, and the water is constrained to remain in the impeller, which, by virtue of its rotation and the action of centrifugal force, drives the water from the periphery at high velocity. (F.T.M.)

IMPETIGO (Impetigo contagiosa). An acute infectious skin disease characterized by the occurrence of discrete, thin-walled vesicles and pustules which rupture, form yellow crusts, and heal without scarring. The lesions may be single or multiple; once started, they often develop and spread very rapidly. The etiologic bacteria are **streptococci; staphylococci** cause a similar but deeper type of skin lesion, which is loosely referred to as impetigo also. Ammoniated mercury, gentian violet and more recently **sulfonamide** ointments are used successfully in the treatment of the disease. (D.M.H.)

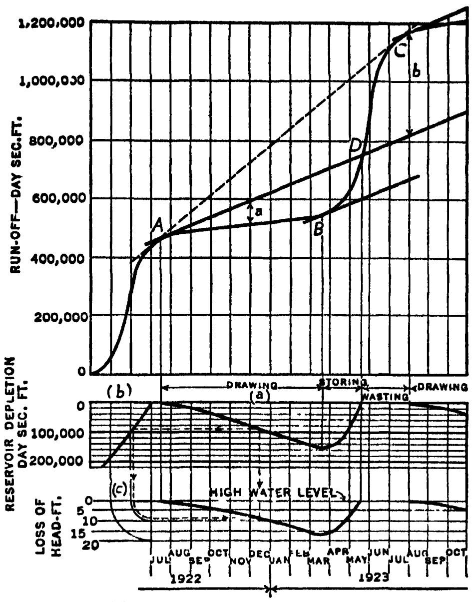
IMPLICIT FUNCTION. If a **function** is defined by a relation between the **variables** given by an **equation** which must be solved in order to express one variable in terms of the other, the function so defined is called an implicit function. (L.L.S.)

IMPOTENCE. A disturbance of sexual function in the male which precludes satisfactory **coitus.** It varies from premature ejaculation to total loss of erection. Impotence should not be confused with **sterility,** which, in the male, means an absence of normal **spermatozoa** and therefore failure of reproduction. An impotent man may be fertile in that his testicles produce spermatazoa; and a sterile individual may be potent.

The causes of impotence are psychic and organic. The psychic are by far the more frequent. Some form of **psychoneurosis** is at the base of most cases. Organic causes are local lesions of the genitalia interfering with the transmission and delivery of semen, endocrine diseases of the testes and other ductless glands, and organic lesions of the nervous system. (D.M.H.)

IMPOUNDING RESERVOIR. When the required flow of water from a reservoir or from a stream is larger than the minimum rate of flow of that stream in a dry season, a reservoir of the impounding type is needed. Ordinarily, storage is relied upon to a greater or lesser extent to regulate flows. For a study of storage conditions the mass curve is indispensable. The mass curve can best be explained by reference to the accompanying figure. The point of origin of the mass curve is a month when the reservoir is known to be full, as after spring floods. The ordinates of the curve represent the total flow, or mass of water, from the date of origin. River gauging records have mass expressed in acre-feet but, for the purpose of the mass curve, acre-feet are converted into "day-second-feet" so that the slope of a straight line drawn on it will represent a rate of flow in second-feet. A day-second-foot is the volume of water equivalent to a flow of one cu. ft. per sec. for one day. One day-second-foot = 1.98 acre-feet. The line *AD* represents a uniform flow of 1000 second-feet. Its ordinate is $1000 \times 30 =$ 30,000 day-second-feet per month. The mass curve of the non-uniform stream flow is *ABDC.* If lines parallel

to AD are drawn tangent to the mass curve, the significance of the points of tangency A, B, C is that, on their dates, the stream flow was equal to the steady flow



Mass curve and its derivatives.

represented by the slope of AD. At A and C the stream flow passes from greater than to less than the required regulated flow, while at B it changes from less than to greater than the required flow. Having passed A and C the stream discharge becomes less than the required regulated flow, and the difference is made up by drawing on the storage in the reservoir. At the end of November, 1922, the reservoir would have supplied the number of day-second-feet indicated by the ordinate a. Passing B the stream flow has increased and is now in excess of the flow requirements, consequently the storage is regained, and regained completely at D. From D to C there is wastage over the crest gates amounting to a maximum as indicated by the ordinate b. The slope of the line AC is the maximum regulated flow that could be realized without wastage over the crest gates or ultimate depletion of the reservoir. (F.T.M.)

IMPROPER INTEGRALS AND INFINITE INTEGRALS. If $f(x)$ is continuous for $x \geqq a$ and if the **definite integral** $\int_a^t f(x)dx$ approaches a **limit** as $t \to \infty$, we denote this limit by $\int_a^\infty f(x)dx$ and call it an infinite integral:

$$\int_a^\infty f(x)dx = \lim_{t \to \infty} \int_a^t f(x)dx.$$

The infinite integral is then called convergent.

We define $\int_{-\infty}^a f(x)dx$ in a similar way.

The infinite integral $\int_{-\infty}^{+\infty} f(x)dx$ is defined by:

$$\int_{-\infty}^{+\infty} f(x)dx = \int_{-\infty}^a f(x)dx + \int_a^\infty f(x)dx.$$

If $f(x) \to \infty$ as $x \to a$, the integral $\int_a^b f(x)dx$ is defined by:

$$\int_a^b f(x)dx = \lim_{\delta \to 0} \int_{a+\delta}^b f(x)dx \quad (\delta > 0);$$

this is called an improper integral, and it is said to be convergent.

Similarly, if $f(x) \to \infty$ as $x \to b$, we define:

$$\int_a^b f(x)dx = \lim_{\delta \to 0} \int_a^{b-\delta} f(x)dx \quad (\delta > 0).$$

If $f(x) \to \infty$ as $x \to c$, where c is between a and b, we define:

$$\int_a^b f(x)dx = \lim_{\delta \to 0} \int_a^{c-\delta} f(x)dx + \lim_{\delta' \to 0} \int_{c+\delta'}^b f(x)dx.$$

These improper integrals are also called convergent. (L.L.S.)

IMPULSE. **Momentum.**

INBREEDING. The mating of closely related animals. As practiced in stock breeding, brothers and sisters are often mated, or parents and their offspring. In most human societies the mating of individuals more closely related than first cousins is not approved, and even cousin marriages are regarded as close inbreeding.

Inbreeding is popularly regarded as a weakening process but this is not entirely true. Closely related individuals are more likely to have a similar complex of hereditary potentialities than those from different lines of descent, hence hereditary characters which may be masked in them have a better opportunity of appearing in their offspring according to the processes of Mendelian **heredity.** These characters may, however, be either desirable or undesirable. In either case if the character in question can be concealed by some other it may appear more often in an inbred line. (A.W.L.)

INCISOR. A sharp-edged cutting tooth. The incisors are located at the front of the jaws of **mammals,** between the canines. (A.W.L.)

INCLINATION. Inclination is that **element** of the **orbit** of a celestial object which indicates the angle between the plane containing the orbit of the object in question and some reference plane. In the case of orbits of members of the solar system the reference plane is the ecliptic, while in orbits of **binary stars** inclination refers to the angle between the plane of the orbit of the stars and the plane perpendicular to the line of sight. (W.K.G.)

INCLINED PLANE. **Machines.**

INCLINOMETER. **Clinometer.**

INCLUSION. This term is used chiefly to connote a fragment of a foreign rock or mineral in an igneous rock. It may also be used to refer to gas or liquid enclosed in a mineral crystal.

In metallurgy, inclusions are small particles of nonmetallic compounds embedded in iron or steel. The principal types are oxides, sulfides, and silicates, all of which are more or less hard and brittle. They may originate as slag particles or pieces of refractory from the furnace or ladle which become entrapped upon solidification of the molten metal. More commonly they are the result of reactions within the metal itself during the finishing or deoxidation period and during pouring and solidification. The term "sonim," from solid nonmetallic inclusion, is sometimes used.

In high-quality heat-treated machine and tool steels subject to impact and repeated stresses, inclusions are considered objectionable. They can be objectionable in any steel if present in large amounts, particularly in segregated areas forming continuous or semi-continuous stringers or plates known as **laminations.** In normal

amounts and when well distributed their effect on strength, ductility, and other properties is negligible. (E.S.C.S., R.H.H.)

INCOMPETENT. Used by structural geologists to designate those formations which when subjected to compressional deformative processes tend to be deformed by multiple fracture or crumpling of the relatively weaker formations. Typical incompetent formations are **shale** and highly carbonaceous sediments especially when interstratified with such **competent** formations as **quartzite, sandstone, limestone** or **dolomite.** (R.M.F.)

INCOMPLETE BETA FUNCTION. The incomplete Beta function $B_x(p, q)$ is defined

$$B_x(p, q) = \int_0^x x^{p-1}(1 - x)^{q-1}\,dx, \qquad 0 \leq x \leq 1, \quad p > 0, \quad q > 0.$$

Generally, however, we desire

$$I_x(p, q) = \frac{B_x(p, q)}{B(p, q)}.$$

Tables of $B_x(p, q)$ and $I_x(p, q)$ have been provided by K. Pearson. The two functions are helpful in finding the area under a Pearson Type I function, or the theoretical class frequency. They are also useful in finding the levels of significance of Snedecor's "F" and Fisher's z. Tables of the levels of significance of the Beta function (Pearson Type I) have been constructed. These may be used to find the **confidence limits** in the **Bernoulli probability function.** (L.A.A.)

INCOMPLETE GAMMA FUNCTION. The incomplete Gamma function is defined

$$\Gamma_x(n) = \int_0^x e^{-x}x^{n-1}\,dx, \quad n > 0, \quad 0 \leq x < \infty.$$

Tables of the incomplete Gamma function have been prepared by Karl Pearson, using the notation $\Gamma_u(p + 1) = \int_0^{u\sqrt{p+1}} e^{-v}v^p dv$. Let $p = n - 1$ and we see that this corresponds to $x = u\sqrt{n}$. More generally we need

$$I_x(n) = \frac{\Gamma_x(n)}{\Gamma(n)} \quad \text{or } I(u, p) = \frac{\Gamma_u(p + 1)}{\Gamma(p)}$$

in Pearson's notation. The incomplete Gamma function is used to find the area or the frequency in a class in **Pearson's Type III function.** However, it is much easier to use Salvosa's tables of the Type III function than it is to use Pearson's tables. The range covered by Pearson's tables is larger while the subdivisions of the argument are finer in Salvosa's tables. (L.A.A.)

INCONSISTENT STATISTIC. A statistic which is not consistent is said to be inconsistent. Such statistics should never be employed. (See **Consistent Statistic.**) (L.A A.)

INCONSISTENT SYSTEMS OF LINEAR ALGEBRAIC EQUATIONS. **Systems of Linear Algebraic Equations.**

INCREMENTAL INDUCTANCE. This is the inductance which an iron-cored coil will offer to a.c. when it is superimposed on d.c. through the coil. This condition occurs very frequently in communication and electronic circuits since many of these involve direct currents for establishing an operating point and then superimpose the a-c signal. The d-c produces a certain amount of saturation in the core so the flux conditions presented to the a.c. are not the same as if no d.c. were present. When the core is in this partially saturated condition the flux changes produced by the a.c. are not as great as they would be otherwise and hence the back e.m.f. of the coil or its inductive effect is reduced. Since the actual inductance presented depends upon the degree of saturation the rating of a coil which is designed to carry both types of current should include both the d-c value of the current and the **inductance** (which is understood in this case to be the incremental inductance). The effect of incremental inductance is due to the change of the permeability of the core, the permeability which is effective in this case being called the incremental permeability. It is given by

$$\mu_\Delta = \frac{\Delta B}{\Delta H}$$

where μ_Δ is the incremental permeability, ΔB the change in flux density produced by the a.c. and ΔH the change in magnetizing force produced by the a.c. (L.R.Q.)

INCREMENTAL PERMEABILITY. **Incremental Inductance.**

INCUBATION PERIOD. That period which elapses between exposure to an infectious disease and the development of an active infection, with clinical manifestations of the disease. (D.M.H.)

INDAZOLE. **Pyrrole and Related Compounds.**

INDEFINITE INTEGRAL. Let $f(x)$ denote a given **function** of x; a function $F(x)$ which has $f(x)$ for its **derivative** (or $f(x)dx$ for its **differential**), is called an integral of $f(x)$ (or of $f(x)dx$).

If $f(x)$ is **continuous** and has an integral $F(x)$ in the interval (a, b), then every integral of $f(x)$ in (a, b) is of the form $F(x) + C$.

Hence, if $F(x)$ be any particular integral of $f(x)$, the general integral of $f(x)$ is $F(x) + C$, where C is an **arbitrary constant.** A general integral is also called an indefinite integral. The constant C is called the constant of integration.

The symbol for the general integral or indefinite integral of $f(x)$ is

$$\int f(x)dx.$$

To integrate $f(x)$ is to express $\int f(x)dx$ in terms of known functions We may interpret the symbol $\int$ as a symbol for this operation of integration and call $f(x)$ the integrand.

By definition

$$\frac{d}{dx}\int f(x)dx = f(x), \quad \text{or} \quad d\int f(x)dx = f(x)dx.$$

Hence, integration is the **inverse operation** of **differentiation,** that is, it is the operation which differentiation undoes.

No general process of integration exists. The process depends ultimately on recognizing a function as a derivative of a known function. It consists, therefore, of reversing differentiation rules. (L.L.S.)

INDEPENDENT CHUCK. **Chuck.**

INDEPENDENT VARIABLE. **Functions.**

INDETERMINATE EQUATIONS. An indeterminate equation is an **equation** with more than one unknown or **variable.** Indeterminate equations are sometimes called Diophantine equations, after the Greek mathematician Diophantus, who studied them.

An indeterminate equation in two variables is frequently studied to determine positive integral values of the variables which satisfy it; similarly for more unknowns. (L.L.S.)

INDETERMINATE FORMS. In various mathematical investigations, when limiting processes are applied to certain types of expressions involving special combinations of **functions**, an indeterminate form arises, which is one having no meaning in itself. To assign useful meanings to these forms, methods (which belong mostly to the **calculus**) have been devised, as follows:

The form 0/0:

If the fraction $f(x)/\phi(x)$ takes the form 0/0 when $x = a$, it is often possible to discover a factor common to $f(x)$ and $\phi(x)$ which vanishes when $x = a$, and after the removal of this factor, to find $\lim_{x \to a} f(x)/\phi(x)$ directly.

A more general method is: If $f(a) = 0$ and $\phi(a) = 0$, and if $\lim_{x \to a} \frac{f'(x)}{\phi'(x)}$ exists, then

$$\lim_{x \to a} \frac{f(x)}{\phi(x)} = \lim_{x \to a} \frac{f'(x)}{\phi'(x)}.$$

If $f'(a) = 0$ and $\phi'(a) = 0$, but if $\lim_{x \to a} \frac{f''(x)}{\phi''(x)}$ exists, then

$$\lim_{x \to a} \frac{f(x)}{\phi(x)} = \lim_{x \to a} \frac{f''(x)}{\phi''(x)};$$

and similarly for higher derivatives.

The form ∞/∞:

If the fraction $f(x)/\phi(x)$ takes the form ∞/∞ when $x \to a$, but if $\lim_{x \to a} \frac{f'(x)}{\phi'(x)}$, exists, then

$$\lim_{x \to a} \frac{f(x)}{\phi(x)} = \lim_{x \to a} \frac{f'(x)}{\phi'(x)};$$

and similarly with higher derivatives.

The forms $0.\infty$ and $\infty - \infty$:

These forms can frequently be reduced to the form 0/0 or ∞/∞ and treated as in the preceding.

The forms 1^∞, 0^0, ∞^0:

A function of the type $[f(x)]^{\phi(x)}$ may take one of these forms. If we put $u = [f(x)]^{\phi(x)}$, take logarithms and get $\log u = \phi(x) \log f(x)$, which will then take the form $0.\infty$, which can be evaluated by the preceding methods. (L.L.S.)

INDETERMINATE STRUCTURE. A statically indeterminate structure is one which cannot be solved by the equations for static equilibrium. These equations state that the components of the forces acting on a body, taken in any two directions, must be equal to zero and that the sum of the moments of these same forces, taken around any moment center, must equal zero. If the axial stresses in the members of a structure are changed by altering the length of one of the members a very small amount the structure is classified as indeterminate.

When there are more **reactions** than equations for static equilibrium the structure is externally indeterminate. After these reactions have been calculated the stresses in the members of the structure become statically determinate unless internally indeterminate, that is, contain redundant members (see **Redundancy**).

In general, statically indeterminate structures can be analyzed by methods such as the energy theory or the deflection theory, although some are so complicated that the analyst must resort to experimental methods. The analysis of any indeterminate structure requires a knowledge of the size, shape and elastic properties of the individual members.

Examples of indeterminate structures are triangular frameworks containing redundant members, rigid frames having **loads** transmitted by the rigidity of the joints, fixed or 2-hinged **arches**, suspension **bridges** with stiffening **trusses**, building frames under the action of **lateral** forces, beams with built-in end supports, beams fixed at one end and simply supported at the other end and beams continuous over a number of supports. (See **Least Work.**) (C.W.C., F.T.M.)

INDEX FOSSIL. Paleontology; Stratigraphy.

INDEX NUMBER. An index number is usually the ratio of 2 sums. It is a statistical device to measure changes in business, wages, prices, cost of living, production and consumption. Formulas are of two types, aggregative or relative and may be weighted or unweighted. There is always a base period to which other periods are compared. A typical aggregative formula weighted by quantities in the base year is

$$I = \frac{\Sigma p_1 q_0}{\Sigma p_0 q_0} = \frac{p_1^{(1)} q_0^{(1)} + p_1^{(2)} q_0^{(2)} + \cdots + p_1^{(N)} q_0^{(N)}}{p_0^{(1)} q_0^{(1)} + p_0^{(2)} q_0^{(2)} + \cdots + p_0^{(N)} q_0^{(N)}}$$

an index number of price where $p_1^{(N)}$ is the price of the Nth item in the period compared to the base period, $p_0^{(N)}$ is the price of the Nth item in the base period, $q_0^{(N)}$ and $q_1^{(N)}$ referring, respectively, to the quantities of the Nth item in the base period and the period being compared to the base period. (L.A.A.)

INDEX OF CORRELATION. The index of correlation, ρ_{yx} is defined as

$$\rho_{yx} = \sqrt{1 - \frac{\sigma_e^2}{\sigma_y^2}},$$

where σ_e^2 is the square of the **standard error of estimate,**

$$\sigma_e^2 = \frac{\Sigma(y - y^1)^2}{N},$$

where y is an actual value, y' is the theoretical or estimated value found from a curvilinear function $y' = f(x)$. The **variance** of y is σ_y^2. The main distinction between the **coefficient of correlation** and the index of correlation is that r_{ey} depends on linear **regression.** To test the significance of ρ_{yx}, the **analysis of variance** is used. (L.A.A.)

INDEX OF DETERMINATION. The index of determination is ρ^2_{yx}, the square of the **index of correlation.** (L.A.A.)

INDEX OF DISPERSION. The purpose of the index of dispersion for the **Bernoulli probability function** and the **Poisson distribution** is to test homogeneity in certain types of data. The index of dispersion for the Bernoulli probability function is defined as

$$D = \frac{\Sigma(x - \bar{X})^2}{npq} = \frac{\Sigma(x - \bar{X})^2}{\bar{X}\left(1 - \frac{\bar{X}}{n}\right)},$$

where the Σ extends over the number of **samples** N, $\bar{X}$ is the **mean** of the number of successes in each sample, n is the number of specimens examined in each sample. Then D is distributed approximately as χ^2 with $N - 1$ **degrees of freedom.** If $np \geq 5$, this approximation is highly satisfactory. For $np < 5$ it should be handled with care.

For the **Poisson distribution,** the index of dispersion D is defined as

$$D = \frac{\Sigma(x - \bar{X})^2}{\bar{X}},$$

where x is the value from each sample and $\bar{X}$ is the mean of the N samples. D is again distributed approximately as χ^2 with $N - 1$ degrees of freedom. This approximation is quite satisfactory for $m \geq 2$, where m is the mean in the Poisson distribution. (L.A.A.)

INDEX OF MULTIPLE CORRELATION. The index of multiple correlation P is defined as

$$P = 1 - \frac{\sigma_e^2}{\sigma_y^2},$$

where

$$\sigma_e^2 = \frac{\Sigma(y - y^1)^2}{N},$$

y is the actual value of an observation, y' is the value obtained by a curvilinear function involving more than one independent **variable**, σ_y^2 is the **variance** of the variable y. The index is essentially the same as the **coefficient of multiple correlation.** The main difference is that in the case of multiple correlation the theoretical or estimated value y' is found by use of the independent variables in the first degree only. (L.A.A.)

INDEX OF MULTIPLE DETERMINATION. The index of multiple determination is the square of the **index of multiple correlation** P^2. (L.A.A.)

INDEX OF PRECISION. The index of precision, h, is defined as

$$h = \frac{1}{\sqrt{2}\sigma_x}$$

when x is **normally distributed.** As the σ_x decreases, the index of precision increases. It is infrequently used. (L.A.A.)

INDEX OF REFRACTION. Refractive Index.

INDEX OF ROOT OF NUMBER. Roots of Numbers.

INDEXING. Milling.

INDICATED HORSEPOWER. The horsepower developed in the cylinder of any **piston and cylinder engine** is called indicated horsepower because it can be measured by the **indicator** mechanism. This power is the result of a gas or vapor pressure pushing against a piston, and is larger than the crankshaft horsepower by the amount of friction and windage losses of the engine.

If, during a certain power stroke in a cylinder, P is the average effective pressure acting against each unit of piston area, the piston will receive and pass on to the piston rod a push of $P \times A$ pounds. In the above, A is the piston area. When the piston moves through a stroke measured as L feet, the work represented by the motion of the push of PA pounds is PAL. In the ordinary double-acting steam engine, the number of these power strokes per minute is double the number of revolutions per minute, since there is an action of steam against the piston on both the out and in stroke. Thus in one minute there are $2PLAN$ foot-pounds of work done in the cylinder. The number of foot-pounds per minute in a horsepower being 33,000, the above explains the origin of the common steam engine horsepower formula,

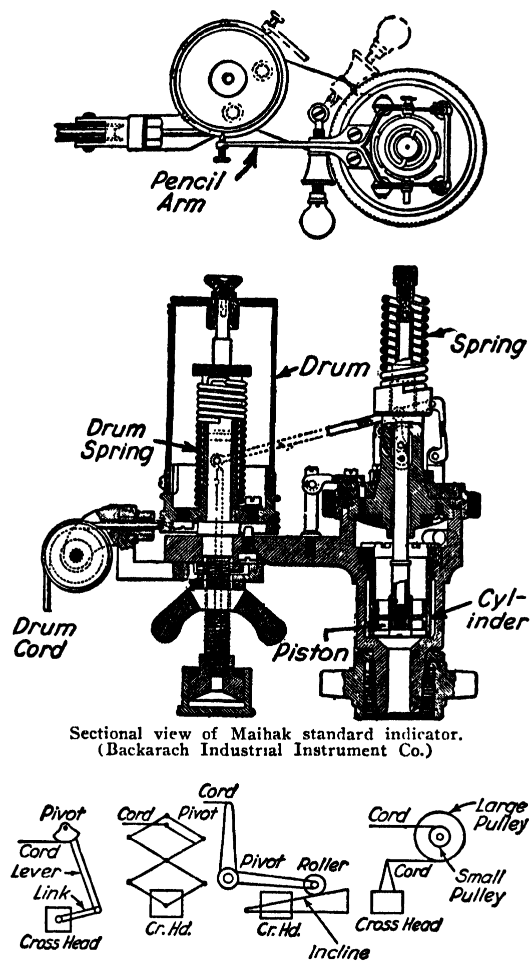
$$IHP = \frac{2PLAN}{33{,}000} \text{ per cylinder.}$$

The actual use of this formula requires knowing the bore and stroke of the engine from which A and L are determined, the operating speed in revolutions per minute, and the mean effective pressure P. This mean effective pressure can be obtained experimentally with the use of the indicator, which is an autographic device by means of which an engine draws its cycle on a PV plane. The average height of the figure so drawn is the mean effective pressure.

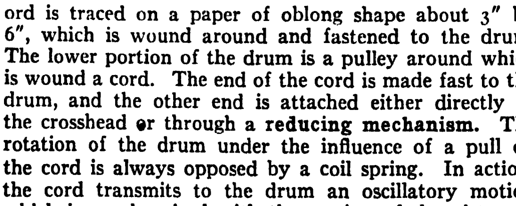
In the case of multi-cylinder internal combustion engines which may be two- or four-stroke cycle, single- or double-acting, the $2N$ of the above formula should be replaced by the number of power strokes made per minute by the engine. The result would be engine indicated horsepower. (F.T.M.)

INDICATOR. Chemical indicators are discussed in the article on **Reactions Involving Recombinations of Ions.**

In engineering the indicator is an **engine** instrument the purpose of which is to give an autographic record of the pressure-volume relationship of the working medium within the cylinder as the engine goes through its **cycle** of operations. The cross-section of a **steam engine** indicator is shown in the accompanying drawing. The rec-



Sectional view of Maihak standard indicator. (Backarach Industrial Instrument Co.)



Indicator reducing motion.

ord is traced on a paper of oblong shape about 3" by 6", which is wound around and fastened to the drum. The lower portion of the drum is a pulley around which is wound a cord. The end of the cord is made fast to the drum, and the other end is attached either directly to the crosshead or through a **reducing mechanism.** The rotation of the drum under the influence of a pull on the cord is always opposed by a coil spring. In action, the cord transmits to the drum an oscillatory motion which is synchronized with the motion of the piston in the cylinder. This places the paper wound around the drum in a position (with respect to a fixed pencil point) which is proportional to the stroke or to the volume of piston displacement at any instant. The other element of the indicator, the pressure element, consists of a piston moving in a cylinder and opposed by a calibrated spring. The indicator cylinder is connected to the engine cylinder by short interconnecting piping through which the instantaneous pressures in the cylinder are transmitted to the indicator piston. The latter rises against the spring pressure until the point of equilibrium is reached. The position of the piston in the indicator

cylinder is proportional to the pressure in the engine cylinder. This position is transferred to the record as a corresponding vertical motion of the pencil arm. At the extremity of this arm, the pencil writes on the drum. It draws a record which, by virtue of the features pointed out above, is a diagram of the cycle of pressure vs. the volume in the engine cylinder. Engines with high rotative speed (over 750 rpm) may not readily be tested with the above described indicator because the inertia of the indicator parts prevents an accurate tracing of the rapidly changing state of the working medium in the engine cylinder. Special high-speed indicators, electrical in nature, have been developed which trace a pressure-time graph. Using data from this curve and the known bore, and rpm of the engine, a pressure volume diagram may be constructed. (F.T.M.)

INDICOLITE. **Tourmaline.**

INDIGESTION. Impairment of **digestion** and the symptoms resulting therefrom. The term is a loose one and covers digestive disturbances which may occur as part of the symptom complex of a number of diseases. The symptoms complained of vary, but usually include discomfort and a feeling of fullness in the abdomen, belching, sour eructations and "heartburn." (D.M.H.)

INDIGO. **Indigofera tinctoria.** Leguminoseae. The indigo-yielding plant is a shrub 4–6′ tall, growing wild in southern Asia. It has **pinnately** compound leaves, which are downy beneath, and bears reddish-yellow flowers.

For thousands of years the plant has been grown in India, where it was first discovered to yield a dye which would give cotton or woolen cloth a deep blue color of great permanence. Curiously enough, no indication of this color is found in the plants. They contain, however, a glucosidal (see **Carbohydrates**) substance which can be extracted from the shoots with water, and which yields indigo blue. This substance is insoluble in water. Before it can be used to color cloth, the dye-stuff must be dissolved in lime-water (or any **alkaline** solution), and some fermenting substance, such as molasses. Then a new compound, indigo white, is formed. When the cloth to be dyed is soaked in this solution and then exposed to the air to dry, it soon acquires the deep blue color characteristic of indigo. (For the chemistry of Indigo, see **Pyrrole and Related Compounds.** See also **Dyes.**)

The development of synthetic indigo has caused the use of the natural product to decline considerably. (R.M.W.)

INDIUM. Symbol: In. Atomic number: 49. Atomic weight: 114.76. Density: 7.28. Hardness: 1.2. Melting point: 155° C. Boiling point: 1450° C. (**Isotopes:** page 290.)

Indium is a silver-white metal, softer than **lead,** malleable, ductile and crystalline: stable in dry air: on heating in air burns with a blue flame to form oxide; does not decompose water at 100° C.; dissolves in **hydrochloric, sulfuric** or **nitric acids** but not in **sodium** hydroxide; combines with **chlorine** and with **sulfur.** Discovered by Reich and Richter in 1863 by means of spectroscope.

Indium occurs in very small amount in **zinc blende, tungsten, tin** and **iron** ores of certain localities. The recovery of indium from zinc flue dust (sometimes, 1 part per thousand) is effected by treating with a slight deficiency of hydrochloric acid and allowing to stand. The residue is subjected to a series of treatments until finally pure indium sulfate is obtained, a solution of which when electrolyzed yields compact indium metal. A thin surface layer of indium is used on some bearings.

Chlorides: Indium monochloride ($InCl$), dark red crystals; indium dichloride ($InCl_2$), colorless crystals; indium trichloride ($InCl_3$), white crystals. Volatile indium salts, such as the chlorides, color the Bunsen flame blue-violet, which accounts for the derivation of the name indium (indigo blue).

Hydroxide: Indium hydroxide ($In(OH)_3$), white, gelatinous precipitate by sodium hydroxide with indium salt solutions, soluble in excess sodium hydroxide, but reprecipitated on boiling.

Oxides: Indium monoxide (InO), black, pyrophoric powder, by heating indium sesquioxide in hydrogen at 300° C.; indium sesquioxide (In_2O_3), light yellow powder, by burning indium in air, or by ignition of indium nitrate below 850° C., above 850° triindium tetroxide (In_3O_4) is formed. (R.K.S.)

INDOLE. **Pyrrole and Related Compounds.**

INDRI. Mammalia, Primates. A **lemur,** *Indris brevicaudatus,* of Madagascar, with a slender body, disproportionately large arms and legs, and a small head resembling that of a dog. (A.W.L.)

INDUCED DRAG. A large portion of the air drag on an airfoil or wing is derived from a source which is independent of surface friction, turbulence, impact, etc. This *induced* drag is theoretically zero if the span is infinitely long. If the Æ were 100 or more, the induced part of the drag would, for all practical purposes, have disappeared. With constant angle of attack, the coefficient of induced drag depends only on Æ, hence activities like smoothing and waxing wing surfaces, fairing projections, etc., would not affect it. Aircraft needing reduction of drag to least possible values (such as sailplanes) must perforce not only have smooth, aerodynamically clean surfaces, but also wings of high Æ. Long tapered wings with Æ's as high as 20 have been used. This might be contrasted with the powered airplane where 5 to 8 is found to be the usual range. (See **Airfoil.**) (F.T.M.)

INDUCED RADIOACTIVITY. **Artificial Disintegration of Elements.**

INDUCTANCE. The inductance of a circuit (such as a coil) is the rate of increase in magnetic linkage with increase of current. If we have a coil of several turns, carrying a steady current, a certain magnetic flux will, as a result, be linked with the coil, depending upon the size and shape of the coil, the number of turns, and the material occupying the surrounding space. If the current is now slightly increased, the resulting increase in flux may or may not be proportional to the change in current; if not, we shall have to consider a very small increase in each. The "linkage" is the product of the flux through the coil by the number of turns. Since magnetic flux is ordinarily expressed in lines or maxwells (see **Magnetic Field**), the linkage may be expressed in maxwell-turns. The inductance unit called the henry corresponds to a rate of linkage increase of 10^8 maxwell-turns per ampere of current. This is a rather large unit, hence the millihenry and microhenry are commonly used.

Since an increase of 10^8 maxwell-turns per sec. induces 1 **volt** of electromotive force in the circuit, a coil may be said to have 1 henry of inductance if an increase of 1 ampere per sec. results in the self-induction of 1 volt; this is an alternative definition of the henry.

Mutual inductance may be explained in the same way and expressed in the same units; except that the current in one circuit causes a flux linkage, or induces an electromotive force, in another, neighboring or coupled circuit. An **induction coil** or a **transformer** involves this kind of inductance, as well as the self-inductance of each circuit. A coil arranged to have its inductance

adjustable and provided with a scale to indicate its inductance in millihenrys is called an inductometer. Inductances of circuits are usually measured in terms of the impedances which they offer to **alternating currents.** For very high frequencies the observed impedance of an inductive circuit presents anomalies due to the "skin effect," as a result of which the inductance apparently changes slightly with frequency in the high-frequency range. (L.D.W.)

INDUCTION COIL. A device for obtaining a high, intermittent voltage from a source of low, steady voltage, such as a battery. This is accomplished by electromagnetic induction. A coil of relatively few turns, called the primary, and provided with a soft iron core, is connected in series with the battery and with some form of interrupter which renders the current intermittent. The rapid variations of magnetic flux thus produced give rise to correspondingly high electromotive forces in the secondary, a coil of many turns

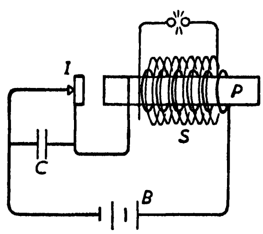


Diagram of an induction coil, showing battery *B*, interrupter *I*, and condenser *C*.

of fine wire wound on the same core and thus effectively coupled with the primary. The secondary electromotive force of course reverses with each make and break of the primary circuit. The performance is improved by placing a **condenser** across the terminals of the interrupter. This takes up the surge of current that would otherwise cause destructive sparking at the interrupter gap, while the discharge of the condenser causes a higher peak electromotive force in the secondary. The change of flux during the charging and discharging of the condenser while the interrupter is open is much more rapid than that while the primary circuit is closed. This gives a partially unidirectional character to the secondary voltage and makes the induction coil suitable for operating Geissler and small x-ray tubes. The largest use of the induction coil at present is for ignition in the operation of internal combustion engines, where it is commonly called a spark coil. Devices of somewhat similar construction, known as vibrators, are commonly used to derive the voltages necessary for operating radio apparatus from low-voltage batteries. (L.D.W.)

INDUCTION FIELD. This is the magnetic field set up around a conductor by the current in the conductor and which causes a back electromotive force to be induced in the conductor. The magnetic fields present around d-c and low-frequency circuits are considered to be of this sort since the error in the assumption is entirely negligible. All the energy stored in this field is returned to the circuit when the current flow is stopped. The induction field is contrasted with the radiation field which has a large value at radio frequencies and whose energy is not returned to the circuit but is radiated outward giving electromagnetic waves in space (the waves by which we communicate in radio). Many short-distance wireless communication systems utilize the induction field since it does not extend very far and hence does not interfere with regular radio reception at any great distance. (L.R.Q.)

INDUCTION FURNACE. **Electric Furnace.**

INDUCTION GENERATOR. When an induction **motor** is driven by mechanical means above synchronous speed its **slip** becomes negative and the machine will act as a **generator** if it has the proper excitation. The induction generator draws its exciting current from the line which puts a definite limit on the usefulness of the machine. For the line current to produce the correct field the load must take a leading current from the generator. This requirement for a **capacitive load** may be met by static **condensers** (almost never used) or synchronous machines on the line. The speed of the induction generator does not determine the **frequency** which is fixed by synchronous machines on the same system. The load which the induction machine can supply does, however, vary with the speed. Since induction generators cannot supply lagging power factor loads and require an appreciable leading current for excitation they are not widely used to give increased generating capacity to a system. The generating characteristic of over-driven induction motors is important in certain applications, notably railway work, where it is used for dynamic braking. (L.R.Q.)

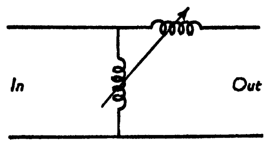
INDUCTION HEATING. **Electric Furnace.**

INDUCTION, MATHEMATICAL. The method of mathematical induction is a general method of proof of theorems in which a positive integral variable is involved. It consists of two main parts: (1) direct verification of the theorem for the smallest admissible value of the positive integer involved, (2) the algebraic proof that if the theorem is true for any value of the integer, it is true for the next greater value. In conclusion, the theorem is proved by combining the above two parts. (L.L.S.)

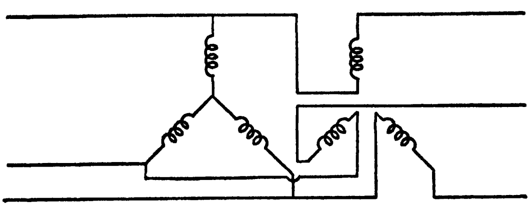
INDUCTION MOTOR. **Motor, Electric.**

INDUCTION REGULATOR. This is a specially constructed **transformer** designed for regulating the line voltage of a-c systems. The single-phase regulator is essentially a transformer with one winding arranged so it may be rotated with respect to the other. When the axes of the two windings coincide the induced voltage in the secondary will be a maximum while when the axes are 90° apart the induced voltage will be a minimum. The primary winding is connected across the line and the secondary in series as shown in the figure. This causes the voltage of the secondary to add vectorially to the original line voltage. By rotating the movable winding the magnitude of the secondary voltage may be changed and it may also be made to add to or subtract from the primary voltage. The resultant output voltage can, then, be varied by plus or minus the secondary voltage. The capacity of the regulator needs to be only a small fraction of the capacity of the line since only a small part of the power is transformed, the remainder going through by direct conduction. The operation of the regulator is usually made automatic by voltage-operated relays controlling driving motors on the rotor. To prevent the series winding offering high impedance when its axis is 90° from the primary a shorted winding is placed on the primary core 90° from the primary winding. Thus this winding serves as a shorted winding coupled to the secondary when it is in its zero position. If it were not for this auxiliary winding the current through the main secondary would be limited to a very low value when the secondary is in its minimum voltage position. Any three-phase wound-rotor **induction motor** with blocked rotor may be used as a three-phase induction regulator or the machine may be built especially for this application, the principle of operation being the same in either case. The secondary voltages will always be of the same magnitude regardless of the position of the rotor but the phase relation of the secondary and primary

voltages may have any value from 0° to 360° so the vector addition will give a variable or adjustable output. (See figure for connections.) (L.R.Q.)



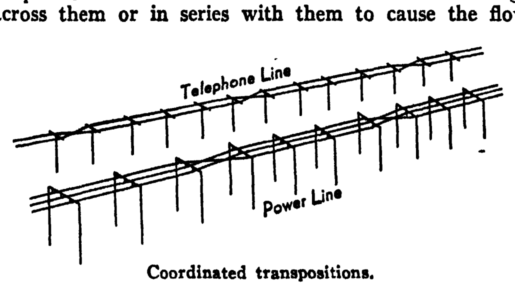
Single-Phase Connections



Three-Phase Connections

INDUCTIVE COORDINATION. This is the coordinated system of line **transpositions** carried out by the telephone and power system operators. (See **Inductive Interference.**) (L.R.Q.)

INDUCTIVE INTERFERENCE. When a telephone line is paralleled by a power line or even another telephone line there is almost certain to be induced interference in the telephone line. This interference is due to voltages and corresponding currents induced in the line by voltages or currents in the paralleling line. If a.c. flows in a line it causes an alternating flux to be set up around the wires. This flux extends outward for a considerable distance and may link another line inducing voltages in series with this second line. Because of their extremely small magnitude the effects produced by telephone lines in power lines are of no consequence but those produced by the power line in the telephone line are very serious since, although they may be small, they are comparable to the normal signal voltages. Sixty-cycle currents are below the transmission limits of most telephone equipment but may cause trouble in telegraph circuits. However, harmonics of the power circuit and especially high-frequency transients induced by switching and lightning cause objectionable interference. Another type of induced voltage is caused by the electrostatic flux from the high-voltage transmission line. The telephone line in this field will assume a potential corresponding to its capacitance with respect to the ground and the power line. Noise currents in the terminal equipment of the phone circuits may be eliminated or materially reduced by accurate balancing of the various line and equipment impedances with respect to ground in the telephone system and by a coordinated system of line **transpositions.** By transposing the lines (both telephone and power) very nearly equal voltages will be induced in both wires of the telephone line and hence there will be no net voltage across them or in series with them to cause the flow of noise currents. Telephone lines are also transposed to avoid **crosstalk** between them. These transpositions must be carefully worked out for all lines concerned if full benefit is to be realized. Inductive interference from power lines is largely eliminated by the shielding by the sheath of a **cable** and is completely eliminated by the use of the **coaxial cable.** An elementary coordinated system of transpositions is shown. (L.R.Q.)



Coordinated transpositions.

INDUCTIVE LOAD. An electrical load consisting of resistance and inductance, that is to say, of **coils, solenoids,** windings, etc., is said to be inductive since the induction in such windings delays the current to the point where variations of current in an a-c circuit lag a certain degree behind variations of voltage. (See **Alternating Currents.**) (F.T.M., L.R.Q.)

INDUCTOMETER. Inductance.

INDUCTOR. An inductor is a conductor or bundle of conductors on an electrical machine in which the voltage is induced by the cutting of lines of flux. The main conductors along the surface or in the slots of a generator **armature** are inductors. (L.R.Q.)

INDURATED. This term as used by petrologists signifies rocks which have been hardened by the action of heat. (R M.F.)

INDURATION. The state of increased resistance or hardness in any tissue or organ. This may be an indication of inflammation, abscess or tumor. (R.S.M.)

INDUSIUM. Ferns.

INDUSTRIAL STATISTICS. Industrial statistics consists of the applications of statistical theory to the problems of industry and engineering. The theory includes **descriptive statistics, probability functions,** the **Bernoulli, Poisson,** and **normal probability functions, analysis of variance, Student's t distribution, Snedecor's F distribution,** consumer protection, production control, the control of defectives in the manufacturing process and **quality control** in general. (L.A.A.)

INEFFICIENT STATISTIC. An inefficient statistic is one which is not efficient. Roughly speaking, it does not make a complete use of all the **variates** in a sample. (See **Efficient Statistic.**) (L.A.A.)

INEQUALITIES. The notation $a < b$ means: a is less than b, and the notation $a > b$ means: a is greater than b. The notation $a \leqq b$ means: a is either less than or equal to b; similarly for $a \geqq b$.

The rules for operating with inequalities are expressed by:

if $a < b$, and $b < c$, then $a < c$,
if $a < b$, then $a + c < b + c$,
if $a < b$ and $c > 0$, then $a \cdot c < b \cdot c$,
if $a < b$ and $c < 0$, then $a \cdot c > b \cdot c$.

If the sense of an inequality is the same for all values of the symbols for which its members are defined, the inequality is called an absolute or unconditional inequality.

If the sense of an inequality holds only for certain values of the symbols involved, but is reversed or destroyed for other values of the symbols, the inequality is called a conditional inequality.

The sense of an inequality is not changed if both members are increased or decreased by the same number.

The sense of an inequality is not changed if both members are multiplied, or divided, by the same positive number. The sense of an inequality is reversed if

both members are multiplied, or divided, by the same negative number. (L.L.S.)

INERT GASES. These are the elements which are found in the first group of the periodic table and consist of **helium, neon, argon, krypton, xenon** and **radon.** (R.K.S.)

INERTIA. Inertia is one of the few properties manifested by all kinds of matter. While its name infers inaction (no doubt from the fact that bodies do not set themselves into motion), inertia is an actual opposition to any alteration of motion. That is, the acceleration of a body in any sense, either as to speed or direction of motion, requires the application of force proportional to the mass of the body and to the amount of acceleration. The reaction to this force, acting always through the **center of mass**, is a measure of the inertia of the body.

It is interesting to speculate as to wherein the inertia of a body resides. Is it inherent in the body itself, or does it in some way concern also its physical environment? The discovery of electromagnetic mass and electromagnetic inertia, and the identification of the latter as a property of the **electromagnetic field** surrounding a moving charge, suggests that the ordinary inertia of neutral masses may be similarly traceable to some reaction in the neighboring space. And when we consider that all matter is, in the last analysis, probably electrical in character, the idea that inertia may actually be an electromagnetic reaction appears not unreasonable. (See **Moment of Inertia.**) (L.D.W.)

INFANTILE PARALYSIS. Poliomyelitis.

INFECTIOUS MONONUCLEOSIS (Glandular fever). An acute disease characterized by fever, sore throat, enlargement of the spleen and lymph nodes, and **leukocytosis** with an increase in large mononuclear cells up to 50 to 85% of the total count. These cells are abnormal lymphocytes which are typical for a number of virus diseases.

The cause of infectious mononucleosis is unknown. The disease seems to be contagious . It occurs chiefly in the age group 15 to 30 years. The clinical picture is extremely variable, but the course is usually mild. The average duration is 2 to 4 weeks, and treatment is symptomatic. The diagnosis is established by the characteristic blood findings plus a serological test. The serum of patients with infectious mononucleosis contains so-called hetrophile **antibodies** which agglutinate sheep red cells. This test is positive the second week, often in very high titer. (D.M.H.)

INFINITE GEOMETRIC PROGRESSION. Geometric Progressions.

INFINITE SEQUENCES. An infinite sequence is an endless set of elements such that we can establish a one-to-one correspondence between these elements and the natural numbers 1, 2, 3, $\cdots$, n, $\cdots$. An infinite sequence may be represented in general by $u_1, u_2, u_3, \cdots, u_n, \cdots$, or more briefly by $\{u_n\}$.

A sequence $\{u_n\}$ is called convergent when it has a **limit**; that is, if a number u exists such that for any arbitrary number $\epsilon > 0$ there exists a number N such that $|u - u_n| < \epsilon$ for every $n > N$, then the sequence $\{u_n\}$ is convergent and has the limit u. We write $u = \lim\limits_{n\to\infty} u_n$.

If a sequence is not convergent, it is frequently called divergent. (L.L.S.)

INFINITE SERIES. Let $u_1, u_2, u_3, \cdots, u_n, \cdots$ be an **infinite sequence**; form the partial sums: $s_1 = u_1$, $s_2 = u_1 + u_2$, $s_3 = u_1 + u_2 + u_3$, $\cdots$, $s_n = u_1 + u_2 + \cdots + u_n$, $\cdots$. The infinite sequence $s_1, s_2, s_3, \cdots, s_n, \cdots$ is called the infinite series whose terms are $u_1, u_2, \cdots, u_n, \cdots$; it is denoted by

$$u_1 + u_2 + u_3 + \cdots + u_n + \cdots, \text{ or by } \Sigma u_n, \text{ or } \sum_{n=1}^{\infty} u_n.$$

If the infinite sequence $\{s_n\}$ converges and has a **limit** S, then the infinite series Σu_n is said to converge and to have the sum S; otherwise the series is usually said to be divergent.

The general principle of convergence for series is: A necessary and sufficient condition for the convergence of a series Σu_n is that, for any $\epsilon > 0$, an index N exists such that for every $n > N$ and for every value of p, we have

$$|u_{n+1} + u_{n+2} + \cdots + u_{n+p}| < \epsilon.$$

A necessary condition for convergence of the series Σu_n is $\lim\limits_{n\to\infty} u_n = 0$; this condition is not sufficient for convergency.

If $\Sigma |u_n|$ is convergent, so also is Σu_n. In this case Σu_n is called absolutely convergent. If Σu_n is convergent but $\Sigma |u_n|$ is not convergent, then Σu_n is called conditionally convergent.

Many tests of convergence and divergence of series are known. We can give only a few of the most useful of these here.

Comparison test: If a positive term series Σc_n is known to be convergent, and if Σa_n is a positive term series to be tested and if $a_n \leqq c_n$ for all values of n (or at least for all values of n beyond a certain point), then Σa_n is convergent. If Σd_n is a positive term series known to be divergent, and if $a_n \geqq d_n$ for all values of n (or for all values of n beyond a certain point), then Σa_n is divergent.

Ratio test: If Σa_n is a positive term series to be tested, and if $\dfrac{a_{n+1}}{a_n} < r < 1$ for all values of n (or for all values of n beyond a certain point), then Σa_n is convergent; if $\dfrac{a_{n+1}}{a_n} \geqq 1$ for all values of n (or all beyond a certain point), then Σa_n is divergent.

Also, if $\lim\limits_{n\to\infty} \dfrac{a_{n+1}}{a_n} = l$ and $l < 1$, then Σa_n is convergent, and if $l > 1$, then Σa_n is divergent, but if $l = 1$, there is no test.

Radical test: If Σa_n is a positive term series to be tested, and if $\sqrt[n]{a_n} < r < 1$ for all values of n (or for all beyond a certain point), then Σa_n is convergent, and if $\sqrt[n]{a_n} \geqq 1$ for all n (or for all beyond a certain point), then Σa_n is divergent.

Also, if $\lim\limits_{n\to\infty} \sqrt[n]{a_n} = l'$, then Σa_n is convergent if $l' < 1$, and is divergent if $l' > 1$, but if $l' = 1$ there is no test.

Integral test· If $f(x)$ is a positive monotonic decreasing function which approaches 0 as $x \to \infty$, then the series $\Sigma f(n)$ is convergent or divergent according as the definite integral $\int_a^\infty f(x)dx$ is convergent or divergent (that is, according as $\lim\limits_{\lambda\to\infty} \int_a^\lambda f(x)dx$ exists (finite) or not).

Alternating series test: If a series Σu_n has its terms alternately positive and negative, and steadily decreasing, so that each term is numerically less than the preceding, and if $u_n \to 0$ as $n \to \infty$, then Σu_n is convergent.

In this case, the error involved in taking the sum of the first n terms as an approximation to the sum of the series is less in absolute value than the absolute value of the $(n + 1)^{st}$ term.

To add or subtract two series Σu_n and Σv_n is to form the series $\Sigma(u_n \pm v_n)$. If the given series are convergent with sums U and V, then the series $\Sigma(u_n \pm v_n)$ obtained by adding or subtracting them is convergent and has the sum $U \pm V$.

The (Cauchy) product of two series Σu_n and Σv_n is defined as the series Σw_n, where $w_n = u_1v_n + u_2v_{n-1} + \cdots + u_nv_1$.

If Σu_n and Σv_n are both absolutely convergent, then the product series Σw_n is absolutely convergent, and if their sums are U and V, then the sum W of the product series is $W = U \cdot V$. (Cauchy's theorem.)

If Σu_n and Σv_n are convergent with sums U and V, and if at least one of them is absolutely convergent, then the product series Σw_n is convergent and its sum is $W = U \cdot V$. (Mertens' theorem.)

If Σu_n and Σv_n are convergent with sums U and V, and if the product series Σw_n is convergent with sum W, then $W = U \cdot V$. (Abel's theorem.)

If two series are only conditionally convergent, their product series may be convergent or may be divergent. (L.L.S.)

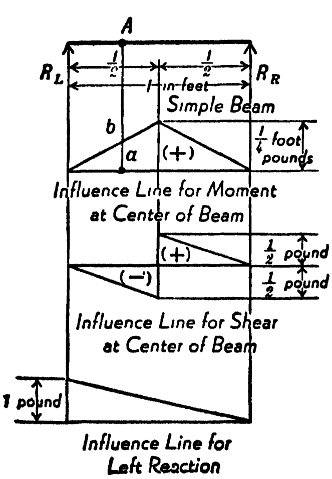
INFINITESIMALS. Limits.

INFLAMMATION. The response of the body to infection or irritation. It is characterized by redness, heat, swelling, and pain. The redness and heat are due to the increased blood supply to the involved area. The blood vessels are dilated and engorged, and there is a loss of plasma fluid from them into the tissue spaces. This results in **edema** or swelling. The swelling distends the tissues, compresses nerve endings, and thus causes pain. The white blood cells or leucocytes take an important part in inflammation. They crowd the tissue spaces, carry on their work as **phagocytes,** picking up bacteria and cellular debris. They aid in walling off an infection and preventing its spread. As the inflammatory reaction subsides, repair of the damaged tissue takes place. If the tissue is one capable of complete regeneration, new cells of the same type may completely replace the old ones. This phenomenon is seen in minor inflammations of the skin. In other tissues, such as nervous tissue, regeneration may be very limited or absent; the damaged cells will then be replaced by fibrous scar tissue. This latter form of repair occurs with all inflammations of great size which cause marked cellular destruction. (D.M.H.)

INFLECTION, POINT OF. Concavity and Convexity of Plane Curves.

INFLORESCENCE. Flower.

INFLUENCE LINE. An influence line is a graphical way of representing the effect of a certain variable circumstance upon a given condition. In particular, the influence line as applied in structural engineering represents the variable effect of a single moving unit concentrated load upon the shear, bending moment, reaction, or any other function of a structure such as a **beam, truss,** or **bridge.** The influence line is plotted in reference to a



base or zero line. Positive or tensile effects are represented above the line and negative or compressive effects below. The ordinate of the influence line is the ratio of the effect to the concentrated load producing it. If the load is in lbs. or tons the effect is in lbs. or tons. It is very useful for locating the position of the load which will produce maximum effect. For instance, the influence line for **bending moment** at the center of the beam shown above indicates that the maximum moment for this point will occur when the moving load which may be taken as unity is directly over the point. Any other ordinate such as ab represents the bending moment at the center due to a load of unity at point A. The maximum moment at the center of this beam due to a uniform load of w lbs. per linear ft., covering the entire length, may be computed by multiplying the area of the influence line by w.

$$\text{Area} = \frac{l}{4} \times l \times \frac{1}{2} = \frac{l^2}{8}$$

$$\text{Maximum moment at center} = \frac{wl^2}{8}.$$

The results obtained from influence lines may also be found by analytical methods but the graphical solution is usually much more efficient from the standpoint of time. This is particularly true when computing the stresses in the members of a large bridge due to its own dead weight and moving loads. (C.W.C., F.T.M.)

INFLUENT. In hydrology designates that portion of a stream which contributes water to, rather than derives water from, the ground-water zone. (R.M.F.)

INFLUENZA. A highly contagious disease which usually occurs in epidemic or pandemic form, spreading with great rapidity. The last great pandemic occurred in 1918–20. Previous epidemics occurred in 1889–92, 1847–48, 1836–37, 1830–33, 1780–82, 1729–32.

Influenza in its uncomplicated form is rarely serious, but it may become so because it predisposes to a particularly fatal secondary infection of the lungs, an extremely severe **pneumonia.**

The disease is caused by a filterable **virus.** Influenza virus is now known to occur in many different strains which are immunologically different. At least two, designated influenza A virus and influenza B virus have been identified in epidemics. In a typical case, the principal symptoms are sudden onset with fever, prostration, severe aching pains in the back and limbs, blood-shot eyes, headache and progressive **inflammation** of the respiratory **mucous membranes.** The disease is self-limited, and runs its course in 2 to 4 days. Complications such as **bronchitis, sinusitis,** and middle-ear infection (**otitis media**) are not uncommon in the simple form. The fatal **pneumonia** form usually occurs in pandemics only. (D.M.H.)

INFRA-RED PHOTOGRAPHY. The first photographs by infra-red radiation appear to have been made about 1880 by Sir William Abney using a specially prepared collodion emulsion. Abney is reported to have photographed a boiling tea-kettle but efforts by others to repeat his work were not particularly successful. In 1903 the first real infra-red sensitizer, Dicyanine, was discovered. While the sensitizing action extended to a wavelength of 960 millimicrons in the infra-red, the exposure was too long for general photography and Dicyanine-sensitized plates were used chiefly in infra-red spectroscopy. The discovery of more efficient sensitizers in the early twenties, beginning with Kryptocyanine and Neocyanine and followed by the penta- and tetra-carbocyanines, has made it possible to prepare films and plates whose sensitivity in the infra-red is such that they can be used for general photography, including aerial and motion-picture photography.

Infra-red-sensitive films and plates may be divided into two classes: (1) materials of relatively high speed to the extreme red and infra-red, i.e., from approximately 700 to 900 millimicrons, and (2) materials sensitive to much longer wavelengths but of lower sensitiveness. The former are used for general photography, for aerial photography and cinematography; the latter for spectroscopy in the infra-red and other scientific applications requiring sensitivity to wavelengths longer than about 900 $m\mu$. All infra-red-sensitive materials are sensitive to violet and blue and to the extreme visible red as well. Photographs made without a filter resemble those made on an ordinary blue-sensitive material. For most purposes it is sufficient to use an orange or light-red filter which will absorb blue and violet light. In this case, the picture is made partly by infra-red and partly by the extreme red. The result, however, is generally only slightly different from that obtained with infra-red radiation alone. For true infra-red photographs, a visually opaque filter transmitting the infra-red only must be used. No filter, however, is required when photographing hot bodies such as an electric flatiron, hot castings, or high-pressure boilers, provided these show no visible glow.

All infra-red sensitive materials must be loaded and developed in total darkness, as safelight screens, even those for panchromatic films and plates, transmit the infra-red freely.

Certain precautions are necessary when making pictures with infra-red-sensitive materials. The bellows and shutter blades of some cameras, although perfectly safe for ordinary photographic films and plates, transmit the infra-red and fog infra-red sensitive films. The slides of some film and plate holders transmit the infra-red sufficiently to cause fog. While some modern lenses are corrected for the infra-red, with most the focal distances for the visible and for the infra-red are different. Usually it is sufficient to extend the lens a distance equal to 2% of the focal length beyond the visual focus. Even this may often be ignored when using a lens of short focal length or a small diaphragm.

Infra-red photographs of landscapes are quite different from those made in the usual way. Green foliage is reproduced light and blue sky and water almost black. The shadow portions of the subject are dark and without detail. The general effect is that of a photograph made by moonlight, particularly if the print is made rather dark. As a matter of fact, most night scenes in motion pictures are really infra-red photographs.

Since infra-red radiation is not scattered by atmospheric haze, as is light, distant objects are rendered sharper and more distinctly in infra-red photographs. Objects invisible to the eye because of the intervening haze are often reproduced sharply in an infra-red photograph. In fact one of the most important applications of infra-red photography is in photographing distant objects, whether from the ground or the air. Infra-red photographs, however, cannot be made through dense fog.

Infra-red portraits are unusual in appearance but not generally pleasing. The lips and eyes are quite dark, almost black, while the face is light and translucent.

The scientific applications of infra-red photography are numerous and important.

1. *In Medical Photography.* To study diseases and conditions affecting the venous pattern not revealed by light. To study the progress of healing beneath certain scabs. Photographs of the eye to determine atrophy. Photographs of histological specimens to reveal structures below the surface and invisible to the eye.

2. *In Industry.* To study irregularities in the dyeing and weaving of textile fibers, the interior of furnaces, the detection of carbon in lubricating oils, infra-red spectroscopy of metals and alloys.

3. *In Astronomy.* To detect nebulae and stars otherwise invisible because of astronomical haze or because their radiation lies chiefly in the infra-red. Infra-red spectroscopy for the determination of the composition, the temperature, and the movement of stars and nebulae.

4. *In Criminology.* Deciphering writing or printing which has been crossed out with other inks to render it illegible. To obtain copies of charred documents, detect erasures, reveal finger prints, identify blood and other stains, uncover secret writings, etc. (C.B.N.)

INFRA-RED RADIATION. That range of radiation which extends from the limit of the visible red to the ultra-short **Hertzian radiation**, and therefore comprises wavelengths from approximately 0.00077 mm. to 0.4 mm. or longer. This radiation is observed and measured by means of very sensitive thermal detectors such as the **bolometer**, the **radiomicrometer**, and different types of **radiometer**; while its **spectrum** is studied by the "spectrobolometer," and its **spectral energy distribution** by the "spectroradiometer." Much of the region may also be photographed, as is the visible spectrum, but special plates are necessary. Pictures may even be taken by infra-red radiation in total visual darkness. Also, since these longer waves penetrate haze with less absorption, landscapes obscured by haze may be photographed by using an infra-red filter with suitable plates. Glass and water are nearly opaque to infra-red radiation, while rock salt is relatively transparent to it. (See **Thermal Radiation.**)

The strong absorption of infra-red by many substances renders it a useful means of applying heat energy. We utilize this principle in baking or toasting bread. Many modern industries use large banks of infra-red lamps for drying paints or lacquers on their products, or for similar purposes.

A convenient laboratory source of infra-red radiation is the "silica pencil," a heated rod of silicon dioxide. When thermal radiation is allowed to fall on quartz reflectors, narrow bands of infra-red **residual radiation** may be isolated for special study. The spectra of elements exhibit lines in the infra-red (see **Atomic Spectra**); for example, hydrogen gives the Paschen series, the Brackett series, and the Pfund series. The wave-number formulae for these are, respectively,

$$w = R\left[\frac{1}{3^2} - \frac{1}{(n+3)^2}\right],$$

$$w = R\left[\frac{1}{4^2} - \frac{1}{(n+4)^2}\right],$$

$$w = R\left[\frac{1}{5^2} - \frac{1}{(n+5)^2}\right];$$

in which R is the **Rydberg constant** for hydrogen. The rotation and vibration bands of **molecular spectra** are also in the infra-red region. (L.D.W.)

INFUNDIBULUM. A funnel-shaped cavity or organ. The alveolar sacs of the lungs from which the minute air chambers (alveoli) open are called infundibula and the end of the mammalian oviduct nearest to the ovary bears this name. A small outgrowth of the ventral wall of the embryonic brain from which the pars nervosa of the posterior lobe of the pituitary gland develops is also named the infundibulum. (A.W.L.)

INFUSION. 1. The injection of a saline or sugar solution into a vein. This is used when, for any reason, the normal amount of fluid or nourishment cannot be given by mouth or when the patient is suffering from dehydration secondary to acute infection and high fever, diabetic acidosis, severe **diarrhea**, etc. The usual quantity is about a quart, but when given slowly by the continuous-drip method, several quarts may be given in

24 hours. 2. The product obtained by steeping a **drug** for the extraction of its medicinal principles. (R.S.M.)

INFUSORIA. A subdivision of the phylum **Protozoa**, no longer included by some taxonomists but used by others in place of the subphylum **Ciliophora** or the class **Ciliata.** (A.W.L.)

INFUSORIAL EARTH. Diatomaceous earth. Diatoms.

INGESTION. The reception of food into the body. The simplest type of ingestion is found in some of the 1-celled animals, whose **protoplasm** merely flows around the food particle and engulfs it. In all groups some means of bringing food to the body or of catching it or cutting it from the parent plant or animal occur. It must then be taken into the body for digestion by an engulfing action of single cells like that of one-celled animals, by ciliary action, or by a muscular process of swallowing, all of which are forms of ingestion. (A.W.L.)

INGOT. A casting designed for reduction by **hot working** to a semi-finished product such as a billet or to a finished product such as a bar, plate, or sheet. Steel ingots are cast in massive cast-iron ingot molds which extract the heat faster than a sand mold and facilitate both the casting and handling of the ingots. (R.H.H.)

INHIBITORS. Corrosion.

INIA. Dolphin.

INITIAL CONDENSATION. The ordinary **steam engine** is double-acting and has at each end of the **cylinder** a port which serves both for the admission and exhaust of steam. The use of one port both for admission and exhaust causes a loss known as initial condensation. This term refers to the condensation of some amount of the incoming steam on the walls of the port and cylinder head. The reason for this condensation is to be found in the cooling of the same surfaces by the outflow of the exhaust steam. Thus the ports have a cycle of heating and cooling which is in unison with the engine cycle. Unfortunately, the heat given up by the port during the cooling cycle is released to steam which is on its way out of the cylinder. Thus any initial condensation, though it may be re-evaporated, is an entire loss in so far as availability of the heat for work is concerned. This is no minor loss; in fact, it is one of the major sources of thermal loss of the dual-flow steam engine. The uniflow engine, which represents the most significant advance in steam-engine practice in recent years, derives its advantage chiefly from the elimination of this loss. Steam flows from the ports towards the center of the cylinder in the uniflow engine. The cool exhaust steam does not backflow through the entrance ports. It escapes through ports located in the center of the cylinder, uncovered by the piston at the end of its stroke. This 1-way flow prevents cooling of the admission ports, and is the essential difference between the uniflow and conventional engine. The Corliss engine, with its valves in the end of the cylinder, but having separate exhaust and admission valves, has much less initial condensation than the single-ported engine. (F.T.M.)

INITIAL STRESS. Stress.

INITIAL TENSION. Stress.

INJECTION. This term is commonly used to designate the act of placing or forcing a fluid, **drug, serum,** or **vaccine** into a vein, tissue (such as a muscle), or a portion of the body (such as the rectum). A hypodermic injection is one that is made with a syringe and needle into the tissues beneath the skin. An intramuscular injection is similar to a hypodermic injection, except that a longer needle is used so that the material injected may be introduced into the muscle. This is used for drugs which would be painful if injected subcutaneously and also because faster and more thorough absorption is so obtained. In an intravenous injection the drug is introduced directly into the blood stream by inserting a needle into a vein. The most rapid absorption is obtained in this way.

The term injection is also used in another sense to denote the state of being congested, inflamed, or reddened, as in beginning **inflammation** when the blood vessels of the affected part are greatly engorged. (R.S.M.)

INJECTION, FUEL. Fuel Injection.

INJECTION GNEISS. A **gneiss** whose banding or **foliation** is wholly or partly due to interlaminar injection of **granitic** magma into already **metamorphosed** and foliated rocks. (R.M.F.)

INK. Inks are aqueous solutions containing organic ferrous compounds, as, for example, the tannate. They are used for writing. (See **Tannins, Iron.**) (R.K.S.)

INK SAC. A glandular sac found in the **squids** and related species (**cephalopod** mollusks) which secretes a dark fluid. The duct of the gland opens into the intestine near the anus. When the animal is aroused the ink is discharged into the mantle cavity and thence through the siphon into the surrounding water. The ink of the **cuttlefish** is the source of the pigment, sepia. (A.W.L.)

INLIER. Used by geologists to designate a structural block, the sides (fault planes) of which separate it from younger formations. Sometimes incorrectly used to designate the partially buried hills or **monadnocks** of an old erosion surface. (R.M.F.)

INORGANIC CHEMISTRY. Chemistry.

INSANITY. A legal term used to describe an individual who, because of mental illness, must be denied the right of personal liberty, as his behavior is such that he is dangerous to himself and society. Popularly the term is used to cover **psychoses,** either **schizophenia,** or the many depressive psychoses. (D.M.H.)

INSECT PESTS. Animals whose ways of living come into competition with those of man may become pests under some conditions. While some animals, like the poisonous snakes, are gradually eliminated as the land becomes more heavily settled and more extensively cultivated, others are tenacious enough to persist against the advance of civilization. Thus mice and rats continue to be a problem to the city dweller, but only on farms are wolves and gophers and woodchucks likely to give trouble. Some of our pests are obscure invertebrate parasites. Against their attacks we need expert medical assistance. Against such pests as rats and mice, or even larger mammals, the familiar methods of poisoning, trapping and shooting are adequate. These facts leave a considerable number of pests that trouble man in any surroundings and require special methods of control. They are chiefly insects (**Insecta**) and other arthropods (**Arthropoda**), and because they are very likely to be small and obscure and ubiquitous, this discussion of general methods of dealing with them seems of practical value.

These little creatures are so numerous and so varied that they come into conflict with human enterprises in many ways. While entomologists have discovered special means of dealing effectively with various species which are commercially important on a large scale, such

as the **codling moth** and the **Hessian fly**, the layman may still master a limited amount of basic information through which he may approach the control of any insect pest intelligently. A work of this kind cannot embrace a multitude of special methods. The purpose of this article is, therefore, to summarize the basic approach to the control of insect pests and the underlying reasons for that approach.

According to their specific contacts with human economy, pests may be divided into those which attack man himself and those which damage things of value to him.

The insects that attack man to a troublesome degree in the temperate zone are comparatively few. The lice (**Louse**) are important in some strata of society and occasionally to human beings whose normal standards of cleanliness are a protection in themselves. If, under special conditions, one must rid his person of lice he may resort to mercurial ointment, which should be used under the direction of a physician, or he may be able to resort to a newer method in the use of DDT (dichlorodiphenyltrichloroethane) as a dusting powder. This insecticide is evidently somewhat dangerous in ointment form. Good housekeeping and high standards of personal hygiene usually prevent trouble with **bedbugs.** Bedbugs may require only the treatment of a single bed, in which case kerosene or fly spray, painted or sprayed into crevices where the bugs may hide, is normally effective, or they may infest an entire dwelling. In the latter case fumigation of the structure is the most effective procedure. It should be carried out by a professional pest-eradicator, since cyanide fumigation is a very dangerous process. The mosquitoes and flies (**Fly**) which "bite" us are sometimes distressing but rarely harmful in themselves. Against such pests as flies and mosquitoes the screening of our houses is a partial defense. When we must be exposed to them in the open in unusually large numbers, repellent compounds may be applied to exposed portions of the skin. The "bite" of all of these insects is really a puncture made by sharp piercing mouth parts which enable the insect to reach the blood on which it feeds. No true biting insect attacks man to an important degree.

Far more serious than the actual damage done to the human body is the possibility that an insect may transmit the germs of a disease, but this danger is far greater in tropical and subtropical regions. Malaria and yellow fever, transmitted by mosquitoes, are classic examples of insect-borne diseases. African sleeping sickness and typhus fever, transmitted by the tsetse fly and by the body louse respectively, are also well known. Protection against these insects where such risks must be run is, of course, an important corollary to the treatment of the diseases themselves.

In the tropics **bot flies** and the **chigoe** flea are also important to man. Since they live as internal parasites the removal of the insect itself is necessary for cure.

Such related pests as the harvest mite, the jigger of temperate North America, and the itch mite, *Sarcoptes scabiei*, come under the same category. The former causes temporary annoyance, but the latter is a troublesome parasite requiring medical attention.

Our domestic animals and birds are subject to similar attacks. Bot flies, horse flies, other biting flies, lice, parasitic flies such as the **sheep tick, flea, bird louse, mite,** and true **tick** may all be serious pests and in some cases may transmit diseases. For most of them repellent powders such as pyrethrum, rotenone, and the newer DDT, and commercial dips, are effective.

In addition to the insects attacking animals we are troubled by those which destroy animal products, notably the **clothes moths** and dermestid beetles (carpet beetles). These forms destroy fur, feathers, and woolens. Fortunately, mothproofing treatments have been devised for carpets and woolen clothing and are readily available on the market. Fur and feathers must still be safeguarded by proper storage when they are not in use. Serious infestations of these pests may often be traced to a breeding place in some forgotten part of the home. An old woolen garment in the attic, stored feathers or a discarded fur may produce clothes moths over a period of years to spread into other garments and into our rugs. The elimination of such breeding places does away with much painstaking work in the protection of our possessions.

The pests attacking plants are legion. Some are biting forms which consume the tissues of the plant while others merely suck the juices. The former may live on flowers or on specific parts of flowers, they may eat leaves or fruits or roots, and they may bore into various parts of the plant as they eat. If they attack a part that is valuable to man, the damage is necessarily greater than if they merely weaken the plant, hence leaf-eaters are usually less serious than borers in stems and fruits. The latter may kill the plant or render its products useless, while the former often do relatively little damage. Such species as the squash and peach borers, the codling moth and the **boll weevil** are good examples of individually serious pests. The **tomato worm** and the tent caterpillars are among the pests which become serious only when excessive numbers of them destroy a considerable part of the leaves of the plant. In the home garden in some parts of the United States the Colorado potato beetle and the Mexican bean beetle are often destructive pests. For any region, state entomologists and county agents can furnish specific information on local pests and their control.

The economically important sucking insects, although most of them are very small, often develop enormous numbers of individuals, hence plant lice (**Aphid**) and scale insects (**Scale**) often seriously injure crop plants and orchard trees. Many species occur, some attacking only a single species of plant while others may be found on various kinds.

Pests of this kind may also be important in transmitting diseases, as in the case of the common melon aphis which carries mosaic disease to numerous species of garden plants.

From the practical point of view, the recognition of biting and sucking insects does not require a detailed knowledge nor observation of insect anatomy. If portions of the plant tissue are cut away, the insect doing the work is a biting form. If the plant remains intact but shrivels, turns yellow, or wilts, it is very likely to be losing more sap than it can spare to some sucking insect or borer. Plant diseases may be responsible for such changes.

Obviously a biting insect will consume anything on the surface of the tissues that it eats, hence the arsenical poisons sprayed or dusted on the plant are effective means of control. Lead arsenate is commonly used against such insects. Sucking insects, however, penetrate the thin layers of poison applied to the surface and suck the unpoisoned juices below. Against them, poisons that kill on contact must be used. Here nicotine sulfate and lime-sulfur sprays are important. Any such spray must touch the insect in order to kill it, hence spraying must be carried out in such a way as to reach the part of the plant on which the insects are lodged. Special difficulty arises when insects lodge in inaccessible places, but these problems are not likely to be important in the ordinary house or garden.

Even after plant products are harvested they are still subject to attack by such insects as the grain **weevils**, the Mediterranean flour moth, and the voracious wood-eating termites (**Isoptera**).

Fumigation of storage spaces is effective against most of these pests and, indeed, against any insect whose occurrence makes the use of the method possible. Volatile poisonous substances such as carbon disulfide and hydrocyanic acid gas are extremely effective but dangerous to use, the former because of its poisonous and explosive

properties and the latter because it is a fatal poison. They should be used only in extreme cases and by experts. In the home the elimination of forgotten breeding places is an important measure. An old box of flour or prepared cereal left on an unused shelf may be a source of starch-eating insects for months.

Methods of dealing with insect pests have reached a high degree of complexity. They may be summarized as follows:

1. *Mechanical Methods.* Destruction of pests by hand-picking or by jarring them from plants into a container holding a little water covered with a film of kerosene is often adequate for small-scale infestations such as the tomato worms and potato beetles in the home garden. It is also important in the well-kept home, where the occasional clothes moth or beetle may be killed by hand. Now that succulents and cacti are raised in the home in large numbers, this method is of particular importance. Some of these plants are badly troubled by mealy bugs, which can be destroyed by using a sable pencil or any similar small brush moistened with alcohol. Even crops raised on a large scale may sometimes be protected by mechanical means, as in the use of the hopper-dozer for the destruction of grasshoppers among plants of moderate height like the clovers.

2. *Repellents.* Volatile materials such as naphthalene (moth balls) and paradichlorobenzene or creosote, when sufficiently concentrated, provide adequate protection. The last, used for the treatment of wood in construction, is rather more than a repellent, however, since it renders the wood unfit for consumption by termites.

3. *Poisons.* The majority of chemical protective measures are designed for the actual destruction of the pests, hence the substances used may be classed as poisons. The division into contact and stomach poisons has already been mentioned, including nicotine sulfate and lime-sulfur in the former category and the arsenates in the latter. Substances which enter the respiratory system of the insect form a border category since they include violent poisons like hydrocyanic (prussic) acid, oils such as kerosene, which evidently cause suffocation, and whale-oil soap whose action is evidently similar.

The application of true poisons may be conditioned by the mode of life of the pest. The ants which enter our homes, for example, come from colonies whose organization guarantees a constant renewal of their numbers no matter how many are poisoned in the course of their wanderings. Sirups including a small percentage of a fairly slow poison such as sodium arsenite are usually effective against these pests since they are carried to the nest and distributed to the individuals of the reproductive caste thus destroying the entire colony. Such ant poisons are commercially available.

The successful use of poisons against insect pests requires an appreciation of the tolerance of the host plant or animal for the same material and an understanding of the effectiveness of distribution attained by the method of application used. Formerly most poisons were used as sprays. Some of the most effective, e.g., kerosene, were very harmful to plants, but combined with soap in an emulsion this insecticide could be used safely. Nicotine sulfate must also be used with care, since it damages foliage if too concentrated. Insecticides are applied at present in four ways: as sprays, by dusting in a fine dry powder, as fumigants, and as aerosols. In the last form they are combined with a highly volatile vehicle. A quantity effective over a considerable area can be confined within a small container in liquid form and vaporized as needed.

One of the most promising of the newer insecticides is DDT, but too little is yet known about its effects upon man and other animals to recommend its general use. The substance is insoluble in water but soluble in organic materials such as oils. Its volatility is low. It is used against many types of insects in sprays and dusts. During the present war its effectiveness against body lice has been given considerable publicity. Unfortunately its use on the human body is attended by some risk since its toxicity is high, its action cumulative, and it may be absorbed through the skin. It is safest as a emulsion or a dry powder and most dangerous in solutions and ointments. For ordinary uses the arsenates, nicotine sulfate, pyrethrum and rotenone powders, naphthalene, paradichlorobenzene, and commercial mothproofing compounds will be found adequate when used according to directions.

4. *Biological Control.* Most of the important insect enemies of crops have been introduced from other lands and have increased rapidly because of favorable conditions or the absence of natural enemies. One goal of the economic entomologist is to restore natural checks so that the pest can no longer persist in damaging abundance. The milky Typhia parasite of the Japanese beetle is one example. Many years ago the San José scale was brought under control in the West by the introduction of a natural enemy from its home in the Orient. This enemy is a predacious beetle of the family commonly called ladybirds. Several species are now known to feed on the scale insects. Since such methods of control are self-operative once they are established, their importance is obvious.

No insect has yet been made extinct through deliberate human effort, so we shall probably always have such pests. They are not likely to be of grave importance in the temperate zone but occasionally they demand attention and usually we can cope with them by simple and readily available means. In some cases the services of a professional pest eradicator may be needed to handle extensive infestations. (A.W.L.)

INSECTA. The insects, a class of the phylum **Arthropoda.** This is by far the largest taxonomic division of the animal kingdom, including approximately three and one-half times as many species as there are of all other animals. About 450,000 species of insects have been described.

Insects are characterized by the hard exoskeleton and jointed appendages of the phylum. Among other arthropods they are distinguished by several characteristics: 1. The body is divided into head, **thorax,** and abdomen. 2. Both compound and simple eyes may be present. 3. They have one pair of antennae. 4. The thorax bears a maximum of three pairs of legs. 5. Wings are found in the adults of many species. Two pairs occur in most orders. 6. The abdomen is usually without jointed appendages although a few primitive forms bear modified derivatives of these structures. 7. Respiration is accomplished by means of tracheae, which are air tubes opening from the exterior and branching among the tissues. 8. Metamorphosis is complex in some orders although lacking in the most primitive forms.

The immense numbers of insects indicate remarkable biological success. They have invaded all possible habitats save the ocean; here only one form, *Halobates,* a genus of marine water striders, is known. On land and in fresh water insects are found in almost every imaginable habitat. They eat plants, animals, and dead organic matter of all kinds and many are parasitic. They walk, run, jump, fly, swim, and burrow. Moreover, their small size permits them to live in very limited habitats, hence the plant feeders include species which are confined to flowers, leaves, stems, fruits, or roots, and parasites are not limited to larger animals but find adequate hosts in other insects; even insect eggs are attacked by parasitic insects. Predacious species are, of course, confined to smaller prey such as other insects and the small members of other groups. This extreme diversity makes it impossible for human beings to avoid experience with insects. The blood-sucking mosquitoes and flies and the scavenger clothes moths and beetles force themselves upon us.

The contacts of insects and man are often of great economic importance, both beneficial and harmful. Among useful insects the honey-bee and silkworm are the outstanding examples, but among harmful species it is more difficult to select, for many species have caused appreciable losses in various fields of human activity. In agriculture the plant-feeding species such as the Colorado potato beetle and the **codling moth**, the **gipsy moth** and the **Japanese beetle** are important pests, and the **bot flies** have at times been serious parasites of domestic animals. Man suffers direct injury from many parasites such as the lice (**louse**), **fleas**, **black flies**, and **mosquitoes**, and in the tropics from the **chigger**, bot flies and other species, but the most serious damage done by insects in his life is through their role as carriers of disease. Malaria and yellow fever are transmitted by mosquitoes, typhus by the body louse, and bubonic plague by fleas. (See **Insect Pests.**)

The classification of insects is necessarily complex and it is impossible for any individual to have detailed knowledge of more than limited subdivisions of the class. Two subclasses, **Apterygota** and **Pterygota**, are commonly recognized. The former includes only primitive wingless insects, the latter the winged species and those which are secondarily wingless. In these subclasses 19–33 orders are recognized by various authorities. The following tabulation summarizes a classification which is widely used:

Subclass **Apterygota.**
- Order **Protura.** Rare and primitive insects of very small size.
- Order **Thysanura.** The **silverfish** or fish moth and allied species.
- Order **Collembola.** The spring-tails.

Subclass **Pterygota.**
- Order **Orthoptera. Grasshoppers, crickets, cockroaches, katydids, mantises, walking-sticks** and their allies.
- Order **Isoptera.** The white ants or **termites.**
- Order **Plecoptera.** The **stone flies.**
- Order **Ephemerida. May flies,** locally called shad flies, salmon flies, **June bugs** and Canadian soldiers.
- Order **Odonata. Dragon flies and damsel flies.**
- Order **Zoraptera.** Rare insects without a common name.
- Order **Corrodentia.** The **book lice** and psocids.
- Order **Mallophaga. Bird** lice or biting lice.
- Order **Anoplura.** True or sucking lice.
- Order **Embiidina.** Rare insects with no common name.
- Order **Thysanoptera.** The **thrips.**
- Order **Hemiptera.** The true **bugs.**
- Order **Homoptera. Cicadas, leaf hoppers, plant lice, scale insects,** etc.
- Order **Dermaptera. Earwigs.**
- Order **Coleoptera.** The **beetles.**
- Order **Strepsiptera.** The stylopids.
- Order **Neuroptera. Lacewings, dobson flies, hellgrammites, ant lions, alder flies,** and others.
- Order **Mecoptera.** The **scorpion flies.**
- Order **Trichoptera.** The **caddis flies.**
- Order **Lepidoptera. Butterflies, skippers,** and **moths.**
- Order **Hymenoptera. Saw flies, ants, bees, wasps,** and many parasitic forms.
- Order **Suctoria.** The **fleas.**
- Order **Diptera.** The 2-winged flies, including true **flies, mosquitoes, midges, gnats,** and others.

(A.W.L.)

INSECTIVORA. An order of mammals made up of small animals, mostly of nocturnal habits, which live on insects and other small invertebrates and in a few cases on vegetation. **Moles, shrews, hedgehogs** and related species. (A.W.L.)

INSECTIVOROUS PLANTS. These are plants which are able to obtain a part of their **nitrogen** supply from the bodies of small insects and other animals which are trapped by the plants in various ways. They are also frequently called carnivorous plants. All of them are green and capable of living without this animal nitrogen, but many seem to thrive better if they have it. They are plants which grow in marshy or boggy places, where the supply of available nitrogen may be very slight. Some of them are water plants.

Insectivorous plants may be divided into three distinct groups, distinguished by the manner in which the plant captures the insects. In one group, the insects are attracted to the plant's leaves by a glandular secretion which is sticky and holds them fast. In some species in this group, the glandular hairs fold inward over the prey to hold it firmly and to aid in digesting it. The most common plants of this group are the sundews, species of the genus **Drosera.** They are small bog plants of fairly common occurrence. In some species the leaves are linear, in others round and long-**petioled.** In all, the upper surface of the leaf is covered with long tentacle-like hairs with swollen tips. This tip secretes a copious quantity of a colorless sticky substance which glistens in the sunlight and attracts many small insects. When the insect alights on the leaf or on one of the hairs, it stimulates the latter to fold inward, gradually carrying the insect towards the center of the leaf. The stimulus is transmitted to other nearby hairs, which fold in likewise, until the insect is carried to the leaf center and pressed firmly against the surface. A digestive **enzyme** is there secreted, which acts on the **proteins** of the animal body, changing them to a soluble form which can be absorbed by the leaf. When digestion is completed, the glandular hairs unfold, and the leaf is ready for another victim.

Another common plant of this group is the Butterwort, *Pinguicola vulgaris.* In this plant the surface of the leaf is shiny with the sticky secretion from the glands, while the edges of the leaf are rolled inward. Insects attracted by the sticky surface are gradually caught under the enrolled margin and there digested. Other plants in this group are tall herbs or low shrubby plants; in them no movement of the glands occurs, the prey being held by the sticky secretions alone.

The second group of insectivorous plants comprises all those in which the leaf is variously modified to form a pitcher in which the prey is entrapped. Plants of this group are often very striking objects. They occur in widely scattered regions. In the eastern part of North America are found species of the genus *Sarracenia,* which are commonly called pitcher-plants. They are found in open marshes where plenty of light will reach them. The leaves occur in basal rosettes, and are green, often deeply mottled with red. Each leaf has the form of an open pitcher with a distinct lip or flange at the top, and a green wing down one side of the pitcher. Around the mouth of the pitcher, on the inner side, are numerous glands which secrete a fluid which attracts insects. Lining the inside of the pitcher are numerous stiff pointed teeth or bristles which project sharply downward, so that it is easy for the insect to crawl down into the pitcher, but practically impossible to crawl up. The lower part of the pitcher is usually full of water, into which the unfortunate insect eventually falls and is drowned. Either due to the action of **bacteria** or that of secretions from glands in the surface of the leaf, the proteins of the animal body become assimilable by the leaf, which thus obtains nitrogenous matter. In California is found *Darlingtonia californica,* the leaves of which are even more remarkable. The same pitcher-like structure occurs, but the opening of the latter is covered by the overgrowing of the upper part of the leaf, which ends in a brightly colored flap. In the arching part of the pitcher which covers the opening there is a clear translucent space, against which insects

persistently move until exhausted, then fall into the pitcher below. Even more remarkable pitchers are found in the leaves of the genus *Nepenthes,* which is native in the East Indies, Malaya, and Madagascar. These plants are herbs or shrubby plants which grow in bogs. At first they have leaves like other plants, but soon very much modified leaves appear and aid the plant in climbing upward to a position having a favorable light supply. The mature leaves of these plants are remarkable objects. In each there is a flat green blade which is prolonged at its tip into a long slender stem-like structure which often tightly twines about any supporting object. Beyond this portion of the leaf the pitcher is found. In size the pitcher varies according to species, from a small object an inch or so long, to bodies capable of holding a quart or more of liquid. The rim of the pitcher is rolled inward and provided with an abundance of glands which secrete a substance attractive to insects. The lower part of the inner surface of the pitcher is slippery, offering no foothold to insects seeking to escape. Often the pitcher is rather brightly colored. Beyond the pitcher the leaf is again prolonged into a slender stalk which ends in an expanded flap which frequently stands over the opening of the pitcher. Because of their curious habit many species of *Nepenthes* are cultivated as hot-house plants.

Other species of pitcher plants are found in South America and in Australia.

The third group of insectivorous plants is composed of those plants which capture their prey by some sort of movable trap. In this group are found Venus' fly-trap, the Bladderworts, and Aldrovanda.

Venus' fly-trap, *Dionaea muscipula,* is a small plant found in the Carolinas. The leaves form a basal rosette close to the ground. Each leaf has a broad blade-like **petiole** which abruptly narrows at its tip and bears a remarkable blade. The latter is formed of two halves which are joined by a movable hinge down the center. The edges of each half are fringed by long stiff bristles, while on the upper surface of each are borne three long slender trigger hairs which are sensitive to contact with any solid object. Each trigger hair is jointed at its base. The upper surface of the blade is abundantly supplied with small glands. When any insect alights on the leaf and comes in contact with one of the trigger hairs, a stimulus is given which causes the two halves of the blade to fold together with the bristles around their edges interlocking and so trapping the insect securely. Once caught the insect is slowly digested by the leaf.

Aldrovanda vesiculosa is a rootless plant found in quiet waters in Europe and Asia. Its leaves are stalked, and have a hinged blade with trigger hairs, and digestive glands very similar to those of Venus' fly-trap. Small aquatic animals are trapped in the leaves of this plant.

The Bladderworts belong in the genus *Utricularia,* which contains some 200 species, widely distributed in tropical and temperate regions. One of the commonest species, *Utricularia vulgaris,* occurs in ponds and slow streams in both Europe and North America. This plant never has any roots, even when it first develops from the seeds. The leaves of the plant are finely dissected and bear small bladders which give the plant its name. The bladders have a narrow opening which is surrounded by a group of radiating hairs which form a funnel-like approach to the opening. This opening is provided with a "trap-door." The inside of the bladder bears many 4-parted hairs. Should a small aquatic creature chance to venture into the funnel of hairs and touch certain sensitive hairs, the bladder suddenly expands, creating a current of water which sweeps the unfortunate creature into the bladder. The "trap-door" closes behind him and he is held prisoner until he dies. Other species of bladderworts have ordinary undissected leaves. In the tropics certain species are found only in the waters contained in the pitchers formed by the wide leaves of certain members of the **Pineapple** family. (R.M.W.)

INSEMINATION. The introduction of the seminal fluid, bearing the reproductive cells of the male, into the genital passages of the female. **Copulation. Mating.** (A.W.L.)

INSEQUENT STREAM. A stream which starts to cut its valley at the edge of a cliff or on the crest of a ridge. (R.M.F.)

INSERT. Plastic Molding.

INSERTION LOSS. The insertion loss of a piece of apparatus, usually expressed in **db.**, is the loss introduced in an electrical circuit by the insertion of the apparatus. Thus in many communication circuits the connecting of essential components of the system may introduce an insertion loss which must often be compensated for by additional **amplifier** gain. (L.R.Q)

INSOLATION. One of the processes of weathering. Extreme diurnal (daily) changes in temperature such as occur on high plateaus, and especially high deserts, causing relatively rapid expansion and contraction of the rocks so that they crack and disintegrate. Differences in temperature between day and night have been registered as high as 120° F. Insolation is only effective on bare rock faces, as a slight blanket of soil or debris serves to protect the rock from relatively rapid heating and chilling. (See **Heat Balance in the Atmosphere.**) (R.M.F.)

INSTABILITY. Stability and Instability.

INSTANTANEOUS CENTER. The instantaneous center is the imaginary point about which a body having general motion may be considered to be rotating for the instant. The instantaneous center is not necessarily on the body; in fact, it can be, in the case of rectilinear motion, infinitely distant. (See **Centrode.**) (F.T.M.)

INSTAR. A single period of growth of an arthropod larva, ending with a moult or **ecdysis.** The term is applied chiefly to insects. In this group normal growth is completed in a fixed number of instars, the last one terminating with pupation. Under abnormal conditions, however, the **larva** may grow slowly and moult more than the usual number of times. It is evident from such cases that the length of instars and their number are conditioned by more factors than growth of the animal to a size which demands a larger integument. (A.W.L.)

INSTRUMENT. The term instrument describes a wide range of objects, but from a technical standpoint, an instrument is a tool or mechanism for scientific and professional service. As far as tools are concerned, instrument might be taken to designate such tools as are delicately, accurately, and scientifically constructed, and whose use requires above average dexterity and technique.

Nearly every technical field exhibits a great number of specialized scientific mechanisms which might be called, with reason, instruments. Obviously, the scope of mechanisms included under so general a heading is too extensive for detailing here. However, a great many measuring devices, meters, gauges, and the like, in their construction, will satisfy the definition of instrument given above. A great many meters and gauges are called instruments, although in some cases there could be some reasonable doubt as to whether they could rightfully be

so designated. For further details, see **Instruments, Electrical; Instruments, Mechanical; Meters.** (F.T.M.)

INSTRUMENT TRANSFORMER. **Transformer.**

INSTRUMENTS, AIRCRAFT. Flight by airplane now involves varied instruments which are read by the pilot or crew member to yield information on the current condition of the engine and other parts of the airplane, on the attitude of the airplane, and on its position and direction of travel. Early aviators flew with few instruments. So may also the modern aviator if he uses small airplanes flown at low altitudes in visual contact with a fixed base. Even so, such flights are accompanied by improved peace of mind of the pilot if instruments indicate continuously that the engine is functioning normally. A tachometer, an engine oil-pressure gauge, and an engine oil-temperature gauge are considered to be the minimum complement of "condition" instruments for any internal combustion engined airplane, however small it may be. At the other extreme, the instrumentation of the large multi-engine transport or military airplane is complex. There are from 40–60 instruments (not including warning lights, switches, etc.) on the board of a modern airliner.

Condition instruments are to indicate the operational state and integrity of crucial parts of the airplane. This group includes engine instruments, fuel and lubricating oil instruments, flap, landing gear, and cowling position indicators, fire warnings, etc. It would also include instruments designed to indicate the readiness-to-function of the several auxiliary systems—electric, pneumatic, or hydraulic.

Attitude instruments show the angular position of the airplane with reference to a horizontal plane; also the rate of change of attitude. They include bank, pitch, turn and bank, rate of climb, and gyro horizon instruments.

Position instruments serve to fix in the pilot's mind the position of his airplane in space and the direction of travel. This classification includes all navigational instruments and communication devices. The minimum group of these instruments required for cross-country contact (visual) flying consists of a magnetic **compass**, an altimeter, and an air-speed indicator. But in more complete instrumentation, "position" instruments also include radio compass, drift indicator, terrain clearance (radio) indicator, and chronometer. (See also **Automatic Pilot.**)

These instruments are either self-actuating or remotely actuated by hydraulic, electric, mechanical, or pneumatic systems. The instruments themselves might be classified by principle of operation as follows:

1. By pressure of liquid or gas on a diaphragm, Bourdon tube, or collapsible capsule. Examples: engine oil pressure, hydraulic brake system pressure, altimeter, air speed.

2. By thermal action, creating pressure, electric resistance, or voltage. Examples: oil temperature, cylinder-head temperature.

3. By mechanical action. Examples: centrifugal tachometer, mechanical position indicators.

4. By gyroscopic action. (Gyroscope electrically or pneumatically driven.) Examples: turn and bank, gyro horizon.

5. By direct electrical action. Examples: remote position indicators, electric tachometer.

An explanation of the construction and action of all aircraft instruments is beyond the scope of the present writing. A few selected instruments will be explained in principle.

Altimeter. The altimeter is used to determine the altitude of the aircraft. The instrument is simply an aneroid **barometer** calibrated to read in feet of altitude instead of barometric pressure. It thus reads pressure, not density, altitude. The heart of this instrument is a circular evacuated capsule, one face of which is fastened to the case, while the other is attached through a system of multiplying levers (terminating in a chain wrapping around the spindle) to a spindle carrying a pointer which moves over a scale. A U-shaped spring holds the capsule distended and atmospheric pressure tends to collapse it.

When mounted in an airplane which is climbing to higher altitudes, the capsule is subjected to weakening atmospheric pressure, allowing the spring to distend the capsule and move the pointer. A small hairspring keeps the mechanism taut and the pointer will move upon the slightest movement of the capsule face in either direction.

The instrument may be made to indicate altitude above any given point, e.g., the airport runway, by rotating the dial containing the scale until the pointer

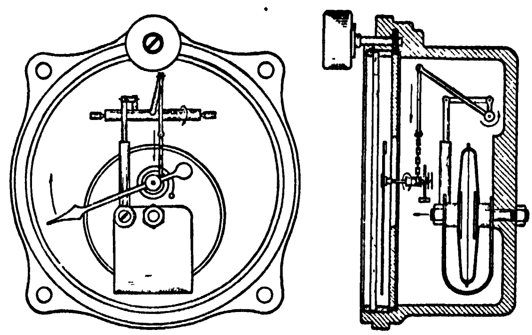


Fig. 1. Simple altimeter. (*Pioneer Instr. Div. of Bendix Aviation Corp.*)

registers with zero altitude, this being done when the airplane is on the runway. A knob having a pinion engaging a gear on the periphery of the dial makes this adjustment. The mechanism of an air-speed indicator is similar except that the case is air-tight and subjected to static-tube pressure, while pitot-tube pressure is communicated to the interior of the capsule. (See **Pitot-Static.**) The U-spring is omitted, but not the hairspring. The distention of the capsule is thus a function of the difference between static and dynamic pressure, i.e., the velocity head. Thus the pointer may travel over a dial calibrated in m.p.h. The dial is usually calibrated for air of sea-level density, and a correction must be applied to indicated air speed to obtain true air speed at an altitude.

Gyro Horizon. This is an instrument designed to simulate the attitudes of an airplane. A miniature airplane on the face of the instrument appears to bank or climb and does so in imitation of the real airplane's attitude. The pilot therefore is relieved of any necessity of interpreting numerical instrument readings in terms of attitude. This instrument makes use of the **gyroscope**—its rigidity in space and its property of **precession.**

A spinning gyro rotor with vertical axis is borne by a gyro housing which, in turn, is supported in lateral horizontal bearings in a gimbal ring. The latter is supported from the instrument case by being pivoted on a fore-and-aft axis. The spinning axis will tend to remain vertical while the airplane (and also the instrument case which is attached to it) is banked or pitched. A horizon bar controlled by the gyro remains horizontal while a small airplane silhouette attached to the case is tilted with the plane. Not only will the horizon bar remain horizontal, but also it will move up or down to indicate diving or climbing flight.

To the pilot riding the airplane through non-level flight, the real horizon is seen "tilted" during banked flight; also the pilot sees the nose of the airplane rise

above the horizon while climbing, and sink below it when gliding. Since he is accustomed to seeing the real horizon tilted, and above or below his center of vision he knows just what the relative position of the horizon bar on this instrument means in terms of his actual flight attitude; consequently, when flying through rain or overcast, or under any condition where a horizon of land, water, or cloud layer cannot be seen, the pilot readily substitutes the impressions gained from the gyro horizon for those he derives normally from the real horizon.

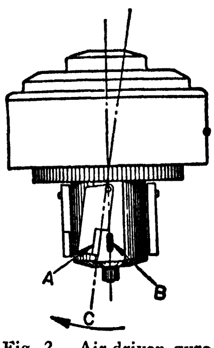

Fig. 2. Air-driven gyro housing during precession. (*Sperry Gyroscope Co., Inc.*)

The gyro is air or electrically driven. Air-driven gyros are small turbine wheels driven by an air jet induced by a vacuum applied to the instrument exhaust. This vacuum may be maintained by a Venturi tube with a suction line at the throat, or by a vacuum pump, engine-driven. The spent air is exhausted from the gyro housing through four equally spaced ports partly covered by pendulous vanes. Any tendency of the gyro axis to depart from vertical is followed by a motion of one or more of these vanes, upsetting the normal balance of the four exhaust jets. The resulting horizontal air reaction on the gyro housing results in a precession which precesses the gyro housing until it has resumed the erect position in which the exhaust jets are again in balance.

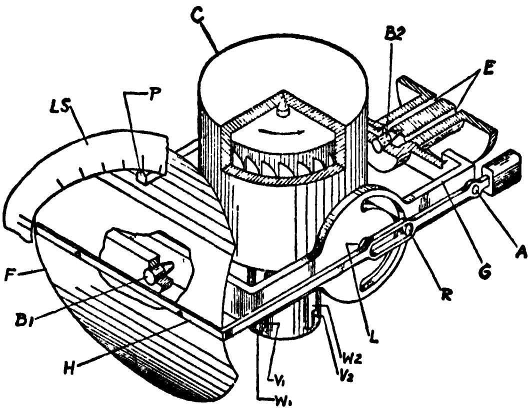

Fig. 3. Principle of the gyro horizon. (*NACA.*)

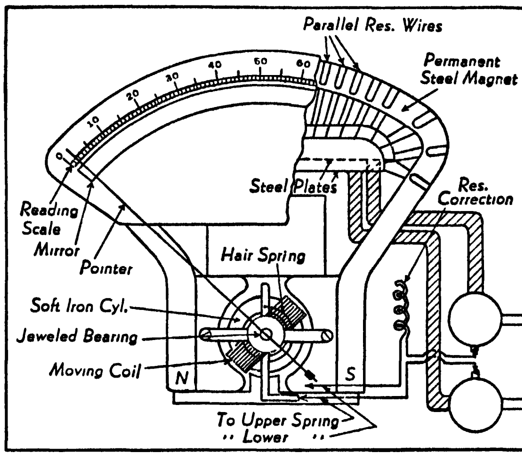
For high-altitude use, electric-driven gyros have been developed since their drive is not affected by diminished air density. The erecting action produced by the vanes in the air-driven model is replaced by a liquid level device in which the liquid level controls torque motors on the roll and pitch axis. (See also, **Blind Flight, Blind Landing, Pressure Gauges.** (F.T.M.)

INSTRUMENTS, ELECTRICAL. The most common electrical instruments are the various meters which, when properly applied and connected, indicate or record the characteristics of flow in an electrical circuit, characteristics which are, by nature, indeterminable by visual inspection of the conductors. The principal electrical instruments are: the **ammeter,** to show flow of current; the **voltmeter,** to show electrical pressure on a circuit; the **wattmeter,** for power; the watt-hour meter, for electrical energy; the synchroscope, which is used to effect parallel operation of current-carrying machinery; the power-factor meter; the volt-ampere meter or **volt-ammeter**; the **frequency meter;** and the ground detector. Indicating instruments are used chiefly for operating guidance, recording instruments, for operating supervision and calculation of performance, and integrating types for cost allocations.

The electrical instrument is commonly a comparatively rugged instrument, enclosed in an iron case having a glass front through which the register of a pointer on a scale may be read. Few electrical instruments for d-c service are applicable to an a-c circuit, and vice versa.

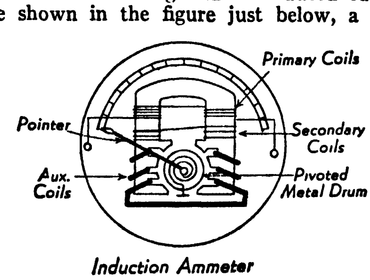


Direct-current ammeter.

The operating principles of instruments include electromagnetic induction, magnetic attraction, and resistance heating. A typical d-c ammeter is the d'Arsonval type consisting of a light coil mounted in the field of a permanent magnet. When the coil is energized by passing the current through it, a torque (see **Statics**) is set up which tends to set the coil to include a maximum of flux lines. A pointer is attached to the moving coil, and the motion of this system is opposed by a coil spring. The spring controls the throw of the pointer, which otherwise would run completely off the scale for all currents. As it is impossible for the delicate moving coil of this instrument to carry large currents, a shunt is employed. The current through the shunt bears a definite ratio to the current through the ammeter, so that the ammeter can be calibrated to read directly the current which is being metered. The shunt is often incorporated within the case of fixed-range instruments.

The voltmeter is similar in construction to the ammeter. One difference arises from the fact that ammeters are used to measure currents, are connected in series in the circuit, and must embody a low-resistance shunt in parallel with the moving coil, while voltmeters are used to measure potential difference, are connected across the circuit, and so must have high-resistance coils in series with the instrument coil.

In a-c practice, induction type instruments are very common. An induction type meter depends on the interaction of an inducing and an induced current. In the type shown in the figure just below, a laminated

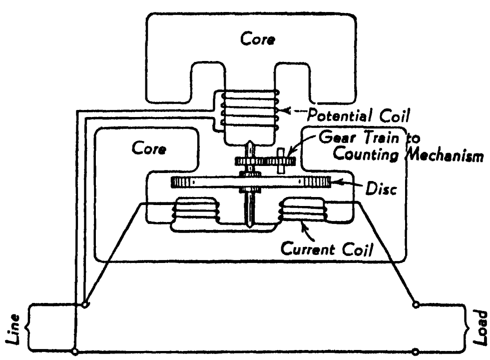


Induction Ammeter

iron core is surrounded by one or more coils of wire. When current flows through the coils, an alternating

magnetic flux is set up in the air gap of the core. The effect of a rotating field may be secured through the action of more than one group of coils, in which the currents differ in **phase.** A drum or disk, usually of aluminum, is supported by pivots in the air gap of the core, and a torque is produced by the rotating field reacting on currents induced in this movable element. A hair-spring produces counter-torque and brings the pointer to rest when the torque produced by the coil is equal to that of the spring. This principle is similarly applied in the induction voltmeter. Another type of a-c ammeter has a thin piece of soft iron, roughly triangular in shape, bent into the form of a cylinder. Another piece of rectangular form is so bent that it is coaxial with the first, and is rigidly attached to a spindle mounted on jeweled bearings. These two iron pieces are encircled by a coil, so as to be included in the field. A pointer is attached to the spindle. When a current is passed through the coil, the iron pieces are similarly magnetized, and repel each other; thus a torque is exerted on the shaft, and moves the pointer against spring pressure. Various types of movable iron vane instruments are frequently used on switchboards.

Practically all modern a-c watt-hour meters operate on the split-phase induction motor principle. The single-phase watt-hour meter is universally used as a



Induction watt-hour meter.

meter for the kilowatt-hour consumption of domestic customers. The essential parts of the watt-hour meter are a current coil, a potential coil, and a rotating disk. The current coil is connected in the line, and the potential coil is across the line. Both coils are mounted on iron cores, and placed in close proximity to the rotating disk. The alternating flux produced by these windings sets up eddy currents in the disk, and these eddy currents, in turn, set up fields which react on the field of the opposite coil. The combined action of the two coils sets up a torque which, at any instant, is proportional to the instantaneous values of the voltage and the current which is in phase with it; hence the meter acts independently of the power factor of the circuit, and measures watt hours, not volt-ampere hours. The speed at which the disk rotates is proportional to power being used; therefore, the number of revolutions the disk turns is proportional to the total energy consumed. By means of a gear train properly calibrated, the total energy consumed is indicated.

The synchroscope is a synchronism indicator for the guidance of station operators when paralleling machines. It indicates the phase relation between two a-c circuits. The usual use is in connection with the joining of an incoming machine to the bus. The General Electric synchroscope resembles a small a-c motor in construction. The field is connected to the line and the armature to the incoming machine. When the frequency of the machine is different from that of the line the resultant field in the synchroscope constantly changes its position, thus making the armature revolve in one direction. When the frequencies are the same the field is stationary in space and the pointer comes to rest in a position to show the phase difference between the two voltages. When the phase difference is zero the pointer will come to rest on the mark indicating perfect synchronism and the switch can be closed.

The growth of high-frequency applications in recent years has given impetus to the development of instruments capable of accurately measuring electrical quantities at frequencies ranging from ordinary **audio frequencies** to very high **radio frequencies.** Among the types developed as a result of this demand are the thermocouple and the rectifier instruments. The first of these utilizes the thermoelectric effect (see **Thermoelectric Phenomena**). The current to be measured is passed through a heater wire which is in contact or adjacent to a thermocouple. A voltage is induced in the couple when current passes through the heater wire so an instrument connected to the couple can be calibrated to indicate the current in the heater. Since the heat is proportional to the square of the current, the scale is an expanded or square law type. These instruments can be constructed to give accurate results to a hundred or more megacycles so are almost universally used for measuring radio frequency currents in this range. The rectifier meter uses some type of **rectifier** to convert the a-c to d-c and then utilizes a regular d'Arsonval type d-c instrument. At low frequencies (audio values) the rectifier is commonly a small bridge type copper oxide unit. At **ultra high frequencies** (radio) some type of rectifying **crystal** such as silicon is used with a sensitive milliammeter. When the frequency gets to these very high values capacitive and inductive effects in the leads, instrument, etc., become very important and must be reduced to a minimum if accurate results are to be obtained. Rectifier instruments indicate the average of the a-c wave rather than the r.m.s. value but are calibrated in terms of the r.m.s. of a sine wave and are not accurate for other wave forms unless specifically calibrated for them.

Another very useful instrument both for d-c and a wide range of a-c frequencies is the vacuum-tube voltmeter. This instrument utilizes the plate current-grid voltage characteristic of a **vacuum tube** as its fundamental feature. The voltage to be measured is applied to the **grid** of the tube and a milliammeter or microammeter in the plate circuit indicates a current which is a function of the grid voltage. By proper calibration of the plate instrument the voltage applied may be read directly from the instrument. There are several variations of this voltmeter, in some the grid voltage being measured is balanced by an internal voltage of the instrument (so-called slide-back voltmeter), in others the voltage applied to the grid is limited and multipliers must be used for larger values. In the better types of this latter group the normal plate current is balanced out in the milliammeter so it reads only the part due to the voltage being measured. These instruments are extremely useful since the input impedance may be made that of the grid of the vacuum tube (many megohms resistance and only a few micromicrofarads of capacity) and the frequency range is limited only by the frequency limit of the vacuum tube. (See also **Frequency Meters.**) (F.T.M., L.R.Q.)

INSTRUMENTS, MECHANICAL. With the broad definition of the term instrument, **mechanical instrument** could apply descriptively to an almost infinite variety of devices used in modern science and technology. By restricting the meaning to measuring instruments in common use for the measuration of physical quantities the following classification was devised. This classification is not of mechanically-operated instruments which are used to measure mechanical quantities. (For measuration of electrical quantities, see **Instruments, Electrical.**)

1. **Temperature** measurement. **Thermometry.**
   a. Glass tube mercury thermometers.
   b. Gas-filled bulb and tube thermometers.
   c. Vapor pressure thermometer.
   d. Electrical resistance thermometer.
   e. Thermocouple thermometer or pyrometer.
2. **Pressure** measurement.
   a. Standard, Bourdon tube type, **pressure gauge.**
   b. Helical tube or diaphragm type low-pressure gauge.
   c. Vacuum gauges. **Manometers.**
   d. **Draft gauges** (inclined glass tube, diaphragm, and liquid-sealed bell types).
3. **Flow** measurement.
   a. Steam **flow meters.**
   b. Water flow meters. Measure condensate, feed water, process flows, etc.
   c. Air flow meters. When these are used, they are generally in the form of a differential draft gauge.
   d. Gas flow meters. Positive displacement and orifice types.
4. **Fuel** measurement.
   a. Coal. Coal is usually weighed in batches, although belt conveyor weighers and some pulverized coal weighers are continuous.
   b. Gas meters.
   c. Oil meters. Positive displacement type.
5. **Carbon dioxide** measurement for combustion. The types of carbon dioxide meters in present use employ one of the following principles:
   Chemical—Modifications of the Orsat apparatus.
   Electrical—Based on measurement of the conductivity of flue gas.
   Mechanical—Flue gas density balanced against air.
6. **Speed** measurement.
   a. Vibrating reed tachometer (local reading).
   b. Electrical tachometer (remote reading).
   c. Clock type tachometer (local reading).
   d. Revolution counter.
7. Level recorders.
   Liquid level in boilers, tanks, canals, etc.
   Pulverized material in bins or silos.
8. Gong alarms.
   Gong alarms, with or without annunciators, are used to give warning of high temperatures, of high water, or low water in tanks.
9. Atmospheric measurements.
   Barometer, hygrometer, thermometer.

(F.T.M.)

INSULATION, HEAT. Bare surfaces at temperatures considerably above atmospheric lose much heat to the atmosphere. The B.T.U. per hour loss from bare pipe may not, on first thought, seem to amount to much, but if it be remembered that this loss is nearly steady 8760 hours per year (unless the pipe is out of service part of the time), and that, in the case of main steam lines, the B.T.U. so lost are high potential heat and therefore more valuable than the average B.T.U. in a pound of steam, it will be understood why practically every hot pipe in the modern plant or factory is covered. Cold pipes are also insulated to keep heat out, and insulation for this service is common in refrigeration plants. By keeping heat in hot lines not only is there a conservation of B.T.U. which have, at considerable expense and trouble, been transferred to the fluid, but also there is the avoidance of an uncomfortably overheated atmosphere in the vicinity of the pipe. Besides the pipe itself, fittings, valves, ducts, boiler drums, tanks and heaters are insulated.

In order to prevent great heat loss, a furnace wall must have an insulating layer, or else be built so thick that, in addition to being costly, it is inelastic and has large thermal storage capacity. In most cases the temperature of the inside furnace wall is near enough to that of furnace gases to be taken the same. The outside wall temperature will be enough higher than the surrounding atmosphere to discharge to it a heat flow sufficient to cause the temperature drop between the furnace and outside wall. Heat is discharged from the outside wall to the atmosphere by convection and radiation. It has been found that the total heat so transferred to still air is about 50% higher than the radiation component.

Other common uses of insulation are in the walls of cold rooms (cork board), coverings for hot and cold pipes, and the walk and ceilings of dwellings and other buildings. For the latter purpose a variety of materials are available, viz.: rock wool, insulating panels of ground wood, etc.

A good pipe covering should, of course, be non-conducting. As perfect non-conductors are not yet available, those materials whose conductivities are the lowest are best. Insulation should be able permanently to withstand the temperature to which it will be subjected; that is, it should be stable and resist deterioration over the working life of the pipe. It should be easily molded and applied and have the requisite mechanical strength. No insulation commercially procurable will overload the pipe by its dead weight, for density is not one of the attributes of a good insulator. In fact, the non-conducting properties seem chiefly to be derived from the presence of large numbers of air cells. The materials most commonly used are asbestos, "magnesia" (magnesium carbonate), cork, hair felt, wool felt, **rock** wool, and diatomaceous earths. Most commercial insulations are either built up from corrugated asbestos paper, or laminated asbestos paper artificially roughened to produce air spaces, or are molded, or felted with asbestos, etc. A very common and effective insulation for temperatures up to 600° F. is the molded "85% magnesia," so called because it is 85% carbonate of magnesium and 15% binder. Pipe insulation for higher temperatures should have an inner layer of some special high-temperature insulation, since 85% magnesia alone will deteriorate. Painting with aluminum or bronze paint will greatly decrease the radiation losses.

As in the case of furnace wall design, calculations of heat transfer through pipe covering take the form of an addition of resistances of a series circuit.

Manufacturers publish insulation efficiency tables for the various standard thicknesses of their different grades of insulation. The "efficiency" of an insulating material is expressed as the per cent heat saved by using the insulation, compared to what would have been lost had the surface been left bare. Like many other design problems, the amount of insulation to apply is, basically, an economic problem. The cost of the covering must be weighed against the saving of heat. (See **Thermal Conduction.**) (F.T.M.)

INSULATOR, ELECTRIC. **Electric Power Transmission.**

INSULIN. Insulin is a **hormone** which is vitally concerned in the **metabolism** of **carbohydrates.** It is secreted by the islet tissue of the **pancreas** and discharged directly into the blood stream. Although its presence was surmised, and it was already named "insuline" as early as 1909, it was not until 1922 that Banting and Best succeeded in isolating the hormone from pancreatic tissue.

Insulin is a complex **protein,** which must be injected to be effective, since gastric juices destroy its activity. Its mode of action is not completely understood, but it is known to promote the **oxidation** of carbohydrate, and to act as an essential in the intermediary metabolism of carbohydrate. An insufficient supply of insulin results in the clinical picture of **diabetes,** with low blood sugar, and all of the character-

istic signs and symptoms of the disease. Diabetes is successfully controlled by insulin in varying doses, depending on the severity of the disease. Insulin derived from hog or beef pancreas, or the crystalline product may be used. With these forms, usually repeated injections must be made throughout the day—2 to 4 times. Protamine-zinc-insulin has been developed to overcome this disadvantage. The protamine form acts slowly over a 24-hour period, and only one daily injection is therefore required.

Hyperinsulinism results from an excessive supply of insulin, and produces a picture roughly opposite to that found in diabetes. If hyperinsulinism follows an accidental overdose of insulin given to a diabetic, the blood sugar may fall to an extremely low level, and the condition is called insulin shock. The clinical picture varies from simple hunger to irritability, pallor, weakness, excessive perspiration, double vision and coma. Insulin shock is now induced purposely in the treatment of certain **psychoses**. Improvement of the symptoms of insulin shock by giving carbohydrate by mouth as orange juice, or glucose intravenously, is sudden and dramatic. **Tumors** of the islet tissue of the pancreas also may cause hyperinsulinism.

The relationship of insulin to other **endocrine glands** is complex. The **pancreas, adrenal, pituitary, thyroid** and **liver** are all interrelated in their action on carbohydrate metabolism. (D.M.H.)

INTEGRAL EQUATIONS. An integral equation may be described in a general way as an equation in which an unknown function appears under a **definite integral.**

A linear integral equation of the first kind is an equation of the form

$$\int_a^b K(x,t)u(t)dt = f(x),$$

where $u(t)$ is an unknown function to be found, $K(x,t)$ and $f(x)$ are known functions, and the limits a and b are known. The function $K(x,t)$ is called the kernel of the equation.

A linear integral equation of the second kind (or Fredholm integral equation) is an equation of the form

$$u(x) = f(x) + \int_a^b K(x,t)u(t)dt,$$

where $u(t)$ is an unknown function to be found, $K(x,t)$ and $f(x)$ are known functions, and a and b are given. The function $K(x,t)$ is called the kernel of the equation.

If $f(x) \equiv 0$, the resulting equation

$$u(x) = \int_a^b K(x,t)u(t)dt$$

is called a homogeneous linear integral equation of the second kind.

The equation

$$u(x) = f(x) + \int_a^x K(x,t)u(t)dt$$

is called Volterra's linear integral equation of the second kind.

Non-linear integral equations have also been investigated.

Three types of solutions of linear integral equations of the second kind have been developed:

1. The first method, which may be called the method of successive substitutions, is due to Neumann, Liouville, and Volterra. It gives the unknown function $u(x)$ in the equation

$$u(x) = f(x) + \lambda \int_a^b K(x,t)u(t)dt$$

as a power series in λ, whose coefficients are functions of x; this series has in general a finite radius of convergence.

2. The second method, due to Fredholm, gives $u(x)$ as a ratio of two power series in λ, each series converging for all values of λ. In the numerator the coefficients of the powers of λ are functions of x, while the denominator is independent of x. The solution is obtained by considering the integral equation as the limiting form of a system of n linear algebraic equations in n variables as n becomes infinite.

3. The third method, which was developed by Hilbert and Schmidt, gives the unknown function $u(x)$ in terms of a set of so-called fundamental functions. These functions are in the ordinary case the solutions of the corresponding homogeneous equation

$$u(x) = \lambda \int_a^b K(x,t)u(t)dt.$$

This equation is in general satisfied only by $u(x) \equiv 0$, but there exists a sequence of numbers $\lambda_1, \lambda_2, \cdots, \lambda_n, \cdots$, called characteristic constants (or fundamental numbers) for each of which the equation has a finite solution: $u_1(x), u_2(x), \cdots, u_n(x), \cdots$. These functions are the fundamental functions. The solution of the given integral equation is then obtained in the form

$$u(x) = \sum_{n=1}^{\infty} a_n u_n(x),$$

where the a_n are arbitrary constants. (L.L.S.)

INTEGRAL FUNCTION. An integral function is a **function** (of a real or complex variable) defined by a **power series** which converges for all finite values of the variable; this includes **polynomial functions** as special cases. An integral function may also be defined as a function of a complex variable which is **analytic** at all finite points of the complex plane. Simple examples of integral functions (besides the polynomials) are the **exponential function,** and the sine and cosine (**trigonometric**) **functions.** (L.L.S.)

INTEGRAPH. An integraph is an instrument which draws the integral curve of a given curve mechanically; from it areas may be read off as ordinates. (L.L.S.)

INTEGRATING METERS. The ordinary electric service meter measures the total of electric energy used over a period of time. It is in principle much like a **wattmeter,** except that the movable coil is replaced by a motor armature rotating against a magnetic damping arrangement. The speed of revolution is proportional to the torque, which, in turn, is proportional to the product of current and electromotive force. The total revolution of the armature is recorded on dials by pointers suitably geared to the armature shaft. Since angle = revolution speed × time, the reading of the dial is proportional to current × electromotive force × time, that is, to amperes × volts × hours or watt-hours. The dial may thus be graduated directly in watt-hours or in convenient multiples or sub-multiples thereof. (See **Power** and **Watt.**) (L.D.W.)

INTEGRATING PHOTOMETERS. The usual types of **photometer** give the luminous intensity of a source as viewed from one direction only. If the lamp under examination is turned around its vertical axis and the measurement thus obtained from various horizontal directions averaged, the result is the mean horizontal **candle power.** Usually a still more significant quantity is the mean spherical candle power, that is, the average luminous intensity from all directions. To obtain such averages, some type of integrating photometer is used.

One plan is to reflect the light emitted in various directions toward one spot by means of a system of mirrors appropriately placed, and to measure the resulting illumination at that point. The most common device at present, however, is the "sphere" or "globe" photometer. This has a large hollow globe painted white inside with barium sulfate paint. The lamp is mounted at any convenient point inside, and the resulting diffuse illumination of a transparent screen covering an opening in one side is measured by a photometer. (The screen must be protected from the direct rays of the lamp.) It was shown by Sumptner (1892) that under these conditions, the illumination on the screen is proportional to the mean spherical candle power and is independent of the orientation or the position of the lamp. Comparison may thus be made with a standard lamp of known spherical candle power by the substitution method. A photovoltaic cell may be substituted for the translucent screen and the readings thus made electrically. (See **Illuminometer.**) (L.D.W.)

INTEGRATION. **Indefinite Integral, also Definite Integral.**

INTEGRATION AS A PROCESS OF SUMMATION. **Definite Integral.**

INTEGRATION, TECHNIQUE OF. Standard integrals:

$$\int u^n\,du = \frac{u^{n+1}}{n+1} + C \quad (n \neq -1),$$

$$\int \frac{du}{u} = \log_e u + C, \quad \int e^u\,du = e^u + C,$$

$$\int \sin u\,du = -\cos u + C, \quad \int \cos u\,du = \sin u + C,$$

$$\int \sec^2 u\,du = \tan u + C, \quad \int \csc^2 u\,du = -\cot u + C,$$

$$\int \sec u \tan u\,du = \sec u + C,$$

$$\int \csc u \cot u\,du = -\csc u + C,$$

$$\int \tan u\,du = -\log \cos u + C = \log \sec u + C,$$

$$\int \cot u\,du = \log \sin u + C,$$

$$\int \sec u\,du = \log(\sec u + \tan u) + C,$$

$$\int \csc u\,du = \log(\csc u - \cot u) + C,$$

$$\int \frac{du}{u^2+a^2} = \frac{1}{a}\tan^{-1}\frac{u}{a} + C,$$

$$\int \frac{du}{u^2-a^2} = \frac{1}{2a}\log\frac{u-a}{u+a} + C, \quad (|u| > |a|),$$

$$\int \frac{du}{a^2-u^2} = \frac{1}{a}\tanh^{-1}\frac{u}{a} + C, \quad (|u| < |a|),$$

$$\int \frac{du}{a^2-u^2} = \frac{1}{a}\coth^{-1}\frac{u}{a}, \quad (|u| > |a|),$$

$$\int \frac{du}{\sqrt{a^2-u^2}} = \sin^{-1}\frac{u}{a} + C, \quad (|u| < |a|),$$

$$\int \frac{du}{\sqrt{u^2 \pm a^2}} = \log(u + \sqrt{u^2 \pm a^2}) + C,$$

$$\int \frac{du}{\sqrt{u^2+a^2}} = \sinh^{-1}\frac{u}{a} + C,$$

$$\int \frac{du}{\sqrt{u^2-a^2}} = \cosh^{-1}\frac{u}{a} + C, \quad |u| > |a|,$$

$$\int \frac{du}{u\sqrt{u^2-a^2}} = \frac{1}{a}\sec^{-1}\frac{u}{a} + C, \quad (|u| > |a|.$$

Integration by substitution:

An integral $\int f(x)dx$ may often be reduced to a standard form by expressing x as a function of another variable t. If $x = \phi(t)$, the substitution $x = \phi(t)$, $dx = \phi'(t)dt$ will transform $\int f(x)dx$ into an equivalent integral in t.

Integration by parts:

This is based on the formula

$$\int u dv = uv - \int v\,du.$$

Integration of rational fractions:

When the function to be integrated has the form of a rational fraction, it should be decomposed into a sum of **partial fractions**; each of these partial fractions can then be integrated separately by standard forms.

Trigonometric forms:

1. Type $\int \sin^m x \cos^n x\,dx$, where either m or n is an odd integer.

Suppose n is an odd integer. Write the integral $\int \sin^m x \cos^{n-1} x(\cos x\,dx)$; by use of $\cos^2 x = 1 - \sin^2 x$, we can express $\cos^{n-1} x$ rationally in terms of powers of $\sin x$ since $n - 1$ is an even integer, and since $\cos x\,dx = d \sin x$, we obtain an expression in powers of $\sin x$ each multiplied by $d \sin x$, so that they can each be integrated by the power law

$$\int u^n\,du = \frac{u^{n+1}}{n+1} + C.$$

2. Type $\int \left.\begin{matrix}\sin\\ \cos\end{matrix}\right\} mx \cdot \left.\begin{matrix}\sin\\ \cos\end{matrix}\right\} nx\,dx$:

To evaluate $\int \sin mx \cos nx\,dx$, we use the trigonometric identity $\sin mx \cos nx = \frac{1}{2}[\sin(m+n)x + \sin(m-n)x]$. To evaluate $\int \sin mx \sin nx\,dx$, we use the dentity $\sin mx \sin nx = \frac{1}{2}[\cos(m-n)x - \cos(m+n)x]$ To evaluate $\int \cos mx \cos nx\,dx$, we use the identity $\cos mx \cos nx = \frac{1}{2}[\cos(m+n)x + \cos(m-n)x]$.

3. Type $\int \sin^m x \cos^n x\,dx$, where m and n are both even integers.

Transform the integrand function into an integrable form in terms of sines and cosines of multiples of x by use of the trigonometric identities:

$$\sin^2 x = \tfrac{1}{2}(1 - \cos 2x), \quad \cos^2 x = \tfrac{1}{2}(1 + \cos 2x),$$
$$\sin x \cos x = \tfrac{1}{2}\sin 2x.$$

4. Type $\int \tan^n x\,dx$ or $\cot^n x\,dx$, where n is any integer.

These forms may be reduced to standard forms by use of $\tan^2 x = \sec^2 x - 1$ or $\cot^2 x = \csc^2 x - 1$, and $\sec^2 x\,dx = d(\tan x)$ and $\csc^2 x\,dx = -d(\cot x)$.

5. Type $\int \tan^m x \sec^n x\,dx$ or $\int \cot^m x \csc^n x\,dx$, where n is an even integer.

In this case we use the relations $\tan^2 x = \sec^2 x - 1$, $\sec^2 x = 1 + \tan^2 x$, $d \tan x = \sec^2 x$, and similar forms in terms of $\cot x$ and $\csc x$, and reduce to use of the power law

$$\int u^n \, du = \frac{u^{n+1}}{n+1} + C.$$

Integration of linear radical forms:

If the integrand contains a linear radical $\sqrt[n]{ax+b}$, the substitution $a + bx = z^n$ will reduce it to a rational form.

Integration by trigonometric substitutions:

Expressions involving $\sqrt{a^2 - x^2}$ or $\sqrt{x^2 \pm a^2}$ are often most easily integrated by aid of one of the following substitutions:

when $\sqrt{a^2 - x^2}$ occurs,

put $x = a \sin\theta$, $\sqrt{a^2 - x^2} = a\cos\theta$,

when $\sqrt{x^2 + a^2}$ occurs,

put $x = a\tan\theta$, $\sqrt{x^2 + a^2} = a\sec\theta$,

when $\sqrt{x^2 - a^2}$ occurs,

put $x = a\sec\theta$, $\sqrt{x^2 - a^2} = a\tan\theta$.

Integrals with quadratic radicals:

If the integrand contains $\sqrt{x^2 + ax + b}$, substitute $\sqrt{x^2 + ax + b} = z - x$, and we obtain a rational integrand in terms of z.

If the integrand contains $\sqrt{-x^2 + ax + b}$, substitute $\sqrt{-x^2 + ax + b} = (\alpha - x)z$ or $(\beta + x)z$, where $\alpha - x$ and $\beta + x$ are the factors of $-x^2 + ax + b$; the integrand becomes rational in z.

An integral in which the integrand is a rational function of $\sin x$ and $\cos x$ is transformed into one having a rational algebraic integrand by the substitution $\tan \frac{1}{2}x = z$, then

$$x = 2\tan^{-1} z, \quad dx = \frac{2dz}{1+z^2},$$

$$\sin x = \frac{2z}{1+z^2}, \quad \cos x = \frac{1-z^2}{1+z^2}.$$

Tables of integrals are published, giving more or less extensive classified lists of integrals. (L.L.S.)

INTEGUMENT, INTEGUMENTARY SYSTEM. For the use of this term in botany, see **Seed.** The body of every multicellular animal is covered with a layer of tissue adapted to meet the external conditions that prevail in the normal environment of the species. This covering is the integument and together with all of the specialized structures derived from the cellular layers it constitutes the integumentary system.

The general functions of the integumentary system are protection against mechanical damage and desiccation, the transmission of materials which must pass into or out of the body, the conservation of heat, and the reception of stimuli. Among the invertebrates such rigid supporting structures as the animal may possess are often developed in the integument, so that it becomes a **skeletal system** or exoskeleton as well as a covering for the body.

The integument is always at least partly ectodermal in origin. In the simpler animals such as the **coelenterates** it is an epithelial layer containing cells specialized for the reception of stimuli, defensive cells, and simple cells bearing contractile basal processes. It bears **cilia** in some of the flatworms, in the **rotifers** and **bryozoans,** and in some of the mollusks (**Mollusca**), and so aids in bringing food to the animal and in locomotion. In parasitic flatworms it degenerates into a **syncytium** and produces a non-cellular **cuticle,** and in roundworms, segmented **worms,** and **arthropods** it also secretes an external cuticle although it remains cellular. It gives rise to the **setae** of the segmented worms and arthropods and to the external portions of sensory organs, and contains glands of various kinds. In the arthropods the cuticula is highly developed as an exoskeleton. The integument also lays down the hard deposits of **corals** and secretes the shells of **brachiopods** and mollusks.

The integument of **vertebrates** is a **skin** composed of two layers, an inner corium or dermis derived from mesoderm and an outer cuticle or epidermis which is ectodermal. It produces various hard structures including the scales of fishes, scales of reptiles, birds and mammals, feathers, hair, horns, claws, hoofs, and nails. In addition it contains glands of various kinds, such as the mucus glands of fishes and amphibians and sweat glands of mammals and forms parts of the sensory organs. (A.W.L.)

INTELLIGENCE TESTS. Mental Deficiency.

INTENSIFICATION. A process for increasing the density and contrast of a photographic image by depositing thereon silver, or a compound of mercury, copper, lead, uranium, or other metal. Intensification may also be effected by mordanting dyes to the image, but this method is not in general use.

Intensification with silver is accomplished by means of an acid solution of silver nitrate and a developer, usually metol, which results in the silver being precipitated preferentially on the silver deposits of the image. The following formula (Crabtree & Muehler) is recommended:

Solution 1		
Silver nitrate, crystals........	60 grams	2 oz.
Distilled water to make......	1 liter	32 oz.
Solution 2		
Sodium sulfite, desiccated... .	60 grams	2 oz.
Water to make	1 liter	32 oz.
Solution 3		
Sodium thiosulfate (Hypo)....	105 grams	3½ oz.
Water to make	1 liter	32 oz.
Solution 4		
Sodium sulfite, desiccated.....	15 grams	½ oz.
Elon.	24 grams	350 gr.
Water to make . . .	3 liters	96 oz.

For use, add 1 part #2 to 1 part #1, shaking or stirring thoroughly. The white precipitate which forms is dissolved by the addition of 1 part of #3. Allow to stand until clear, then add with constant stirring 3 parts of #4. Use at once. The time of intensification should not exceed 20 minutes or the negative may be stained. After intensification, fix in a 30% solution of hypo and wash thoroughly.

One of the simplest and most reliable methods of intensification consists in bleaching the image in a solution of potassium or ammonium bichromate and hydrochloric acid—or chromic acid and sodium chloride—followed by redevelopment in an ordinary developer. The chemistry of the process is not definitely known but the increase in density is due to the formation on the image of a reduction product of the chromate whose composition is assumed to be either CrO_2 or Cr_2Cl_3.

The following forms a satisfactory bleaching solution:

Potassium bichromate.....	90 grams	3 oz.
Hydrochloric acid, C.P. ..	64 cc.	2 oz.
Water to make	1 liter	32 oz.

For use dilute 1 part of the above with 10 of water.

After bleaching the image, wash in running water until every trace of the bichromate has been removed and develop in an ordinary metol-hydroquinone developer. Borax and other metol-hydroquinone developers containing a high concentration of sulfite, however, should not be used.

After redevelopment, wash for 15–20 minutes in running water and dry.

The process may be repeated if the density and contrast are insufficient after the first application.

There are a number of methods of intensification with mercury. Probably the most popular consists in bleaching the negative in a solution of mercuric bromide and blackening in (1) an ordinary developer, (2) a 10% solution of sodium sulfite, (3) strong ammonia, (4) a 2% solution of sodium sulfide, (5) a 10% solution of sodium sulfantinioniate. When the image is redeveloped the process may be repeated if necessary; little or no increase in density or contrast is obtained if the other blackeners are used. The permanency of images intensified with mercury is always questionable and these processes offer no advantage over the chromium intensifier just described.

If the bleached image is blackened in silver cyanide, however, an extremely high degree of intensification is obtained. This process is known as Monkhoven's intensifier and is especially suitable for the intensification of negatives of drawings, printed matter and other black and white subjects. The silver cyanide solution is prepared as follows:

Potassium cyanide............	15 grams	2 oz.
Silver nitrate................	22.5 grams	3 oz.
Water to make............. ..	1 liter	1 gal.

Each is dissolved separately in water and the solutions mixed. It is then allowed to stand for an hour and filtered.

NOTE: The cyanides are deadly poisons and should be handled with care.

A useful single solution intensifier is compounded as follows:

Mercuric iodide......	2 grams	90 gr.
Potassium iodide....	2 grams	90 gr.
Hypo.....	2 grams	90 gr.
Water to make...........	100 cc.	10 oz.

This solution may be used until exhausted. While the intensifier contains hypo, negatives should be washed before intensification. The action of the intensifier is progressive and may be stopped when the required density and contrast have been reached by washing under the tap, followed by 15–20 minutes washing in a tray or washing tank.

The intensified image is not permanent. (C.B.N.)

INTENSITY SCALES. Systems of rating equal intensity by various earthquake effects on persons and things. The Rossi Forel scale is simple, has ten grades, and has been long in use. The Mercalli scale is more accurate and has twelve grades. A modified form called the Wood-Neumann scale is used in the United States, and is coming into more general use, both in complete and abridged form. (R.M.F.)

INTERCEPT. **Celestial Navigation.**

INTERCHANGEABLE MANUFACTURE. The principle of interchangeability requires manufacture to such specification that component parts of a device may be selected at random and assembled to fit and operate satisfactorily. This necessitates parts made to definite limits of error, fitting gauges instead of mating parts. Interchangeability does not necessarily involve a high degree of precision; stove lids, for example, are interchangeable, but not particularly accurate.

Interchangeable manufacturing procedure requires specification for the permissible error in each dimension, as well as for the size of the part, since it is practically impossible to manufacture to an exact dimension, and is therefore based upon the limit system of dimensioning. In limit dimensioning, nominal size is a designation given to a dimension which has no specified limits of accuracy, but is a close approximation to a standard size. Basic size is an exact theoretical size from which all variations are made. Allowance is an intentional difference in the size of mating parts. Tolerance is the permissible variation in the size of a part. Limits are the extreme permissible dimensions of a part.

Two types of tolerance are used in limit dimensioning. Unilateral tolerance is related to a basic size in one direction only. In a running fit, for example, the hole size may vary between limits of 1.2500″–1.2514″ where the tolerance is .0014″, above the basic size of 1.2500″. A bilateral tolerance is one in which the variation from the basic size is in both directions. In a similar example, the hole size may vary between 1.2493″–1.2507″, giving a tolerance of +.0007″ and −.0007″ from the basic size.

The use of tolerances makes it impossible to maintain exact theoretical allowances for fits; where more precise allowances are desired, selective assembly is used. Selective assembly consists of trial selection of mating parts to obtain a desired precision of fit. An example of this process is in the assembly of ball bearings. All ⅜″ diameter balls are not alike, since there is a tolerance of about .0001″ in manufacture. The balls are sorted into three groups: .3751″, .37505″, and .3750″ in diameter, and assembled in similarly selected races. The assembled ball bearing is not strictly interchangeable, since a replacement ball may be slightly under or over the size of the rest of the balls in the assembly.

Fractional dimensions indicate that ordinary scale measurements are sufficiently precise, and thereby imply limits, in general, of plus or minus .010″ on each dimension. (H.C.H.)

INTERCLASS CORRELATION. When two variables x, y are correlated and each variable refers to a different group, then we have an interclass correlation as distinct from the **correlation** among items in the same group. If we find the correlation between the height and weight of people we are determining an interclass correlation. If we find the correlation among the weights of adults in the same family we are finding an **intraclass correlation.** (L.A.A.)

INTERCONNECTION. Each year witnesses interconnections and mergers which are slowly uniting the power and light companies of the United States into one vast interconnected network of transmission lines. The justification for interconnection can be presented on a financial basis, but the ability to render intersystem assistance during local trouble and in that way to prevent interruption of service to the customer should be the basic reason for interconnection, even though no definite financial expression may be attached to it. Of more tangible value is the use of the more efficient plants as base load stations. Off-peak power may be exchanged on some prearranged basis when the load peaks on one system do not occur simultaneously with those on another. This has the effect of delaying, for a time, the purchase of new equipment to care for increasing peaks. Also, it renders economical the installation of additional capacity beyond that justified by the gain in the individual system; that is, a new station or unit causes temporary surplus capacity and consequent annual charges for idle equipment which may be reduced by adjacent systems installing their new equipment alternately. A decrease in the total of emergency standby capacity is possible when two or more systems operate interconnected. Systems predominantly hydroelectric, but with steam standby, realize the maximum economy in interconnected operation because of the diversity of stream flow in different localities.

Interconnection relieves the necessity of splitting up the plant capacity into a number of small units for the sake of uninterrupted service.

A superpower system is a vast interconnected system which has for its basis the maximum exploitable water power of the country, relying on excess flows at one

point to counteract low water at another, and having steam plants suitably located to care for deficiencies in water power. While it would be possible to transmit over great distances, actually transfers of energy between groups constituting the superpower system would rarely occur over distances greater than 200 miles. (F.T.M.)

INTERELECTRODE CAPACITANCE. This is the capacitance which is present between the various electrodes of an electron **tube.** Thus the **grid** and **plate** of a **vacuum tube** are normally not connected directly to one another but because they are conductors separated by a dielectric (the vacuum space in the tube) they have a certain capacitance. The same situation exists between the other electrodes of the tube. These various electrode capacitance offer paths through which alternating currents may flow between the electrodes. Since these currents are not under the control of the signal they are very undesirable in most cases. In an **oscillator** this interelectrode capacitance is utilized to transfer energy from the plate to the grid circuit and thus make the circuit oscillate. However, in an **amplifier** such action is normally highly undesirable and various means such as neutralizing and screen grids are employed to reduce it. While the capacitance in a receiving tube, for example, may be only a few micromicrofarads appreciable current may flow through it at high frequencies. (L.R.Q.)

INTERFACIAL TENSION. **Surface-Active Compounds.**

INTERFERENCE. This is the undesirable mixing of two signals and is commonly used to designate the mixing of one or more undesired signals with a desired communications signal. Various forms of interference are power-line interference, i.e., noise introduced by a power circuit in a communication circuit (see **Inductive Interference**), **Crosstalk, Cross-Fire,** heterodyning of desired and undesired stations in radio reception and many others. (See **Fit; Gearing.**) (L.R.Q.)

INTERFEROMETERS. The term interferometer may be applied to any arrangement whereby a beam of light from a large, luminous area (as a sodium flame) is separated into two or more parts by partial reflections, the parts being subsequently reunited after traversing different optical paths. The two components then produce **interference.** The best known instrument is that of Michelson, shown diagrammatically in the accompanying figure. The original beam *a* is separated at

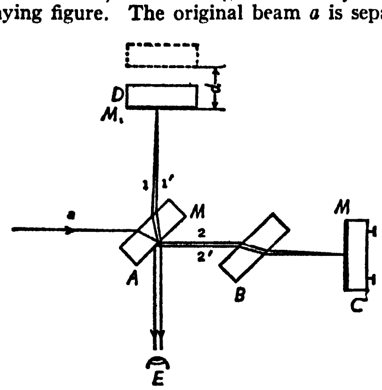


Diagram of Michelson interferometer.

the surface *AM* of a glass plate, part of it (1,1′) going to a mirror M_1 and part (2,2′) going on through a second, exactly similar plate *B* to the mirror M_2. They reunite at *AM* and are observed together at *E*. One of the mirrors, M_1, is mounted on a micrometer screw so that its distance from *AM* can be varied, the phase difference of the reunited beams thereupon passing through a series of cycles. If M_1 or M_2 is not quite perpendicular to the beam reflected by it, the field at *E* is crossed by interference fringes, which move across the field as the mirror M_1 is moved. Each complete cycle corresponds to a displacement of M_1 equal to a half-wavelength. The Fabry and Perot interferometer is somewhat simpler in design, but utilizes multiple reflection and produces very sharp fringes (high resolving power).

Interferometers are used for precise measurements of wavelength, for the measurement of very small distances and thicknesses by using known wavelengths, for the detailed study of the **hyperfine structure** of spectrum lines, for the precise determination of refractive indices, and, in astrophysics, for the measurement of **double-star** separations and the diameters of very large **stars.** (L.D.W.)

INTERFLUVE. The area or watershed between two neighboring streams or rivers. (R.M.F.)

INTERGRANULAR CORROSION. **Corrosion.**

INTERLACING. **Scanning.**

INTERLOBATE MORAINE. If large glaciers and continental ice sheets advance irregularly so that their margins are lobate, when the margins retreat by melting the resulting **terminal moraines** of boulders, clay, and sand simulate the original interlobate shape of the glacier or glaciers, and therefore such moraines are called interlobate. (R.M.F.)

INTERMEDIATE FREQUENCY. **Superheterodyne.**

INTERMEDIATES. **Coal Tar Products and Intermediates.**

INTERMETALLIC COMPOUND. A solid compound of two or more metals united in definite atomic proportions as in the case of chemical compounds but not following the usual rules of chemical valence. Examples are $CuAl_2$, Mg_2Si, CuSn, Bi_2Te_3. Compounds between metals and **metalloids** such as Fe_3C and MnS are generally classed as intermetallic compounds also. In alloys these compounds are of great importance. They may form directly from the molten metal upon solidification or from **solid solutions** upon cooling to lower temperatures. They generally are present in the **microstructure** as hard particles embedded in a more plastic matrix. They are often soluble to a limited degree in the matrix and thus make it possible to harden and strengthen the alloy by a **precipitation-hardening** heat treatment. (R.H.H.)

INTERNAL COMBUSTION ENGINE. The internal combustion engine is one in which **combustion** of a **fuel** takes place within the **cylinder,** and the products of combustion form the working medium during the power stroke. As it is a self-contained power supply unit, the internal combustion engine assumes a position of great importance in the power field, especially for that class of service where portability, light weight, and compactness are important. Witness the majority of self-propelled vehicles powered by internal combustion engines. The principal cycles of internal combustion engines in use at present are the **Otto** and **Diesel** cycles. Other cycles are of some historical importance, but these two have supplanted the others in the course of time by possessing certain points of superiority such as economy, reliability, compactness, etc.

An internal combustion engine consists primarily of a cylinder, almost always stationary, and a **piston,** gener-

ally single acting, which, together, form a **combustion chamber** of variable volume. Both of these parts are constructed of metal, and as the temperatures attained during combustion are well above the ability of uncooled metals to withstand, the cylinder of an internal combustion engine must be adequately cooled by transferring through the cylinder wall a certain amount of the heat contained in the gases of combustion. This is accomplished in a practical way by surrounding the cylinder with a **jacket** of cooling water, or by providing it with an extended outer surface of fins so that air can absorb enough heat to keep the metal cool. The required motion is given to the piston by a crank and connecting rod mechanism which also serves to take from the piston the power developed by gas pressure.

An engine operating with flaming gas in its cylinder would not last long with simple metal to metal contact of the moving parts, therefore a lubricating system, embodying oil as the lubricant, is an important feature of every internal combustion engine. The most difficult job is that of lubricating the piston in the cylinder. During a portion of the stroke, at least, the lubricated wall is exposed to incandescent gases which tend to burn off the film of lubricating oil. The cooling system must be adequate to maintain the metal surfaces cool enough to save the lubricating film.

The events of the cycle upon which an internal combustion engine works are controlled chiefly by the operation of **valves** located in ports leading to and from the cylinder. Generally, an admission or inlet valve, and an exhaust valve, are provided in each cylinder. The operation of these valves is derived mechanically from the crankshaft through the **valve gear** system.

The combustion of fuel in an internal combustion engine is not a continuous affair, but a series of individual explosions, each one requiring a metered amount of fuel to be individually ignited. For this reason, every internal combustion engine must incorporate an **ignition system**, whose function it is to supply in proper time the ignition temperature required for combustion. The internal combustion engine is of a type tending to deliver its power cyclically, and in a fashion which would be very fluctuating unless balanced by the use of heavy **flywheel**, or by overlapping of power impulses through multi-cylindered arrangements. It is usual, in fact, to build internal combustion engines with more than one cylinder so that the delivery of power will be more uniform, and flywheel proportions will not be excessive. The supply of fuel to multi-cylindered engines from a common source, and the conduction of exhaust from them, leads to another service feature for the internal combustion engine, namely, the inlet and exhaust **manifolds**.

The production of power by this type of engine represents a thermodynamic conversion of a portion of the heat energy developed into mechanical energy. The heat energy enters the engine latently in the form of fuel. Mechanical energy appears as power available at the crankshaft. Unavailable or rejected heat is found in exhaust, cooling, and friction. The conversion of the energy of the fuel into useful power takes place about as follows: Air is brought into the cylinder and, either after, before, or during compression, depending on the cycle, fuel is introduced into the air and mixed with it. Upon ignition of this fuel, the heat developed raises the pressure of the products of combustion, or, at least, maintains the pressure during some motion of the piston. The fact that the piston has, against one face of it, a gas pressure greatly exceeding that on the other, inevitably results in the transmission of energy through the train of mechanism consisting of moving piston, wrist pin, connecting rod, and crankshaft. During the motion of the piston, the gases of combustion expand and are cooled somewhat. It has not been found economical to build an engine sufficiently bulky to expand the gases until they reach ordinary atmospheric temperature, and there is always considerable heat loss in the exhaust. In spite of the losses the internal combustion engine of the present is the most efficient prime mover that has been devised. (See **Diesel Engine, Otto Engine, Two-cycle, Four-cycle, Aeronautical Engine, Engine, Ignition System, Carburetion.**) (F.T.M.)

INTERNAL FRICTION. **Viscosity.**

INTERNAL GEAR. **Spur Gearing.**

INTERNAL PRESSURE. **Adhesion and Cohesion.**

INTERNAL SAC. An organ of larval **bryozoans** by which the animal attaches itself to a supporting surface before transforming into the adult. (A.W.L.)

INTERNATIONAL DATE LINE. In accordance with the fundamental definition of civil **time** the date changes when the mean sun crosses the **meridian** at lower culmination, i.e., at midnight. It would be possible for a traveler to travel around the earth on a sufficiently high parallel of **latitude** in 24 hours. Say such an observer starts out at one o'clock in the afternoon, i.e., with the sun about 1 hour west of his meridian, and travels westward at just the proper rate to maintain the sun in that position. For such a traveler the date would not change and he would return to his starting point on the same date, as he would reckon it, as that on which he set forth on his journey. If the traveler had taken 100 days to complete his journey instead of only 1, he would still return to his starting point a day earlier, on his own reckoning, than the date of those who had remained at home. To avoid confusion of this sort the so-called international date line has been established.

This date line is approximately 180° west of Greenwich in **longitude** but is adjusted so that, so far as is possible, the Pacific insular possessions of the different countries shall carry the same date as the home nations, and also so that the line shall not cross any land. Ships crossing the date line from east to west skip one day. That is, if it is Monday when the ship arrives at the line from the east it immediately becomes the same hour on Tuesday after crossing the line and the day so dropped is omitted from the log book. On crossing the line from west to east a day is repeated. (W.K.G.)

INTERNATIONAL TEMPERATURE SCALE. **Thermometry.**

INTERNODE. **Stem.**

INTERPHONE. This is a small private telephone communication system installed in a building for use in communicating within the building only. Such systems may be miniature replicas of the regular telephone systems or they may consist only of two or three stations operating as the simplest type of telephone system. In such systems the switching may be done by pushbuttons or switches at each phone, or even in some operated without any switching on a sort of party line, or they may utilize regular dial or automatic switching equipment. Often in the more extensive systems provision is made for connecting all or certain selected phones with the public telephone lines. (L.R.Q.)

INTERPOLATION. Interpolation is a process by which an appropriate value is placed between tabulated values of a function.

Simple interpolation, by first differences, is based on a principle of proportional parts: when the variable (or argument) changes by a small amount, the change in the tabulated function is very nearly proportional to the change in the variable.

For more accurate work, interpolation by second and higher differences is needed, and more complicated interpolation formulae are then used. (L.L.S.)

INTERPOLE. This is an auxiliary pole placed between the main poles of a d-c **motor** or **generator** to give a flux which will aid in **commutation.** When a machine is operating under load the armature current sets up a flux which combines with the field flux, giving a resultant distortion of the main flux. When a coil is being commutated it is, of course, short-circuited by the brushes so any voltage present in the coil will cause a circulating current around the coil by way of the **brush** or brushes. (See **Commutation.**) Such currents are very undesirable as they introduce extra losses and cause unnecessary burning of the brushes and commutator. If the coil being commutated has its sides lying in a position of zero flux while undergoing commutation there will be no field induced voltage. However, the current in the coil is reversed during commutation (by very definition of commutation) and as a reversal of current causes an inductive or reactance voltage to be induced the coil still has this e.m.f. to cause currents. The distortion of the field flux by **armature reaction** and this reactance voltage make it necessary to provide interpoles or shift the brushes from the mechanical neutral. When brushes are shifted they must be shifted forward in the direction of rotation for generators and backwards for motors, hence must be changed if the rotation is reversed. In addition this is a not too satisfactory method for curing the trouble since the amount of shift is proportional to load. Introducing interpoles between the main poles and connecting the interpole windings in series with the **armature** gives an auxiliary flux which will tend to counterbalance the distortion of the flux by the armature current and at the same time give an auxiliary flux which will induce a voltage in the armature coils to counteract the reactance voltage. Thus much improved commutation results and shifting of brushes is eliminated. (L.R.Q.)

INTERQUARTILE RANGE. The interquartile range is defined as $Q_3 - Q_1$ where Q_3 and Q_1 are the third and first **quartiles** in a distribution. It is a measure of **variability** and is not recommended. In its place the **standard deviation** should be used. (L.A.A.)

INTERRAY. A division of the body of a starfish (**Asteroidea**) between the axes of two rays or arms, or a corresponding division of the sea urchins which lack radiating arms but have radii indicated in the structure of the compact body. (A.W.L.)

INTERRUPTED CONTINUOUS WAVE. An interrupted continuous wave is the result of chopping up or interrupting a normal **continuous wave** radio signal at an audio rate. This interruption is distinct from the normal **keying** and is at a rate high enough to give several interruptions even for a dot of the International code. The result is an audio output from the **receiver** without the use of some method of **heterodyning.** The interruption of the wave, however, causes the radiation of many more **sideband** frequencies and hence the need of a wider **channel.** For this reason such transmissions are not widely used. (L.R.Q.)

INTERSTITIAL CELL. 1. Small undifferentiated cells in the outer layer of polyps such as *Hydra* which develop into the **cnidoblasts** and reproductive cells. 2. Cells between the reproductive structures of the ovaries and testes of vertebrates. They have been interpreted as glands of internal secretion but the point is disputed. (A.W.L.)

INTERTENTACULAR ORGAN. A temporary duct leading from the coelom to the exterior within the tentacle-bearing ridge (lophophore) of **bryozoans.** Germ cells escape through it. (A.W.L.)

INTESTINAL OBSTRUCTION. An organic or functional block interfering with the continuity of the bowel. This is a serious condition which is compatible with life for only a short period. It is one of the grave surgical emergencies.

The causes of intestinal obstruction are many. The organic ones include all lesions which mechanically obstruct the bowel, such as **cancer** in its walls, **adhesions** constricting the gut, twists in the intestines, **intussusception,** etc. A **hernia** which becomes incarcerated and strangulated is one of the commonest causes. Functional obstruction of the bowel results in paralytic ileus in which the peristaltic movement of the intestinal-wall muscles is inhibited, and the bowel dilates. This occurs as a postoperative complication in abdominal surgery, and is part of the picture of **peritonitis.**

The symptoms of mechanical obstruction are intermittent abdominal pain, vomiting and constipation. The abdomen may be distended and tender. With the aid of a stethoscope, great roaring peristaltic rushes can be heard. In paralytic ileus, the abdomen is quiet since there is complete absence of peristaltic movement.

The treatment of mechanical obstructions is surgical. In ileus, suction by means of a tube inserted through the mouth, esophagus and stomach to the bowel, relieves the gaseous distention; **drugs** are used to help restore tone and movement to the intestinal muscles. (D.M.H.)

INTESTINE. Digestive System; Alimentary Tract.

INTRACLASS CORRELATION. Often we are interested in finding the **correlation** among items within a group such as the correlation in the heights of brothers. In this case, both heights are entered as an x value and a y value since there is no way of differentiating as to which **variable** is x and which is y. Let $p =$ the number of groups or families, $k =$ the number of **variates** in each family, $\bar{x}_i =$ **mean** of the ith group, $\bar{x} =$ the mean of all kp variates, $s^2 = \dfrac{\sum_{j=1}^{k}\sum_{i=1}^{p}(x_j - \bar{x}_i)^2}{p(k-1)}$, then r the intraclass correlation coefficient is calculated by the formula

$$r = \frac{1}{k-1}\left\{\frac{k\sum_{i=1}^{p}(x_i - \bar{x})^2}{ps^2} - 1\right\}.$$

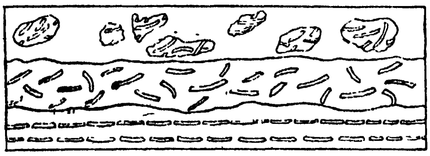
The intraclass coefficient of correlation cannot have a value less than $\frac{-1}{k-1}$, and if k is very large as it may be in most cases, then r will be positive. The intraclass coefficient of correlation may be tested for significance by the **analysis of variance,**

$$F = \frac{k\sum_{i=1}^{p}(\bar{x}_i - \bar{x})^2/p - 1}{\sum_{j=1}^{k}\sum_{i=1}^{p}(x_j - \bar{x}_i)^2/p(k-1)}$$

with $n_1 = p - 1$ **degrees of freedom,** and $n_2 = p(k-1)$ degrees of freedom. (L.A.A.)

INTRAFORMATIONAL. This term is used by **stratigraphers** to denote textures and structures developed in **sedimentary rocks** at the time of the deposition of the sediments and thus previous to their consolidation through **lithification.** While normal structures, such as different types of bedding and stratification, may

be considered as intraformational, the term is usually confined to such phenomena as mud-cracks (desiccation fractures), raindrop imprints, and intraformational or



Intraformational conglomerates, in cross-section. (*Field, Outline, Barnes & Noble.*)

"edgewise" conglomerates whose "pebbles" or **phenoplasts** were formed from mud while it was still plastic. (R.M.F.)

INTROMITTENT ORGAN. A protuberance or protrusible organ of the male for the introduction of the seminal fluid into the genital passages of the female in the act of **copulation.** (A.W.L.)

INTROVERT. In zoology, a portion of the body which can be thrust out or retracted by a process of involution. Applied to the proboscis of sipunculids (**Annelida**) and sometimes to the eversible portion of the body of the **bryozoans.** (A.W.L.)

INTRUSIVE ROCK. Igneous Rock.

INTUBATION. The insertion of a tube into the **larynx** through the throat to permit breathing when the larynx becomes closed through swelling such as occurs in severe laryngeal diphtheria. This procedure was formerly used extensively, but since the widespread use of **diphtheria** immunization and antitoxin there is less occasion for it at present. It was first introduced by Dr. Joseph O'Dyer of New York City in 1885. (R.S.M.)

INTUSSUSCEPTION. The telescoping of one section of the intestine into the part below, causing **intestinal obstruction.** Intussusception may occur in either the small or large intestine; it is generally caused by the pulling up of one section of bowel over another of marked spasm just above. Other causes are **polyps, cancer,** and foreign bodies. Intussusception occurs most often in infants and children. The clinical picture is striking: the onset is sudden and marked by severe abdominal pain and vomiting occurring in paroxysms. Collapse and **shock** soon follow with pallor, feeble pulse and subnormal temperature. Without surgery **peritonitis** develops; the temperature rapidly rises, and death soon occurs. Bloody stools are almost a constant accompaniment of this disease, with diarrhea in which only blood and mucus are passed. Death often results unless surgery is undertaken, and the mortality rises in direct proportion to the time lost before operation.

For the use of this term in zoology, see **Growth.** (D.M.H.)

INULIN. Carbohydrates.

INVAR. Metals and Alloys; Expansion; Nickel Alloys.

INVARIANTS AND COVARIANTS. An invariant of a **quantic** is a **function** of the coefficients of the quantic which is transformed into the same function of the new coefficients, multiplied by a power of the modulus of the transformation, when the variables of the quantic are subjected to a **linear transformation.**

A covariant of a quantic is a function of both coefficients and variables of the quantic which retains its form, multiplied by a power of the modulus of the transformation, when the variables of the quantic are subjected to a **linear transformation.** (L.L.S.)

INVERSE FEEDBACK. Feedback.

INVERSE FUNCTIONS. If $y = f(x)$ is a given **function** of x, then x regarded as a function of y is called the inverse function of the given function.

Examples of pairs of inverse functions are. the square of a variable and the square-root function, the **exponential function** and the **logarithmic function,** the **trigonometric functions** and the **inverse trigonometric functions.** (L.L.S.)

INVERSE HYPERBOLIC FUNCTIONS. Hyperbolic Functions.

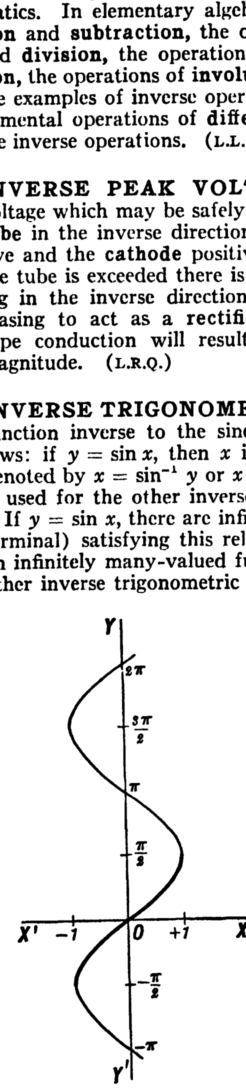
INVERSE OPERATIONS. Two operations are said to be inverse operations when each one counteracts the effect of the other.

Inverse operations occur in many places in mathematics. In elementary algebra, the operations of **addition** and **subtraction,** the operations of **multiplication** and **division,** the operations of **evolution** and **involution,** the operations of **involution** and taking **logarithms** are examples of inverse operations In calculus, the fundamental operations of **differentiation** and **integration** are inverse operations. (L.L.S.)

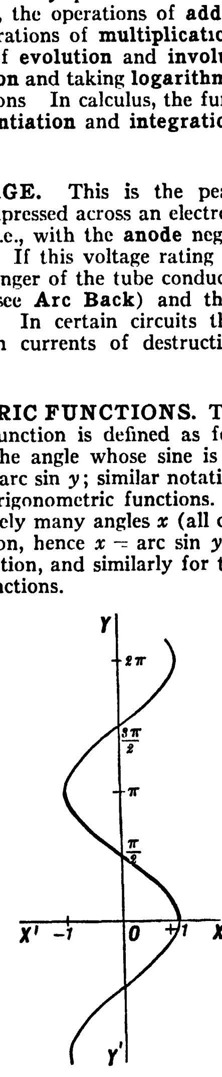
INVERSE PEAK VOLTAGE. This is the peak voltage which may be safely impressed across an electron **tube** in the inverse direction, i.e., with the **anode** negative and the **cathode** positive. If this voltage rating of the tube is exceeded there is danger of the tube conducting in the inverse direction (see **Arc Back**) and thus ceasing to act as a **rectifier.** In certain circuits this type conduction will result in currents of destructive magnitude. (L.R.Q.)

INVERSE TRIGONOMETRIC FUNCTIONS. The function inverse to the sine function is defined as follows: if $y = \sin x$, then x is the angle whose sine is y, denoted by $x = \sin^{-1} y$ or $x = \text{arc}\sin y$; similar notation is used for the other inverse trigonometric functions.

If $y = \sin x$, there are infinitely many angles x (all coterminal) satisfying this relation, hence $x = \text{arc}\sin y$ is an infinitely many-valued function, and similarly for the other inverse trigonometric functions.



$y = \text{arc}\sin x$
Fig. 1.

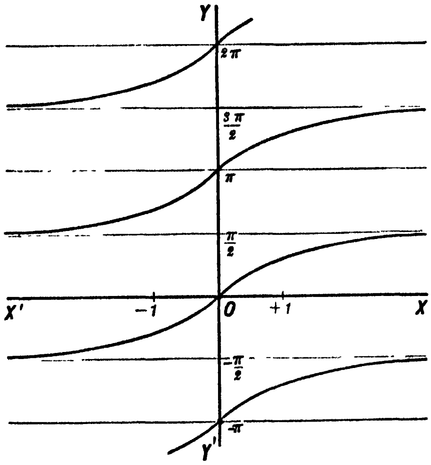


$y = \text{arc}\cos x$
Fig. 2.

The principal value of the inverse sine, arc sin y, is the value which lies between $+90°$ and $-90°$ (or $+\frac{\pi}{2}$ and $-\frac{\pi}{2}$). It is often denoted by Arc sin y or $\text{Sin}^{-1} y$.

Usage is not uniform in regard to the definition of principal values.

Sometimes, Arc cos y is taken as the value between $0°$ and $180°$ (or 0 and π); sometimes Arc tan y is taken as the value between $+\frac{\pi}{2}$ and $-\frac{\pi}{2}$.



$Y = \textit{arc-tan}\ X$

Fig. 3.

General values of inverse trigonometric functions are given by:

$$\text{arc sin } x = n\pi + (-1)^n\alpha, \text{ where } \alpha = \text{Arc sin } x,$$

$$\text{arc cos } x = 2n\pi \pm \alpha, \quad \text{where } \alpha = \text{Arc cos } x,$$

$$\text{arc tan } x = n\pi + \alpha, \quad \text{where } \alpha = \text{Arc tan } x,$$

where n is any positive or negative integer or 0.

The graphs of the inverse trigonometric functions are shown in Figs. 1–3. (L.L.S.)

INVERSION. The temperature below the stratosphere normally decreases with altitude. When temperature increases with altitude, normal conditions are inverted, and the condition is said to be an inversion. Inversions in the troposphere are usually restricted to shallow layers of air which most frequently occur in the lower 5000′ above the surface. In low latitudes the stratosphere is a slight inversion more or less permanently. (P.E.K.)

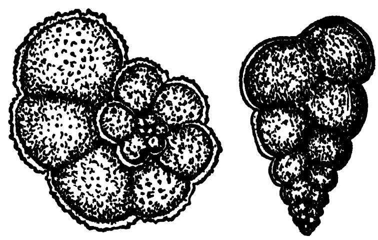
INVERSIONS. Determinants.

INVERTASE. Enzymes.

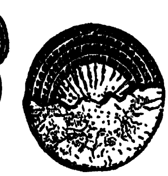
INVERTEBRATA. The portion of the animal kingdom containing all but the Phylum Chordata. The true skeletal distinction of that phylum as now defined is the notochord but, since the great majority of the included species have a backbone made up of vertebrae, the terms vertebrate and invertebrate were established very early in the development of zoology and still persist. (See **Classification.**) (A.W.L.)

INVERTEBRATE PALEONTOLOGY. The study, description, and geologic use of invertebrate **fossils** in relation to paleo-biological and **stratigraphic** problems. The science of invertebrate paleontology is primarily founded upon invertebrate zoology. Since thousands of invertebrate fossils, ranging in age from the **Cambrian** to the **Pleistocene,** have been figured and described, it is not possib'e to list them all in a general science encyclopedia. Also there is no single reference work in existence which covers the entire subject. For detailed information the student must consult special bibliographies which list the references in a large number of special papers and monographs. The following condensed classification of the invertebrates serves as an outline of the more significant facts relating to invertebrate paleontology.

I. **Protozoa.** Single-celled animals. While most of the protozoa are naked, a particular marine group called the foraminifera (a term derived from words meaning a hole and to bear) form shells which occur as fossils from



Cretaceous foraminifers, greatly enlarged. (*LeConte, Elements of Geology, Appleton-Century Co.*)

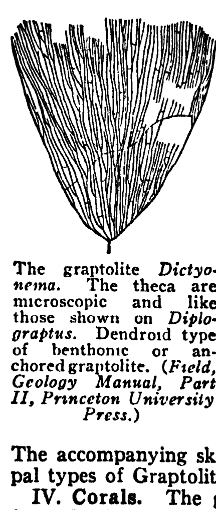


An Eocene foraminifer, *Nummulites.* (*LeConte, Elements of Geology, Appleton-Century Co.*)

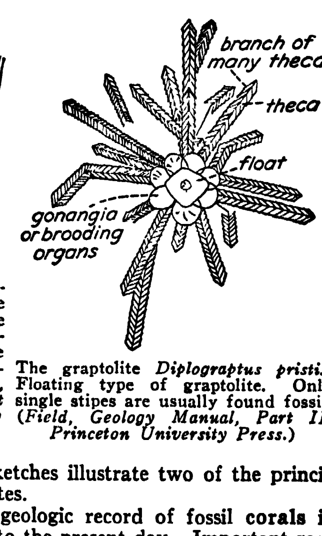
the Cambrian to the present. Foraminifera are an important constituent of chalk. Due to the large number of distinctive and rapidly evolving species foraminifera are useful index fossils, especially in the **Mesozoic** and Cenozoic periods.

II. **Porifera** or **Sponges.** The name porifera is derived from words meaning a pore and to bear. Fossil sponges occur from the Cambrian to the Pleistocene. Except for a few species they are not particularly valuable index fossils. A particularly interesting genus is *Hydnoceras,* a delicate glass sponge which has left its imprint in the fine-grained muds of **Devonian Age.**

III. **Graptolites.** This term is derived from words meaning written and stoned, because the fossils look like pencil marks on slate. Graptolites were colonial marine animals with chitinous skeletons. Their stratigraphic range is from the **Ordovician** to the **Silurian,** inclusive. Because the graptolites evolved rapidly and have a world-wide distribution they are excellent index fossils.



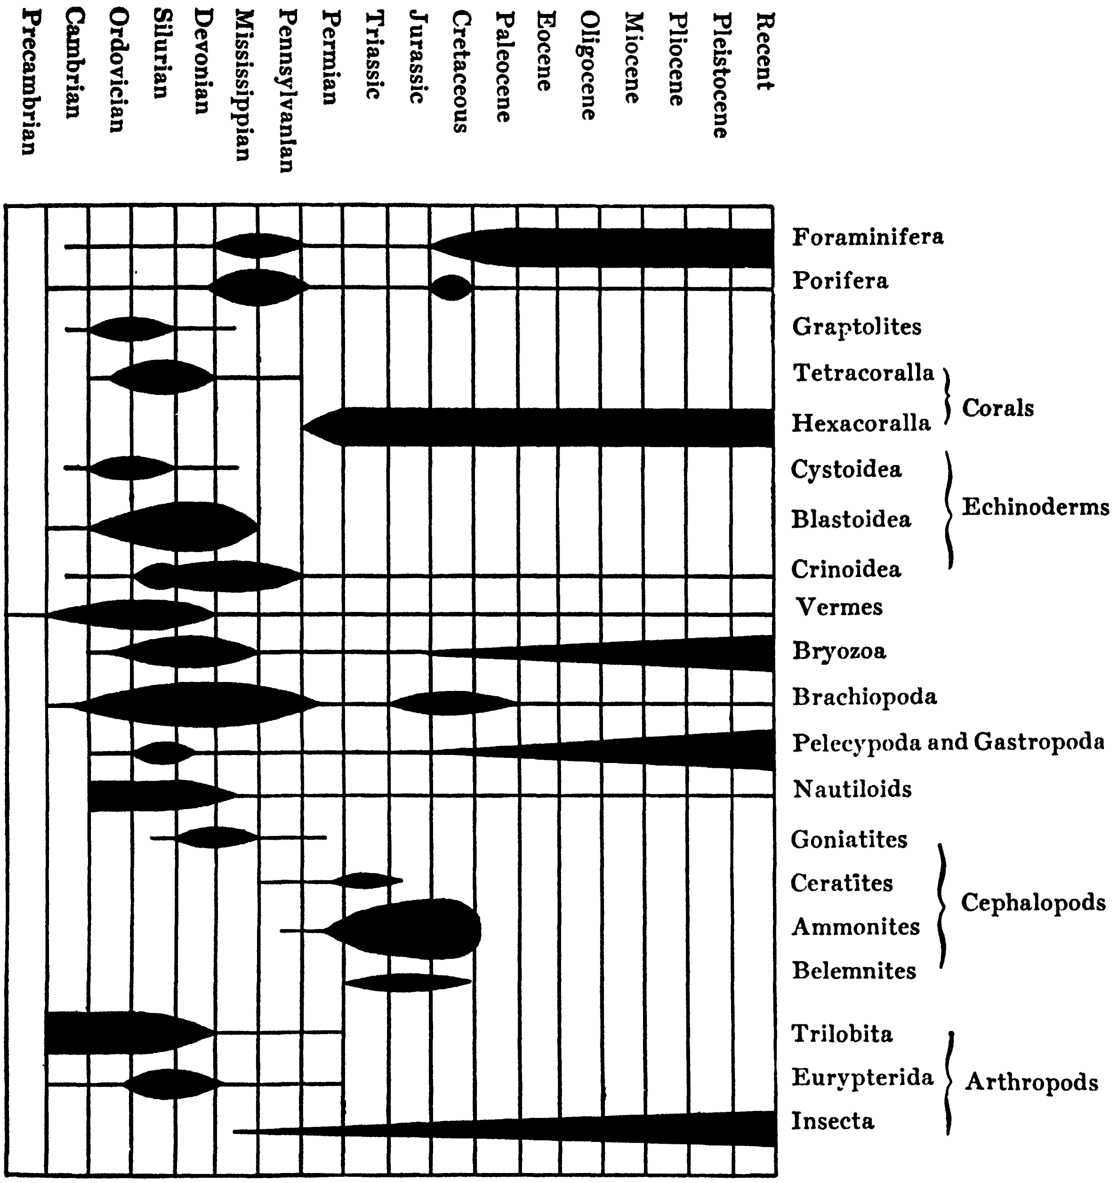
The graptolite *Dictyonema.* The theca are microscopic and like those shown on *Diplograptus.* Dendroid type of benthonic or anchored graptolite. (*Field, Geology Manual, Part II, Princeton University Press.*)



The graptolite *Diplograptus pristis.* Floating type of graptolite. Only single stipes are usually found fossil. (*Field, Geology Manual, Part II, Princeton University Press.*)

The accompanying sketches illustrate two of the principal types of Graptolites.

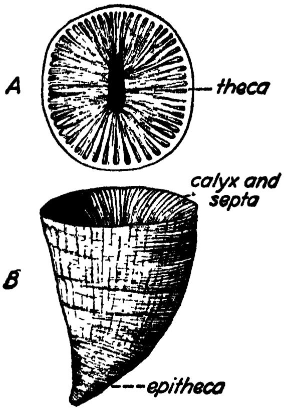
IV. **Corals.** The geologic record of fossil **corals** is from the Ordovician to the present day. Important reef builders in the tropical waters of the present oceans and seas. The earliest forms are both colonial and single. The accompanying illustration is that of a single or rugose coral of Ordovician age. Corals are important and useful index fossils in the strata of certain geologic periods.



GEOLOGIC RANGE OF THE INVERTEBRATES

NOTE: The "lifelines" are swelled during the periods in which there were the greatest number of genera and species, or when the particular class of organisms is most important as "index fossils."

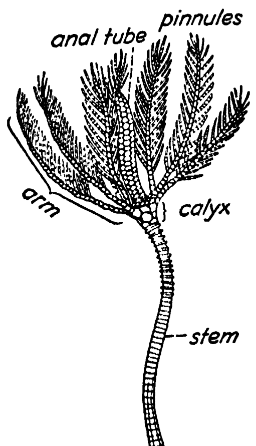
(Field, Laboratory Manual, Princeton University Press.)



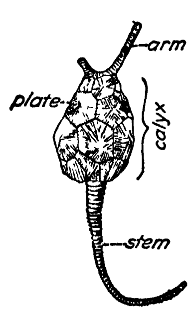
Single, rugose or cup coral. *A*, Top view. *B*, Complete coral skeleton. (Corallite.) (*Field, Geology Manual. Part II, Princeton University Press.*)

V. Vermes, or **Worms.** Worm trails and worm tubes are found in the sedimentary strata of all ages from the pre-Cambrian to the present. Not particularly useful as index fossils, except in the early Silurian. The jaws and teeth of worms, called conodonts, are useful index fossils.

VI. **Echinoderms.** The term is derived from words meaning hedge hog and skin, because certain types of **echinoderms** have sharp barbed spurs. Echinoderms

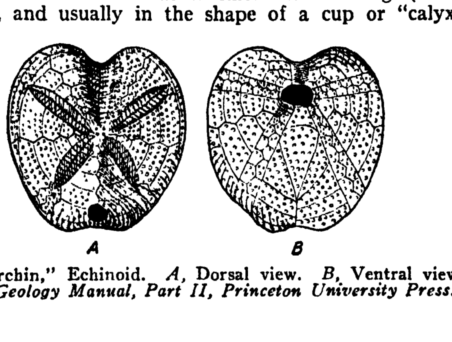


Crinoid
(*Field, Geology Manual, Part II, Princeton University Press.*)



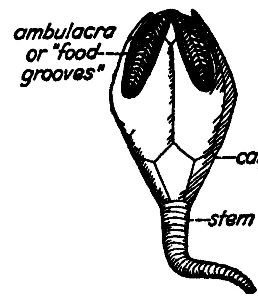
Cystid
(*Field, Geology Manual, Part II, Princeton University Press.*)

are aquatic, marine animals with radial symmetry. The test or skeleton is composed of plates of **calcium** carbonate, with or without a chitinous covering (when living), and usually in the shape of a cup or "calyx"



"Sea Urchin," Echinoid. *A*, Dorsal view. *B*, Ventral view. (*Field, Geology Manual, Part II, Princeton University Press.*)

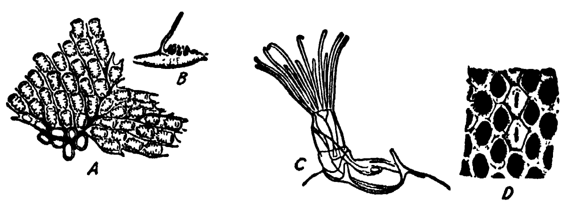
with or without "arms." Some forms are attached to the sea bottom by means of "stems" and "roots"; others are floating or free swimming. The echinoderms are subdivided into the following characteristic groups. 1. Cystoids (Cystids). Stratigraphic range from the Cambrian to the **Mississippian.** 2. Blastoids. Strati-



Blastoid. An anchored echinoderm without free "arms." (*Field, Geology Manual, Part II, Princeton University Press.*)

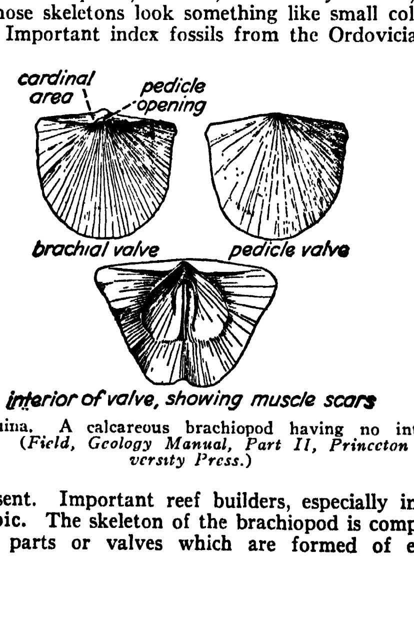
graphic range from the Cambrian to the Mississippian. An important and frequently beautiful preserved genus is *Pentramites.* 3. **Crinoids,** or sea lilies. Stratigraphic range Cambrian to present. 4. **Asteroids,** or starfishes. 5. **Echinoids,** sea urchins, from which the echinoderms take their name. 6. **Holothouroids,** or sea cucumbers.

VII. **Molluscoidea,** meaning the form of a mollusk. A group of diverse forms of aquatic, and usually marine, animals with chitinous calcareous skeletons. Free swim-



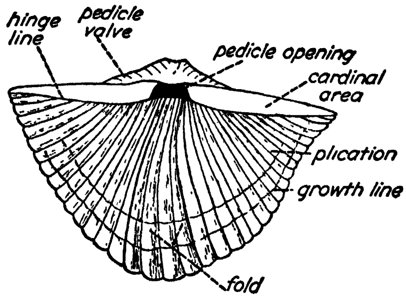
Bryozoans. *A*, Portion of modern colony seen from above (× 15), *B*, an individual expanded; *C*, fossil form. A-C after Verrill and Smith; *D*, from Ulrich. (*Shimer's Introduction to the Study of Fossils, The Macmillan Co.*)

ming only in the young stages. The two principal subdivisions are the **bryozoa** (moss-like animals) and the **brachiopoda** (arm-footed), which are bivalves. The bryozoans are aquatic, colonial, and usually marine, animals whose skeletons look something like small colonial corals. Important index fossils from the Ordovician to



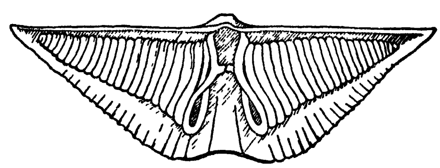
Rafinesquina. A calcareous brachiopod having no interior skeleton. (*Field, Geology Manual, Part II, Princeton University Press.*)

the present. Important reef builders, especially in the **Paleozoic.** The skeleton of the brachiopod is composed of two parts or valves which are formed of either



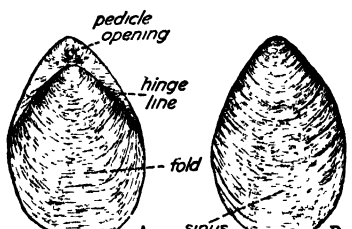
Front view of spirifer, showing full view of brachial valve. (*Field, Geology Manual, Part II, Princeton University Press.*)

"horn" or calcium carbonate. The brachiopod skeletons are principally distinguished from the pelecypods (clams, etc.) by a different type of bilateral symmetry.



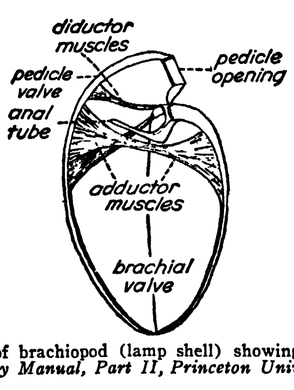
Interior of brachial valve of spirifer showing brachidia, or spires. (*Field, Geology Manual, Part II, Princeton University Press.*)

The higher forms have internal skeletons. Brachiopods are excellent index fossils, especially in the Paleozoic, where they share their importance with the graptolites



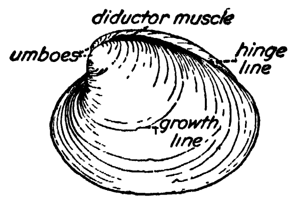
Brachiopod, "Lamp Shell." A, Front view. B, Rear view (Pedicle valve.) (*Field, Geology Manual, Part II, Princeton University Press.*)

and the trilobites. The accompanying figures illustrate some of the principal types of brachiopods.



Cross-section of brachiopod (lamp shell) showing musculature. (*Field, Geology Manual, Part II, Princeton University Press.*)

VIII. **Mollusca,** meaning soft-bodied animals. This class includes the **Pelecypoda,** meaning axe-footed bivalves whose shells are formed of calcium carbonate with a "horny" covering. No interior skeleton, even in the higher types. The skeleton is distinguished from that of the brachiopods by a different type of bilateral symmetry. A few species, such as the oyster, have no symmetry. All pelecypods are aquatic, but may be either fresh-water or marine. Most species are attached to the bottom in the adult stage, but a few are free-



Quahog, modern pelecypod. (*Field, Geology Manual, Part II, Princeton University Press.*)

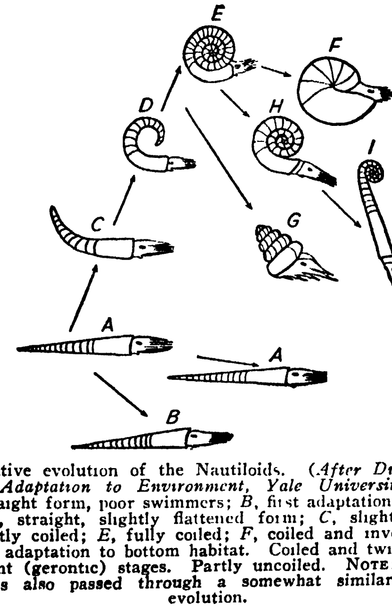
Interior view of left valve of pelecypod. Showing muscle scars. (*Field, Geology Manual, Part II, Princeton University Press.*)

swimming. Pelecypods are not particularly good index fossils except at certain horizons in the Mesozoic and Cenozoic.

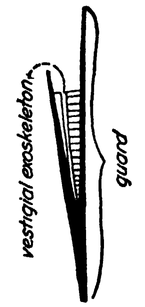
IX. **Gastropoda,** or snails, meaning stomach-footed. Mollusca with single unchambered shells composed of calcium carbonate. All shapes and types of ornamentation, frequently well-preserved. Gastropods are only important as index fossils in the **Canadian,** and at certain horizons in the Mesozoic and Cenozoic.

X. **Cephalopoda.** Meaning head-footed. Existing forms are **nautilus, cuttlefish, octopus,** etc. Shells composed either of calcium carbonate or horn, and either external or internal in relation to the living animal. The shell differs from that of the gastropods because the in-

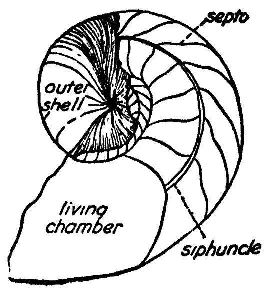


Adaptative evolution of the Nautiloids. (*After Dunbar, Organic Adaptation to Environment, Yale University Press.*) *A*, Straight form, poor swimmers; *B*, first adaptation to bottom habitat, straight, slightly flattened form; *C*, slightly coiled; *D*, partly coiled; *E*, fully coiled; *F*, coiled and involuted; *G*, second adaptation to bottom habitat. Coiled and twisted; *H-I*, decadent (gerontic) stages. Partly uncoiled. NOTE: The ammonoids also passed through a somewhat similar adaptive evolution.

terior is divided into a number of compartments by means of platforms or septa, the animal living only in the outer compartment. The cephalopods are naturally divisible into the following groups, which, because of their anatomical and stratigraphical history, make the cephalopods one of the best known paleontological examples of **Adaptive Evolution.** The forms with external shells are: 1. Nautiloids. Straight to coiled forms with smooth septa. Important as index fossils from the Cambrian to the Devonian, inclusive. 2. Goniates. Coiled forms with septa wrinkled into saddles and lobes.

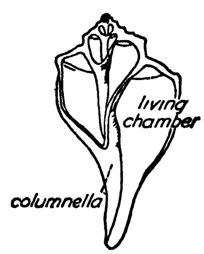


Belemnite.

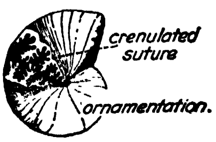


Nautilus, with outer shell broken away to show septa and siphuncle.

Goniatite, showing sutures with simple saddles and lobes.



"Conch Shell." Gastropod, cut away to show interior whorls.

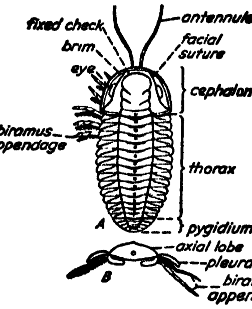


Ammonite with exterior of shell broken away to show dendritic form of sutures.

(*Field, Geology Manual, Part II, Princeton University Press.*)

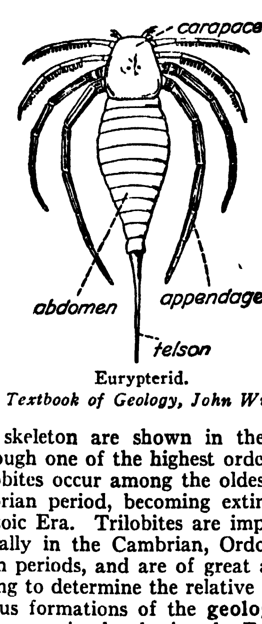
Range from the **Silurian** to the **Permian.** Important index fossils in the **Devonian.** 3. Ceratites. Similar to the goniatites except that the saddles are smooth and the lobes are wrinkled or crenulated. Range from the Devonian to the **Jurassic.** Important **index fossils** in the **Triassic.** 4. Ammonites. Similar to the ceratites except that both the saddles and lobes are highly crenulated. Range from the Upper **Pennsylvanian** to the close of the **Cretaceous.** Important index fossils. The forms with interior skeletons are divided into the **squids, cuttlefishes,** and belemnites. Only the latter are important as fossils, ranging from the Triassic to the Cretaceous, inclusive.

XI. **Arthropoda.** Meaning joint-footed. Transversely segmented animals with mouth and anus at opposite ends of an elongated body that is composed of the following fairly well-defined regions, "head" or cephalon, thorax or pleura and pygidium. A few or most of the segments bear paired appendages. Arthropods range from the Cambrian to the present, and are both fresh water and marine. The four most important subdivisions of this group, from the paleontological point of view, are the Trilobites, Ostracods, and Eurypterids. The first insects appear as fossils in the Carboniferous and several of the ancestral types of the older order appear in the Permian. The fossil insects of the **Tertiary** are particularly interesting as they prove that social life in the insect world began as long ago as the **Oligocene.** From the Paleontological point of view however the trilobites are the most interesting. 1. Trilobites. Extinct group of arthropods, or transversely segmented invertebrates with mouth and anus at the opposite ends of an



Trilobite. *A*, dorsal view; *B*, cross-section of thorax. (*Field, Outline, Barnes & Noble.*)

elongated body which is made up of a variable number of segments each of which bears a pair of appendages. The term trilobite means "three-lobed," referring to the bilateral symmetry. The major anatomical features of



Eurypterid.

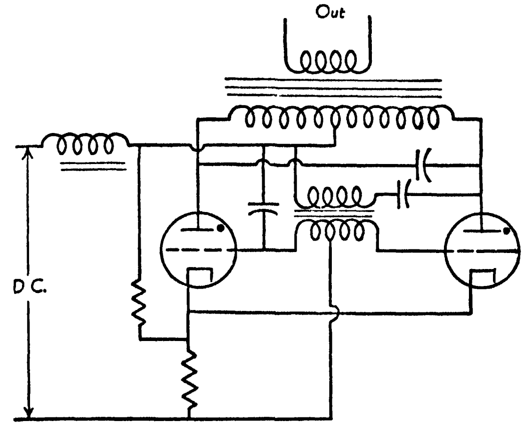
(*Schubert, Textbook of Geology, John Wiley & Sons.*)

the external skeleton are shown in the accompanying figure. Although one of the highest orders of the invertebrates, trilobites occur among the oldest known fossils of the Cambrian period, becoming extinct at the close of the Paleozoic Era. Trilobites are important as index fossils, especially in the Cambrian, Ordovician, Silurian and Devonian periods, and are of great aid to the geologist in helping to determine the relative ages of the oldest fossiliferous formations of the **geologic time-scale.** 2. Eurypterids, meaning head-winged. Extinct marine or estuarine scorpion-like arthropods, related to the horseshoe crab. Body elongated, with appendages attached to the head region only. Eurypterids also differ from the trilobites in that the former always have a regular number of appendages. The Eurypterids range from the Cambrian to the **Permian,** and are important index fossils in certain horizons of the Silurian and Devonian. (R.M.F.)

INVERTED SPEECH. **Secrecy Systems.**

INVERTER. An inverter is a device for converting d.c. into a.c. but the term is commonly employed to designate a gas-filled electron-tube circuit for performing this function. In recent years the development of reliable **thyratrons** and **ignitrons** and of inverter circuits utilizing these tubes has opened up the possibility of high voltage d-c transmission. One of the major deciding factors in the selection of a.c. for the standard electrical supply was the ease with which it could be transformed in voltage for transmission and distribution. (See Elec-

tric Power Transmission.) D-c transmission at high voltage has certain advantages over a.c. but heretofore there has been no suitable means for transforming volt-



Self-excited parallel type inverter

ages. The inverter offers the possibility of generating power as a.c., then stepping it up to the desired transmission voltage, rectifying it with high-efficiency gas-filled **rectifiers**, transmitting as high-voltage d.c. with attendant advantages, inverting it to a.c. at the receiving end and stepping down to the normal distribution voltage by using **transformers**. While the system sounds complicated, the greatly decreased losses of d-c transmission and the high efficiency of gas-filled tubes indicate that this type of transmission may offer serious competition to the established a-c system. Certain experimental systems are already in use.

A basic self-excited inverter circuit is shown. This circuit is so set up that the tubes conduct alternately, causing the d.c. to switch back and forth through the primary of the output transformer. This will induce a-c voltage in the secondary. There are numerous variations of inverter circuits but all use the tubes to switch the d-c supply back and forth to produce an a-c output. (L.R.Q.)

INVOLUTE. The locus of a point on a curve rolled along another curve termed the directrix of the involute. In gearing and in gear-tooth formation, the involute is the locus of a fixed point on a straight line rolled on a circular directrix termed the base circle of the involute. (H.C.H.)

INVOLUTION. The operation of raising numbers to powers. (L.L.S.)

INYOITE. Colemanite.

IODIC ACID AND IODATES. Iodic acid (HIO_3) is a white soluble solid. Upon heating to 110° C. forms iodic anhydride, **iodine** pentoxide (I_2O_5). A solution of iodic acid can be concentrated by evaporation up to 70% HIO_3. Iodic acid is an oxidizing agent in hot solution, smoothly converting **sulfur** to **sulfuric acid, phosphorus** to **phosphoric acid, carbon** to **carbon dixoide, silicon** to **silicic acid.**

Prepared by reaction (1) of iodine and **chloric acid** (25% $HClO_3$), (2) of iodine and **nitric acid** ("fuming") —the yield is low, but the product, upon evaporation, is pure, (3) of iodine and excess **chlorine** in water.

Potassium iodate is formed (1) by electrolysis of potassium iodide solution, with stirring, heated, and over some hours, (2) by reaction of iodine and potassium chlorate solution, (3) by allowing potassium **hypoiodite** solution to stand a few hours at ordinary temperature.

Metallic iodates are solids, moderately soluble in water, except that silver, lead, barium, thallous iodates are insoluble. Potassium hydrogen iodate ($KH(IO_3)_2$) recalls potassium hydrogen fluoride (KHF_2), an acid salt. Iodates, when heated, evolve oxygen and leave the iodide (or oxide) as residue.

Test: Upon addition of hydriodic acid (or iodide plus dilute sulfuric acid), iodate liberates iodic acid, which reacts with hydiodic acid to form iodine. (R.K.S.)

IODIDE. Iodine.

IODINE. Symbol: I. Atomic number: 53. Atomic weight: 126.92. Density: 4.94. Melting point: 113.5° C. Boiling point: 184.4° C. No isotope, but of single atomic form: 127.

Iodine is a violet to black solid, of characteristic odor, color of vapor violet, easily purified by **sublimation,** insoluble in water, soluble in alcohols, ether, **carbon disulfide, carbon tetrachloride.** Discovered by Courtois in 1812. Used (1) **in photography,** (2) in certain chemicals and **dyes,** (3) as an antiseptic solution in ethyl alcohol (3% to 7%), (4) as a reagent for testing starch, and in estimating such substances as **sulfites,** (5) in medicine, various salts of iodine are given internally in the treatment of such diseases as arteriosclerosis, hypertension, syphilis, actinomycosis, emphysema, chronic bronchitis, some forms of arthritis, and in certain thyroid disorders. When overdosage occurs, or when an idiosyncrasy is present in the patient, acne and other skin disorders may result.

Iodine occurs in the ashes of sea plants, e.g., kelp, especially California and Bay of Biscay; in the petroleum oil well brines of California; and in small percentages in sodium nitrate of Chile, which source for a long time furnished the world's supply.

Iodine is soluble (1) in carbon disulfide, in chloroform, and in carbon tetrachloride, yielding a violet solution, and upon evaporation leaves a residue of iodine crystals, (2) in ether, in ethyl alcohol, and in potassium iodide solution, yielding a brown solution. Iodine reacts (1) with **sodium** thiosulfate solution to form dithionate, (2) with **sulfurous acid** to form **sulfric acid,** (3) with **hydrosulfuric acid** to form **sulfur,** (4) with starch to form a dark blue solid.

Acids: Hydriodic acid (HI), hypoiodous acid (HOI), iodic acid (HIO_3), periodic acid (H_5IO_6 or HIO_4). (See each acid.)

Bromide: Iodine bromide (IBr).

Chlorides: Iodine chloride (ICI); iodine trichloride (ICl_3).

Fluorides: Iodine pentafluoride (IF_5).

Hydride: Hydrogen iodide (HI), colorless gas when pure (frequently contains free iodine as violet to brown gas), melting point −51° C., boiling point −35° C., very soluble in water, yielding **hydriodic acid.** Formed by reaction of red phosphorus, iodine, and water under the proper conditions.

Hypoiodite. (See **Hypoiodous Acid.**)

Iodate. (See **Iodic Acid.**)

Iodides: **Sodium** iodide (NaI), **potassium** iodide (KI), **ammonium** iodide (NH_4I) are soluble iodides; **silver** iodide (AgI), **mercurous** iodide (HgI), **mercuric** iodide (HgI_2), **lead** iodide (PbI_2) are insoluble iodides; **nitrogen** iodide ($N_2H_3I_3$). (See **Hydriodic Acid.**)

Oxides: Iodine dioxide (IO_2 or I_2O_4), pale yellow solid, formed by grinding iodine and cold fuming **nitric acid;** iodine pentoxide (I_2O_5), white solid, decomposes upon heating to 300° C. into iodine and oxygen, formed by heating iodic acid to 170° C. Reactive with, and used to detect **carbon monoxide,** with accompanying formation of iodine and carbon dioxide.

Periodate. (See **Periodic Acid.**)

Organic Iodo-Compounds:

Hydrocarbons are generally without reaction with iodine or hypoiodous acid, except under special condi-

SELECTED REPRESENTATIVE ORGANIC COMPOUNDS OF IODINE

Name	Formula	Melting Point, °C.	Boiling Point, °C.
1. Methyl iodide	CH_3I	...	45
2. Ethyl iodide	C_2H_5I	...	72
3. Normal-propyl iodide (1-iodopropane)	$C_2H_5\cdot CH_2I$	...	102
4. Iso-Propyl iodide (2-iodopropane)	$CH_3\cdot CHI\cdot CH_3$	...	89
5. Vinyl iodide (iodoethylene)	$CH_2:CHI$	...	56
6. Allyl iodide	$CH_2:CH\cdot CH_2I$	...	101
7. Benzyl iodide	$C_6H_5\cdot CH_2I$	24	93 (10 mm.)
8. Glycol iodohydrin (ethylene iodohydrin)	$CH_2I\cdot CH_2OH$	...	85 (25 mm.)
9. (Mono)iodoacetic acid	$CH_2I\cdot COOH$	82	
10. Alpha-iodopropionic acid	$CH_3\cdot CHI\cdot COOH$	45	105 (0.3 mm.)
11. Beta-iodopropionic acid	$CH_2I\cdot CH_2\cdot COOH$	82	
12. Acetyl iodide	$CH_3\cdot COI$	...	108
13. Benzoyl iodide	$C_6H_5\cdot COI$	...	135 (25 mm)
14. Cyanogen iodide	$CN\cdot I$	146 (sealed tube)	
15. Iodofurane	$C_4H_3O\cdot I(2)$	...	
16. Iodobenzene (phenyl iodide)	C_6H_5I	...	189
17. Ortho-iodotoluene (1,2-)	$C_6H_4(I)(2)(CH_3)(1)$	...	211
18. Meta-iodotoluene (1,3-)	$C_6H_4(I)(3)(CH_3)(1)$	...	204
19. Para-iodotoluene (1,4-)	$C_6H_4(I)(4)(CH_3)(1)$	35	211
20. Alpha-iodonaphthalene	$C_{10}H_7\cdot I(1)$	...	305
21. Beta-iodonaphthalene	$C_{10}H_7\cdot I(2)$	54	309
22. Ortho-iodophenol (1,2-)	$C_6H_4(I)(2)(OH)(1)$	40	186 (160 mm.)
23. Meta-iodophenol (1,3-)	$C_6H_4(I)(3)(OH)(1)$	40	decom.
24. Para-iodophenol (1,4-)	$C_6H_4(I)(4)(OH)(1)$	93	decom.
25. Ortho-iodoaniline (1,2-)	$C_6H_4(I)(2)(NH_2)(1)$	60	
26. Meta-iodoaniline (1,3-)	$C_6H_4(I)(3)(NH_2)(1)$	33	
27. Para-iodoaniline (1,4-)	$C_6H_4(I)(4)(NH_2)(1)$	67	
28. Ortho-iodonitrobenzene (1,2-)	$C_6H_4(I)(2)(NO_2)(1)$	53	
29. Meta-iodonitrobenzene (1,3-)	$C_6H_4(I)(3)(NO_2)(1)$	37	
30. Para-iodonitrobenzene (1,4-)	$C_6H_4(I)(4)(NO_2)(1)$	171	
31. Ortho-iodobenzoic acid (1,2-)	$C_6H_4(I)(2)(COOH)(1)$	162	
32. Meta-iodobenzoic acid (1,3-)	$C_6H_4(I)(3)(COOH)(2)$	187	
33. Para-iodobenzoic acid (1,4-)	$C_6H_4(I)(3)(COOH)(3)$	269	
34. Iodoso benzene	C_6H_5IO	210 (expl.)	
35. Iodoxy benzene	$C_6H_5IO_2$	236 (expl.)	
36. Methylene iodide	CH_2I_2		180
37. Ethylene iodide (1,2-diiodoethane)	$CH_2I\cdot CH_2I$	81	
38. Ethylidene iodide (1,1-diiodoethane)	$CH_3\cdot CHI_2$	...	178
39. Diiodoacetic acid	$CHI_2\cdot COOH$	110	
40. Ortho-diiodobenzene (1,2-)	$C_6H_4I_2(1,2)$	27	286
41. Meta-diiodobenzene (1,3-)	$C_6H_4I_2(1,3)$	40	285
42. Para-diiodobenzene (1,4-)	$C_6H_4I_2(1,4)$	129	285
43. Diphenyl iodonium iodide	$(C_6H_5)_2I\cdot I$	182	
44. Iodoform	CHI_3	119 (subl.)	
45. Methyl iodoform (1,1,1-triiodoethane)	$CH_3\cdot CI_3$	93 (decom.)	
46. Benzotriiodide (phenyl iodoform)	$C_6H_5\cdot CI_3$		
47. Triiodoacetic acid	$CI_3\cdot COOH$	150 (decom.)	
48. Carbon tetraiodide	CI_4	decom.	
49. Tetraiodoethylene	$CI_2:CI_2$	190	
50. Hexaiodoethane (ε)	$CI_3\cdot CI_3$		
51. Hexaiodobenzene	C_6I_6	340 (decom.)	

tions, but olefins react readily with hydrogen iodide by addition, to form, for example, ethyl iodide (CH_3CH_2I) from **ethylene**.

Oxygen-function compounds, e.g., **ethyl alcohol, acetaldehyde, acetic acid,** react with **phosphorus** iodide to form corresponding oxygen-function iodides, e.g., ethyl iodide (C_2H_5I), ethylidene diiodide ($CH_3 CHI_2$), acetyl iodide (CH_3COI).

Iodoform is made by reaction of **acetone or ethyl alcohol** with sodium **hypoiodite.**

Use is made of the diazo-reaction (see **Azo- and Related Compounds**) to introduce iodine into benzenoid compounds. Iodine-substituted carboxylic acids are made by heating the selected chloro or bromo acid, with potassium iodide, e.g., monochloroacetic acid yields monoiodoacetic acid (potassium chloride is formed). Many of the iodo-compounds are used as reagents or as intermediate compounds in organic chemistry. When paraffin iodo-compounds are treated with sodium hydroxide dissolved in alcohol, hydrogen iodide is removed, e.g., ethyl iodide (CH_3CH_2I) yields ethylene ($CH_2:CH_2$). (R.K.S.)

IODINE NUMBER. Esters.

IODOFORM. A yellow, insoluble, crystalline powder (for its chemical properties, see **Iodine**) with a very penetrating and disagreeable odor. It is antiseptic in action, but only when in direct contact with raw surfaces. It is used in infected cavities and abscesses which are packed with gauze saturated with the powder. In certain susceptible subjects toxic symptoms may result. (R.S.M.)

IOLITE. Cordierite.

ION. **Reactions Involving Recombinations of Ions; Ionized Gases.**

ION COUNTER. **Counting Tube.**

IONIC THEORY. **Reactions Involving Recombination of Ions.**

IONIUM. Symbol: Io. A radioactive element of the uranium-radium series. (See **Radioactive Changes.**) (R.K.S.)

IONIZATION CONSTANT. **Reactions Involving Recombination of Ions; Acids, Carboxylic; Amines.**

IONIZATION CHAMBER. The term applies to a variety of enclosures used in the study of **ionized gases** or of ionizing agencies. The essential features are a closed vessel containing a gas at normal or altered pressure, and furnished with two electrodes kept at different potentials. These may be in the form of parallel plates or of coaxial cylinders, or one of them may be the vessel itself with the other inside and insulated from it. When the gas between the electrodes is ionized by any means, as by **x-rays** or **radioactive** emission, the ions move to the electrodes of opposite sign, thus creating an ionization current which may be measured by a **galvanometer** or an **electrometer.** If, when ions are being produced at a fixed rate, the potential difference between the electrodes is gradually increased, a point is reached at which further increase of voltage causes no increase in current, because the ions are removed as fast as they are formed. This limiting current is called the saturation current, and its value may be used as a measure of the rate of ionization and hence of the intensity of the ionizing radiation. (See also **Counting Tube.**) (L.D.W.)

IONIZED GASES. Various agencies, such as fast-moving **electrons, alpha particles,** various forms of **radiation,** and high temperature, are capable of dislodging electrons from **atoms** or **molecules** of a gas and thereby leaving them positively charged. Some of the dislodged electrons may attach themselves to other molecules and render them negatively charged. In some cases two or more electrons may be removed from the same molecule, or a molecule with a double positive charge may unite with a singly charged negative molecule, forming a singly charged complex, etc. Such charged atoms, molecules or molecular groups are called ions, and their production from neutral molecules is called ionization. The complete separation of an electron from a molecule or an atom requires a definite amount of energy. This may be expressed in **ergs,** but is more commonly given in **electron volts** (1.59×10^{-12} erg), its value being the "ionizing potential." A less amount of energy may excite the atom or molecule to emit radiation, but will not ionize it.

If an ionized gas is left to itself, the ions soon recombine and become neutral. But if it is subjected to an electric field, as in an **ionization chamber,** the ions pass to the electrodes, such a migration being an "ionization current." Such currents, commonly called electric discharges, are attended by diverse phenomena and vary widely in character from the silent glow discharge to the **lightning** stroke.

At ordinary pressures, discharges may be classified into four types. (1) If the voltage between two electrodes in open air is gradually increased, the electrodes become surrounded with a luminosity. This "glow" or "corona" gives way, at the negative electrode first, to (2), a "brush," composed of hair-like branches. (3) Finally the disruptive **spark** passes. (4) Under other conditions an arc may be formed. If, however, the electrodes are enclosed in a tube and the pressure reduced, a point is reached at which the tube becomes filled with a beautiful luminosity. Close examination shows this to have structure. Very close to and surrounding the cathode is a thin, luminous layer *c*, the cathode glow (see figure);

and outside this, the Crookes dark space *C*. Next, extending toward the anode, is the short negative glow *n*, then the Faraday dark space *F*. From this to the anode extends the long positive column *p*, with its regular, transverse striations. As the pressure is further reduced, the cathode dark space enlarges and the other features dwindle toward the electrodes until they finally disappear at about 0.001 mm. pressure. From this point on, the **cathode rays** are the predominant feature.

Upon exploring the discharge in a Crookes tube with suitable probes, it is found that in certain regions the positive and negative ions are so nearly equal in number as to neutralize each other's effect. Such a region is called a "plasma." The plasma may be surrounded by a "sheath" of ionized gas in which ions of one sign greatly predominate, the effect being that of a **space charge.** (See also **Anode Rays, Canal Rays, Cloud Chamber, Cosmic Rays, Counting Tube, Crookes Tube, Electrodeless Discharge, Geissler Tube, Vacuum Tube.**) (L.D.W.)

IONIZING POTENTIAL. **Ionized Gases.**

IONOSPHERE. A layer of ionized air high above the earth's surface, the existence of which was surmised by Heaviside and verified later by Kennelly. It is also called the Kennelly-Heaviside layer. Its importance in the transmission of radio signals is now well recognized. Waves from a transmitting station *T*, proceeding obliquely upward and encountering this layer, are deflected (reflected or refracted) downward, so that a distant receiving station *R* may receive waves from *T* either by the direct path along the surface or over the longer route via the ionosphere. Were it not for this layer, much more of the energy emitted from the transmitter would escape into space.

The height of the ionosphere has been ascertained by measuring the time interval between an emitted signal and its "echo." It appears to be composed of at least three layers, E, F_1, F_2, at heights varying from 40–50 to 175 or 200 miles. The two higher layers together constitute the Appleton or *F* layer, the name Kennelly-Heaviside being now usually applied to the lowest, or *E* layer. There is reason to believe that the ionization is produced largely by sunlight, especially by the absorbed ultraviolet radiation. The ionosphere generally recedes at night, sometimes apparently to the region outside the earth's shadow, and approaches the earth during the daylight hours. (See **Atmosphere.**)

Interference between waves reaching the receiver by different routes, that is, after different numbers of reflections by ionosphere and ground, gives rise to the troublesome phenomenon of radio **"fading."** (L.D.W.)

IPECAC. (Ipecacuanha) the root of *Cephaëles ipecacuanha* from Brazil. (See **Madder Family.**) It is an irritant and promotes secretion, especially of the skin and respiratory tract. It is used as an expectorant in respiratory infections. In larger doses it is an **emetic.** (R.S.M.)

IRIDIUM. Symbol: Ir. Atomic number: 77. Atomic weight: 193.1. Density: 22.42. Hardness: 6.0–6.5. Melting point: 2350° C. **Isotopes:** page 290.

Compact iridium is a white, very hard metal, and is not attacked by acids. Discovered by Tennant in 1804. Iridium metal is used chiefly as an alloy with platinum,

which latter metal is thereby hardened. Standard measures and weights are made of such an alloy (10% Ir), also pen points, and parts of scientific apparatus and surgical tools.

Iridium occurs native with platinum, and with **osmium** as osmiridium (50%–75% Ir). When osmium is present it is removed as volatile osmium tetroxide, and the residue is converted into soluble chlorides by chlorine. From the resulting solution ammonium iridium chloride ($(NH_4)_2IrCl_6$) is precipitated, and then ignited and fused to obtain iridium metal.

Chloroiridate: Ammonium chloroiridate ($(NH_4)_2IrCl_6$) is insoluble in alcohol.

Hydroxide: Iridium hydroxide ($Ir(OH)_4$), dark blue precipitate, by excess of **sodium** hydroxide solution, and boiling. (R.K.S.)

IRIDOSMINE. A mineral alloy of iridium and osmium in the platinum group. (R.M.F.)

IRIS. The pigmented structure in front of the lens of the **eye**. It is contracted and expanded by muscular action so that the opening in its center, known as the pupil, varies in size according to the brightness of the light. By this means the quantity of light that reaches the sensitive retina is regulated. An iris occurs in **molluscan** and **vertebrate** eyes. In the **insect** eye a group of iris cells shut out light except from the direction of the lenticular cornea. Also a plant. (A.W.L.)

IRON. Symbol: Fe (ferrum). Atomic number: 26. Atomic weight: 55.85. Density: 7.86. Hardness: 4–5 (iron), 5–8.5 (steel). Melting point: 1535° C. Boiling point: 3000° C. (**Isotopes**: page 290.)

Iron is a silver-white metal, capable of taking a high polish, ductile, malleable; can be welded when hot; pure iron is attracted by a magnet but does not retain the **magnetism** (silicon steel is preferred for **electromagnets** because it retains magnetism even less than pure iron). Discovery prehistoric.

Iron is seldom encountered as a "chemically pure" metal, but usually as steel (ordinary, with **carbon** as the essential alloying element; special, with various elements); iron is the most largely used of the metals, and considerable scrap metal is recovered. Steel is used in construction of machines and apparatus where workability is required, and definite resistance to corrosion is supplied by the metal. The metal is at times protected (1) by depositing a surface layer of metal, e.g., **tin, zinc, lead, chromium, nickel, aluminum,** (2) by formation of a chemical surface layer, such as the black oxide of iron, or the phosphate, (3) by painting the surface, (4) by applying oil or grease. Commercially pure iron is satisfactory for galvanized sheet, for porcelain enameling sheet, and for direct current electromagnets.

Iron occurs abundantly as oxide, **magnetite** (ferroferric oxide, triiron tetroxide, Fe_3O_4), black, **hematite** (ferric oxide, Fe_2O_3), red, **limonite** (hydrated ferric oxide) yellow to brown; as carbonate, **siderite** (ferrous carbonate, $FeCO_3$), colorless to pale brown; as sulfides, **pyrite** (iron disulfide, FeS_2), brass colored, **arsenopyrite** (iron sulfoarsenide, FeAsS), and as **aluminosilicates** in most rocks, evidenced by green coloration of ferrous, by yellow to red to brown of ferric, and by black of ferroferric. The element iron is fourth in abundance of the elements of the earth's crust (5.1% of the solid crust) and is responsible for practically all of the coloration of ordinary rocks. Native iron is rarely found except in **meteorites**. In the United States about 85% of the iron ore mined comes from the Lake Superior region of Minnesota and Michigan, and, in the south, Alabama is a producing state. The ore is at present commercially usable when somewhat above 50% Fe content. The industrial nations (Britain, France, Germany, U.S.S.R., Japan, the United States) are the great consumers of iron and steel. The oxide is smelted in a **blast furnace** with **carbon** (coke) and **flux (limestone)** at a high temperature. In operation, all products are withdrawn as liquid or gas, the heavier liquid iron settles beneath the lighter liquid **slag**, and each is drawn off separately. The iron is cast into cast iron bars or treated immediately in a furnace for the removal of impurities, such as carbon, **silicon, sulfur, phosphorus,** then the desired additions, such as carbon, **manganese**, are made, and the resulting steel is fabricated.

Four allotropic forms of iron are known, namely, (1) alpha-iron below 769° C., (2) beta-iron between 769° C. and 906° C., (3) gamma-iron between 906° C. and 1404° C., (4) delta-iron between 1404° C. and 1535° C.; the properties of iron are markedly affected by the addition of other elements, notably carbon, silicon, sulfur, phosphorus, manganese in steel, and **chromium, manganese, nickel, molybdenum, tungsten, vanadium** in special steels. Iron is scarcely attacked in dry air, but is rapidly corroded in moist air at ordinary temperatures, forming iron rust, hydrated ferric oxide; burns when heated in air to form ferroferric oxide; reacts with steam at a red heat to form ferroferric oxide plus hydrogen gas; dissolves in **hydrochloric** or dilute **sulfuric acid**, forming ferrous salt solution and **hydrogen gas**, dissolves in hot concentrated sulfuric or in cold dilute **nitric acid**, forming ferric salt solution; no reaction (passive) with cold concentrated nitric; no reaction with alkalis, except hot solutions of high concentration.

Acetate: Ferrous acetate "iron liquor" ($Fe(C_2H_3O_2)_2 \cdot 4H_2O$), prepared as an industrial chemical—a black solution—by reaction of scrap iron and pyroligneous acid (see **acetic acid**), and then evaporation. Used as a mordant in dyeing; ferric acetate ($Fe(C_2H_3O_2)_3$), formed by the reaction of iron and acetic acid and oxygen of the air, and then **crystallization**. Used in textile and leather dyeing, as a wood preservative, and in medicine; basic ferric acetate formed as a precipitate upon boiling ferric acetate solution.

Bromides: Ferrous bromide ($FeBr_2$), green solid, soluble, formed by reaction of iron and **hydrobromic acid**, and then evaporating out of contact with air; ferric bromide ($FeBr_3 \cdot 6H_2O$), red solid, soluble, formed by reaction of ferrous bromide solution and **bromide**, and then evaporation; ferric bromide anhydrous ($FeBr_3$), red solid, formed by reaction of iron and dry bromine upon heating.

Carbide: Iron carbide, cementite (Fe_3C), black hard solid, melting point 1837° C., formed by reaction of iron and carbon at high temperature, an important component of steels.

Carbonate: Ferrous carbonate ($FeCO_3$), white precipitate, when pure, but soon changes to green in air, then to black ferroferric hydroxide, and then to red ferric hydroxide, formed by reaction of soluble ferrous salt solution and **sodium** carbonate solution.

Carbonyl: Iron tetracarbonyl ($Fe(CO)_4$), gas, formed by reaction of iron and **carbon monoxide** at 80° C., burns with a yellow flame; iron pentacarbonyl ($Fe(CO)_5$), yellow liquid, boiling point 103° C., formed by reaction of finely divided iron and carbon monoxide at ordinary temperatures, is decomposed by light.

Chloride: Ferrous chloride ($FeCl_2 \cdot 4H_2O$), greenish solid, soluble, formed by reaction of iron and **hydrochloric acid**, and then evaporation out of contact with air; ferric chloride ($FeCl_3 \cdot 6H_2O$), reddish-yellow solid, soluble, formed by reaction of ferrous chloride solution and **chlorine**, and then evaporation, used in photography and as an oxidizing agent; ferric chloride anhydrous ($FeCl_3$), red solid, formed by reaction of iron and dry chlorine upon heating. Used as a reagent in organic chemistry; ferroferric chloride ($FeCl_2 \cdot 2FeCl_3 \cdot 18H_2O$), yellow solid, soluble; ferric ammonuium chloride ($FeCl_3 \cdot NH_4Cl$), orange solid, soluble.

Citrate: Ferric citrate ($Fe(C_6H_5O_7)_3 \cdot 3H_2O$), reddish-brown solid, soluble, formed by reaction of ferric hydrox-

ide and citric acid, and then evaporation. Used in preparing **blue print** paper; ferric ammonium citrate, brown solid, soluble. Used in preparing blue print paper.

Ferrate: Sodium ferrate (Na_2FeO_4), purple solution, formed (1) by fusing **sodium** nitrate and finely divided iron, and then extracting with water, (2) by reaction of ferric hydroxide suspension in concentrated **sodium** hydroxide and addition of **chlorine** in excess.

Ferrites: By fusion of ferrous oxide with the appropriate basic oxide, hydroxide or carbonate, e.g., calcium ferrite ($Ca(FeO_2)_2$), barium ferrite ($Ba(FeO_2)_2$), magnesium ferrite ($Mg(FeO_2)_2$), ferrous ferrite ($Fe(FeO_2)_2$), sodium ferrite ($NaFeO_2$).

Ferricyanides: Potassium ferricyanide, red prussiate of potash ($K_3Fe(CN)_6$, red crystals, soluble to reddish-brown solution, formed by reaction of potassium **ferrocyanide** solution and an oxidizing agent such as chlorine, and then crystallizing; ferrous ferricyanide, "Turnbull's blue" ($Fe_3(Fe(CN)_6)_2$) blue precipitate by reaction of ferrous salt solution and potassium **ferricyanide** solution, unattacked by acids, but blue color destroyed by alkalis. Used as a pigment.

Ferrocyanides: Sodium ferrocyanide, yellow prussiate of soda ($Na_4Fe(CN)_6 \cdot 10H_2O$) and potassium ferrocyanide, yellow prussiate of potash ($K_4Fe(CN)_6 \cdot 3H_2O$) are yellow solids, soluble, formed by treating "spent oxide" of coal gas works with **calcium** hydroxide to extract the ferrous cyanide as soluble calcium ferrocyanide, and converting, with **sodium** or **potassium** carbonate, into the respective ferrocyanide. Used (1) in the preparation of other ferrocyanides (e.g., ferric ferrocyanide), and of ferricyanides, (2) in blue print paper, (3) in tanning; ferric ferrocyanide, "Prussian blue" $Fe_4(Fe(CN)_6)_3$ blue precipitate formed by reaction of ferric salt solution and sodium ferrocyanide solution, unattacked by acids, but blue color destroyed by alkalis. Used as a pigment.

Hydroxides: Ferrous hydroxide ($Fe(OH)_2$), white precipitate, when pure, but soon changes in air to ferroferric hydroxide and then to ferric hydroxide, formed by reaction of soluble ferrous salt solution and **sodium** or **ammonium** hydroxide solution, soluble in acids, insoluble in alkalis; ferroferric hydroxide ($Fe(OH)_2 \cdot 2Fe(OH)_3$), black precipitate, soon changes in air to ferric hydroxide, formed by reaction of mixture of soluble ferrous and ferric salt solution and **sodium** or **ammonium** hydroxide solution; ferric hydroxide ($Fe(OH)_3$), reddish-brown gelatinous precipitate, formed by reaction of soluble ferric salt solution and sodium or ammonium hydroxide solution, soluble in acids, insoluble in alkalis.

Iodide: Ferrous iodide ($FeI_2 \cdot 4H_2O$), grayish-black solid, soluble, formed (1) in solution by reaction of soluble ferric salt solution and **potassium** iodide solution, with accompanying separation of iodine, (2) by reaction of **iron** and **iodine**.

Nitrate: Ferrous nitrate ($Fe(NO_3)_2 \cdot 6H_2O$), greenish solid, soluble, unstable, formed (1) by reaction of ferrous hydroxide or carbonate and dilute **nitric acid**, (2) by **barium** nitrate and ferrous sulfate solutions, filtration, and then evaporation at low temperature out of contact with air; ferric nitrate ($Fe(NO_3)_3$), violet solid, soluble, formed by reaction of iron metal, or ferric oxide, and dilute nitric acid, and then crystallization. Solution is colorless when freshly prepared in excess of nitric acid.

Oxalate: Ferrous oxalate ($FeC_2O_4 \cdot 2H_2O$), yellow precipitate, formed by reaction of soluble ferrous salt solution and **ammonium** oxalate solution, yields ferrous oxide on heating at 160° C. out of contact with air; ferric oxalate ($Fe_2(C_2O_4)_3$), greenish solid, soluble, formed by reaction of ferric hydroxide and **oxalic acid**, and then crystallization; ferrous potassium oxalate ($Fe(C_2O_4)_2 \cdot K_2C_2O_4 \cdot 2H_2O$), yellow solid, soluble; ferric potassium oxalate ($K_3Fe(C_2O_4)_3 \cdot 3H_2O$); ferric ammonium oxalate ($(NH_4)_3Fe(C_2O_4)_3 \cdot 3H_2O$), green solid, soluble.

Oxides: Ferrous oxide (FeO), black solid, insoluble, formed (1) by heating ferrous oxalate at 160° C. out of contact with air, (2) by heating ferric oxide or ferroferric oxide and **hydrogen** gas at 300° C., (3) by heating iron metal and steam above 570° C., soluble in hydrochloric or dilute **sulfuric acid** to ferrous salt; ferroferric oxide, black oxide of iron, **magnetite**, "iron scale," (Fe_3O_4), black solid, insoluble, formed (1) by heating iron metal, ferrous or ferric oxide in air, (2) by heating iron and steam below 570° C., believed to be ferrous ferrite ($Fe(FeO_2)_2$); ferric oxide, red oxide of iron, **hematite** (Fe_2O_3), red solid, insoluble, formed by heating ferric hydroxide or nitrate to a high temperature. The mineral is the important source of iron, and when pulverized is used as a paint pigment, various naturally occurring hydrated forms serve as brown or yellow pigments—umbers and siennas from **limonite**.

Perferrates: Sodium perferrate (Na_2FeO_4), formed (1) by fusing **sodium** peroxide and ferric hydroxide, (2) by heating finely divided iron, ferrous oxide, or ferric oxide in **sodium** nitrate to a red heat; barium perferrate ($BaFeO_4$) precipitate, formed by reaction of sodium perferrate solution and barium chloride solution.

Sulfates: Ferrous sulfate, green vitriol, "copperas" ($FeSO_4 \cdot 7H_2O$), green solid, soluble, formed by reaction of iron and dilute **sulfuric acid** and then crystallizing. Obtained as a by-product in the cleaning or "pickling" of steel. Used widely (1) as a source of ferrous compounds, and of ferric compounds by easy oxidation. (2) as a disinfectant, water purifier, wood preservative, weed exterminator, (3) in the preparation of inks, pigments, medicines, (4) in the purification of coal gas, (5) in the textile and leather industries; ferrous ammonium sulfate, "Mohr's salt" ($FeSO_4 \cdot (NH_4)_2SO_4 \cdot 6H_2O$), green solid, soluble, more easily purified, more stable than ferrous sulfate; ferric sulfate ($Fe_2(SO_4)_3$), brownish solid, soluble, formed (1) by reaction of ferric hydroxide and sulfuric acid, and then evaporation, (2) by reaction of iron and hot concentrated sulfuric acid, (3) in solution by reaction of **chlorine** and ferrous sulfate in acid solutions. Used (1) to prepare iron alum, (2) in water purification as basic ferric sulfate, ferric "persulfate" or "subsulfate," yellow solid, soluble, (3) in medicine; ferric ammonium sulfate "iron alum" ($Fe_2(SO_4)_3 \cdot (NH_4)_2SO_4 \cdot 24H_2O$), violet solid, soluble, more easily purified than ferric sulfate.

Sulfides: Ferrous sulfide (FeS), black precipitate, formed by reaction of soluble ferrous salt solution and **sodium** or **ammonium** sulfide, soluble in acids, also formed by heating finely divided **iron** and **sulfur**, reacts with dilute **hydrochloric** or **sulfuric acid** to yield ferrous salt and hydrogen sulfide; iron disulfide, pyrite (FeS_2), brass-colored mineral, when heated in air yields ferric oxide plus **sulfur dioxide** gas; ferric sulfide (Fe_2S_3), black precipitate, formed by reaction of soluble ferric salt solution and sodium or ammonium sulfide.

Sulfite: Ferric sulfite ($Fe_2(SO_3)_3$), red solution, by reaction of soluble ferric salt solution and **sodium** hydrogen sulfite solution, is unstable, quickly forming ferrous sulfite and dithionate.

Thiocyanate: Ferric thiocyanate ($Fe(CNS)_3$), red solution, by reaction of soluble ferric salt solution and ammonium **thiocyanate** solution. Used as a delicate test for ferric (1 part ferric in solution in 1,500,000 parts of water may be detected), more soluble in ether than in water and easily concentrated in the ether layer by mixing.

Ferrous salts are generally green, sometimes yellow to brown by slight oxidation, and in solution are generally green, but are quickly oxidized in part by air to ferric, brownish. Ferrous is chemically related to zinc, cobaltous, nickelous, manganous, magnesium. Ferroferric compounds are black. Ferric salts are generally violet to brown, sometimes orange or greenish, and in solution generally red and on boiling yield red precipitate of basic salt or ferric hydroxide; ferric hydroxide, in various partially dehydrated forms in nature, is brown to yellow. Ferric is chemically related to chromic, aluminum. (R.K.S.)

IRON AGE. Paleontology of Man.

IRRADIATION. 1. Exposure to **x-rays, radium,** or other forms of radioactivity. 2. Exposure to **ultraviolet** rays to increase the **vitamin D** content of a substance. (D.M.H.)

IRRATIONAL EQUATIONS. Radical Equations.

IRRATIONAL FUNCTION. An irrational function is an **algebraic function** which is not a **rational function**; it therefore involves one or more root-extractions involving the variable. (L.L.S.)

IRRATIONAL NUMBERS. Number.

IRRATIONAL ROOTS OF POLYNOMIAL EQUATIONS. Polynomial Equations.

IRREGULAR VARIABLES. There are many **variable stars** which vary in brightness in such non-systematic manner as to be best designated as irregular variables. In some cases their manner of variation and spectral class is so similar to that of the **long period variables** that they are classed as members of this class of stars by some authorities. Notable among stars of this type are the bright stars **α Orionis** and **α Herculis,** both of which are **giant** red stars.

There are certain groups of irregular variables which have enough characteristics in common that they may be considered as groups. Such groups are usually designated by some typical star of the group. The RV Tauri group resemble to some extent the **Cepheids** although their periods, of the order of magnitude of 75 days, is far too long to permit their inclusion in the true Cepheid class. These stars are of G and K **spectral classes** and their light curves are characterized by shallow minima coming between two deep ones. A few stars of the R Coronae Borealis type remain, often for several years, practically constant in brightness and then drop suddenly one or two magnitudes, returning to normal brightness after a few oscillations.

The problem of the irregular variables is at present the subject of a great deal of research and observation, but to date there is no adequate explanation of their variability. (W.K.G.)

IRRITABILITY. A fundamental property of living matter which enables it to be stimulated by external factors. Although the simplest forms of living things are capable of receiving stimuli from various environmental factors such as light, mechanical contacts, and chemical compounds, the property is most highly developed in animals with a complex nervous system. The **sense organs** of such animals show a high degree of specialization and diversification of this property. (A.W.L.)

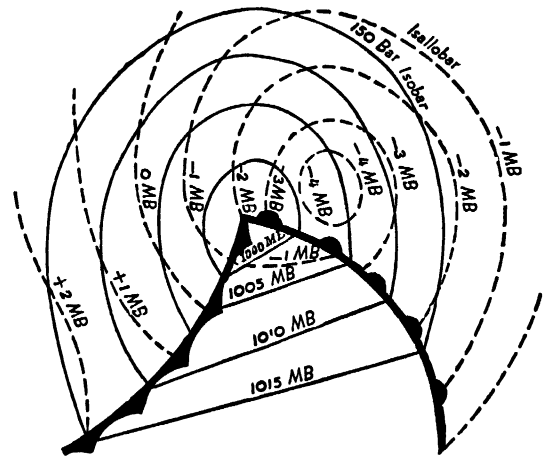
IRROTATIONAL VECTOR. If the **curl** of a **vector function** of position vanishes everywhere in a certain region, the function is said to be an irrotational vector (or a lamellar vector) in this region.

If a given vector function **v** is the **gradient** of a scalar function ϕ, then **v** is irrotational. (L.L.S.)

ISACOUSTS. Lines of equal sound of an **earthquake.** (R.M.F.)

ISALLOBARS AND ISALLOBARIC FIELDS. Atmospheric pressure changes at every point in the atmosphere from time to time. It is possible to measure such changes with considerable accuracy. The unit used to express pressure change (or pressure tendency) is conventionally the total net change occurring in a 3-hour interval. It is customary to indicate the nature of the change because the pressure change character may have varied during the selected time interval.

Three-hourly pressure changes are plotted on a synoptic chart (weather map) and lines drawn to join points of equal pressure change. Care is exercised, however,



Isallobars in isallobaric field of wave cyclone.

in noting the character of the change in judging the real value of Δp. Lines joining points of equal pressure change are isallobars. Isallobars taken together constitute an isallobaric field. Where there is present an isallobaric field superimposed on a pressure field, a component of the actual wind blows along the isallobaric gradient which is directed perpendicular to the isallobars toward regions of greatest pressure fall or least pressure rise, as the case may be. Normally the isallobaric wind component is small unless the isallobaric field is pronounced When there is no isallobaric field, the wind is defined approximately by the orientation and spacing of isobars themselves. Isallobaric fields also are used to compute the movement of pressure centers, wedges, troughs, cols, fronts, and isobars. Centers of low pressure will tend to move toward the region of greatest pressure fall, whereas centers of high pressure tend to move toward regions of maximum pressure rise. Both cases have modifying factors and the direction is not always exactly as would be expected from a casual glance. In all cases of computation of movement, it is necessary to know the isallobaric field, the pressure field, and the orientation of the system whose movement is to be computed.

In establishing an isallobaric field it is imperative that the diurnal pressure change be accounted for and a correction applied. Diurnal pressure changes do affect movement of pressure systems, but the effect is transient and therefore must be neglected in any study extending for more than 6 hours into the future.

In general, isallobars and isallobaric fields are as useful in weather forecasting as the pressure field itself. (P.E.K.)

ISINGLASS. Mica.

ISCHIOPODITE. Biramous appendage.

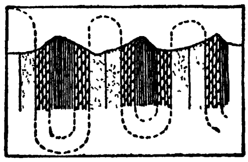
ISCHIUM. Skeletal System.

ISOBARS. Lines joining points of equal pressure. The field of isobars is known as an isobaric field. Isobaric fields are of prime importance in determining winds and weather. (P.E.K.)

ISOBASE. In geology, a **contour line** which intimates the former equal elevation of a series of **points,** or level surface, now deformed. (R.M.F.)

ISOBATH. Meaning equal depth. 1. A line on a land surface all points on which are the same vertical distance above the ground water table. 2. A **structural contour** or **isopach.** (R.M.F.)

ISOCLINE. Vertical duplication of formations by close folding, as illustrated in the accompanying diagram. (R.M.F.)



Isoclinal folds.

ISOCYANATES. Cyanic Acid and Cyanates.

ISOCYANIDES. Hydrocyanic Acid and Cyanides.

ISOELECTRIC POINT. In solutions of proteins and related compounds, the **hydrogen ion** concentration at which the dipolar **ions** are at a maximum is the isoelectric point. At this point the solution shows minimum **conductivity, osmotic pressure,** and **viscosity.** At this pH the protein shows the least swelling with water and does not undergo cataphoresis. That is, the colloidal particles move toward neither electrode. Proteins coagulate best and contain the least amount of inorganic matter at their isoelectric points. (See also **Aminoacids, Polypeptides, and Proteins.**)

ISOELECTRIC POINTS

SUBSTANCE	ISOELECTRIC POINT (pH)
Proteins:	
Glutenin	4.5
Gelatin	4.7
Egg albumin	4.8
Serum albumin	5.4
Edestin	5.7
Oxyhemoglobin	6.8
Gliadin	9.2
Clupeine	12.1
Dipeptides:	
Glycylglycine	5.5
Alanyl glycine	5.5
Leucyl glycine	5.7
Aminoacids:	
Glycine	6.6
Alanine	6.7
Leucine	6.5

(R.K.S.)

ISOGAMY. A type of sexual **reproduction** in which the male and female **germ cells** are similar in form. (A.W.L.)

ISOGEOTHERM. Depths of equal temperature in the earth. (R.M.F.)

ISOGONIC CHART. A chart showing lines of equal magnetic declination, or lines on which the variation of the magnetic needle from true north is the same. (See also **Agonic Line.**) (R.M.F.)

ISOGONIC LINE. Compass Corrections.

ISOLATION. A principle of organic **evolution.** Animals separated from the remainder of their kind are supposed to have a characteristic heritage which determines the nature of their descendants. This foundation may differ from that of the rest of the species and so may give rise in time to a different variety or species as a result of the isolation, independent of the adaptive value of the heritage.

Isolation may be geographic or biological. The Galapagos Islands offer famous examples of geographic isolation. They are regarded as the remnants of a once continuous land mass and are now inhabited by distinct varieties of birds of several species. These varieties are characteristic of certain islands and do not pass from one to the other, hence they are interpreted as the descendants of birds which remained on the islands when they were first formed.

Biological isolation may be due to cytological incompatibility, physical differences or to time of reproductive activity. Some varieties of dogs, for example, are physically incapable of interbreeding although they belong to the same species. Time is a decisive factor in interbreeding among the insects, especially in species whose adult life is short. If some individuals emerge early and others late in the normal season, those of the two groups have little or no chance to interbreed. The result is that any distinctive characters of the two are likely to be perpetuated in different strains. (A.W.L.)

ISOLEUCINE. Aminoacids, Polypeptides, and Proteins.

ISOMAGNETIC. Lines of equal magnetic force, but not necessarily **isogonic.** Isomagnetic lines may represent local magnetic anomalies such as caused by magnetic ore bodies, magnetic minerals in sediments, or the vertical rather than the horizontal deviation of the compass or magnetic needle. (R.M.F.)

ISOMERISM AND STEREOISOMERISM. Two substances are said to be isomeric when they possess the same ordinary molecular **formula** and different properties. A simple instance is that of C_3H_8O, which represents two propyl **alcohols,** one (A) of boiling point 98° C. and density 0.804, the other (B) of boiling point 82° C. and density 0.789. These two alcohols differ in other properties including their chemical behavior It is believed that the difference is due to the arrangement of **atoms** in each **molecule,** thus:

```
     H  H  H
(A) HC—C—COH, propanol 1, ethylcarbinol, normal-propyl
     3  2  1
     H  H  H               alcohol, C2H5CH2OH

     H  H  H
(B) CH—C—CH, propanol 2, dimethylcarbinol, iso-propyl
     3  2  1
     H OH  H               alcohol, (CH3)2CHOH
```

Therefore, the ordinary molecular formula, C_3H_8O, represents two different isomeric substances; $C_2H_5\cdot CH_2OH$ and $(CH_3)_2CHOH$ are isomers; and the phenomenon displayed by these is known as isomerism.

The ordinary molecular formula, C_4H_{10}, corresponds to two butanes, namely, normal-butane, $CH_3CH_2CH_2CH_3$, (diethyl) of boiling point 0.6° C. and density 0.60, and iso-butane $(CH_3)_3CH$ (2-methyl propane, trimethyl methane) of boiling point −10° C. and density 0.60.

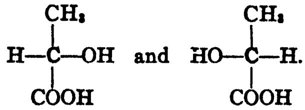
In any series of compounds, as alcohols and **hydrocarbons** above, the number of isomers increases rapidly with increase in the molecular formula, thus, there are four isomeric alcohols of C_4H_9OH, and eight of $C_5H_{11}OH$, and three isomeric hydrocarbons of C_5H_{12}, and five of C_6H_{14}.

The hydroxyacids represented by the ordinary formula $C_3H_6O_3$ show other forms than the two plain isomers:

```
 CH3
  |
 HCOH    alpha-hydroxypropionic acid,
  |        lactic acid (3 forms)
 COOH

 H2COH
  |
 HCH     beta-hydroxypropionic acid,
  |        hydracrylic acid (1 form)
 COOH
```

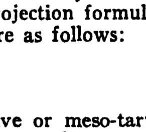
Plain isomerism is not sufficient to account for these three known forms of **lactic acid.** The explanation that is accepted was offered by van't Hoff and LeBel, independently (1874). This explanation demands that the four valencies of the **carbon** atom be disposed *equally in space.* The carbon atom may be pictured as occupying the center of a regular tetrahedron. The four **valencies** are disposed from the carbon atom at the center towards the four corners of the tetrahedron. When *four different groups* are attached (at the corners of the tetrahedron) to the carbon atom (at the center of the tetrahedron) it is possible to arrange the resulting compound in *two different ways.* Upon projection these two forms appear thus:



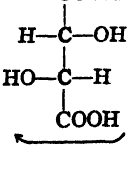
These are called space-isomers or stereoisomers, and the phenomenon displayed is known as stereoisomerism. One of these forms rotates the plane of **polarized light** to the right (dextro-lactic acid, d-lactic acid or sarcolactic acid) and the other to the left (laevo-lactic acid or l-lactic acid). A mixture of the two forms in equal amounts is ordinary lactic acid (dextrolaevo-lactic acid, dl-lactic acid, racemic-lactic acid) from sour milk, which does not rotate the plane of polarized light. These are the three forms of lactic acid, namely, dextro, laevo, and dextrolaevo or externally compensated. From dl-lactic acid, the other two forms may be obtained in the following manner, (1) d-lactic acid, by treatment with the mold, ***Penicillium glaucum,*** whereby l-lactic acid is destroyed, (2) l-lactic acid, by treatment with an optically active base, **strychnine,** followed by fractional crystallization, and subsequent treatment with an acid.

These two methods are of general application to racemic or externally compensated stereoisomers, the first, **biochemical,** in which one-half of the racemic substance is destroyed by the organism used, and the second, resolution, which can be applied in the case of acidic or basic stereoisomers. A third method, involving plain **crystallization,** is described below (Pasteur's separation of tartrates).

The simplest alcohol displaying stereoisomerism is amyl **alcohol,** which is known in the three forms dextro, laevo, dextrolaevo or racemic.

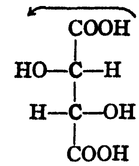


The **carbon atom,** to which are attached the four different groups to produce stereoisomerism or optical isomerism, is known as *asymmetric,* and, when it is desired to identify this carbon atom as such, it is written or printed more prominently than non-asymmetric carbon atoms. The projection formulas of the four forms of **tartaric acids** are as follows:



inactive or meso-tartaric acid (internally compensated; possesses a plane of symmetry; optically inactive).

dextro-tartaric acid (arrangement of groups around each asymmetric carbon atom is cumulative; optically active; dextrorotatory).

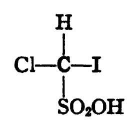


laevo-tartaric acid (arrangement of groups around each asymmetric carbon atom is cumulative; optically active; laevo-rotatory).

d-tartaric acid, l-tartaric acid: Dextrolaevo-tartaric acid, racemic tartaric acid (externally compensated; optically inactive; can be resolved into d and l components).

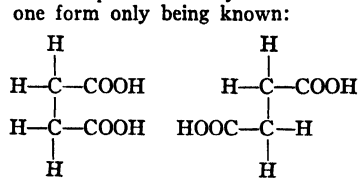
The two optically active tartaric acids when crystallized differ in the arrangement of the faces—one is the mirror image of the other. Pasteur (1848), observing this difference, was able to separate the two optically active forms of ammonium sodium tartrate crystals made from racemic tartaric acid.

When stereoisomeric substances are synthesized using *inactive* materials, the product is optically inactive, since, it is believed, the chances of dextro and laevo forms being produced are equal. Pope and Read (1914) prepared optically active forms of chloroiodomethanesulfonic acid



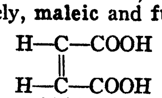
The sugars, $C_6H_{12}O_{16}$, have attracted much attention in this field. (See **Carbohydrates.**) Many substances in nature, especially the alkaloids and glucosides, are optically active.

Ethylene Stereoisomerism. While it might appear that succinic acid, $C_4H_6O_4$, could demonstrate the phenomenon of stereoisomerism, the same has not been detected. It is assumed that there is free rotation about the single bond joining the two central carbon atoms and the position finally assumed is one of equilibrium, one form only being known:

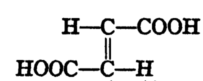


(only one form of **succinic acid** known)

But in the case of olefin linkage between the central carbon atoms in an analogous compound, stereoisomerism is detected. Thus, two acids, $C_4H_4O_4$, are known, namely, **maleic** and **fumaric:**

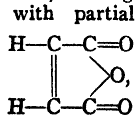


Maleic acid
Cis-butenedioic acid
or
Cis-1,2-ethenedicarboxylic acid



Fumaric acid
Trans-butenedioic acid
or
Trans-1,2-ethenedicarboxylic acid

Each of these acids has distinctive properties. Maleic acid, melting point 130° C., decomposes above 135° C., with partial transformation into maleic anhydride.



, solubility 79 grams per 100 grams water at 25° C., optically inactive; fumaric acid, melting point 287° C., boiling point 290° C., no anhydride, 0.7 gram per 100 grams water at 17° C., optically inactive.

Oleic and elaidic acids display this type of isomerism.

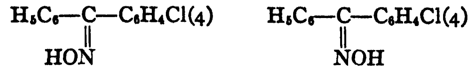
Carbon-Nitrogen (*group* $> C = N -$) *Stereoisomerism.* Analogous to ethylene isomerism is that of carbon-nitrogen in such compounds as the **oximes.**

Benzaldehyde with **hydroxylamine** yields two oximes. Stereoisomerism is utilized to explain the difference in structure.

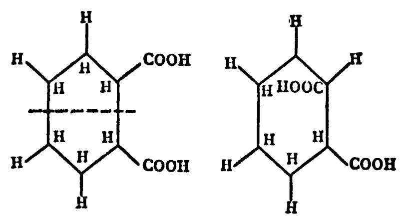
Benzantialdoxime	Benzsynaldoxime	Phenyl cyanide
Melting point 35° C.	Melting point 128° C.	Boiling point 191° C.
Optically inactive	Optically inactive	(For comparison)

Benzsynaldoxime is transformed into benzantialdoxime by treatment with acids, and is more readily converted by loss of water into phenyl cyanide (this is a debated point).

The **ketone** para-chlorobenzophenone with hydroxylamine yields two stereoisomeric oximes:



Cyclic Cis-Trans Stereoisomerism in non-benzenoid compounds. This phenomenon is illustrated by the two forms of hexahydroorthophthalic acid ($C_6H_{10}(COOH)_2$ (1,2)):



Cis-Hexahydro-1,2 phthalic acid	Trans-Hexahydro-1,2 phthalic acid
Melting point 192 C.	Melting point 221°C.
Soluble in water	Soluble in water
Plane of symmetry (the dotted line), therefore, optically inactive	No plane in symmetry, therefore, two optically active forms

This type of isomerism is believed to explain the existence of two forms of glucose, namely, alpha and beta (not dextro and laevo, which is of the lactic acid and tartaric acid non-cyclic type). (See **Carbohydrates.**) (R.K.S.)

ISOMETRIC REPRESENTATION. **Pictorial Representation.**

ISOMETRIC SYSTEM. **Crystallography.**

ISOMORPHOUS. The term applied to two or more minerals whose molecules can form intimate crystalline mixtures. Such mixtures are called solid **solutions,** in which the physical properties vary with the chemical proportions. The bulk of the silicate minerals are isomorphous, especially **albite** and **anorthite,** varying mixtures of which produce different species of **plagioclase feldspar.** (R.M.F.)

ISONITRILES. **Amines and Amides.**

ISOPACHOUS LINE. ISOPACH. A line, on a geological (stratigraphical or structural) map, all points on which show equal thickness of a formation. (R.M.F.)

ISOPHANE. A line plotted on a map through regions presenting uniform association of biological and climatic factors. Isophanes of the United States curve upward from the southeast toward the northwest. Phenomeridians crossing the isophanes at intervals in degrees of longitude corresponding to the spacing of the isophanes complete the division of the map into quadrangles. In each quadrangle the same conditions prevail within certain limits of variation. This system has been used for the computation of safe dates for sowing wheat to avoid the attack of the **Hessian fly** in various parts of the United States. (A.W.L.)

ISOPLETH. **Alignment Chart.**

ISOPODA. **Crustacea.**

ISOPORS, ISOPORIC FOCI. Lines or contours joining points of equal geomagnetic (compass direction) change are called *isopors.* The geographic coordinates of rapid geomagnetic changes are called *isoporic foci.* These foci are concentrated in the large continents and the sub-Atlantic lithosphere. (R.M.F.)

ISOPRENE. **Hydrocarbons.**

ISOPTERA. The white ants or termites. An order of insects of great economic importance and biological interest, made up of social species which eat wood and other vegetable matter. Most termite species are tropical or subtropical but a few live in temperate regions.

Termites have biting mouth parts and are moderate to small soft-bodied insects. They live in dark nests and tunnels except when the winged sexual individuals emerge to leave the parent colony. The bodies of these flying individuals are dark but the termites that remain in the nest are whitish with dark heads. They do not resemble ants in form, hence their similar habits are probably responsible for the name white ant. The temporary wings of termites are long and slender and the two pairs are similar in form. In most species the veins near the anterior margin are strong and the rest are faintly marked. The wings are shed after the swarming termites find a new nesting place.

The termite colony contains workers, soldiers, and reproductive individuals of both sexes. The workers are developed in subordinate castes in several species. Soldiers have large heads and strong jaws. The queen in some colonies becomes relatively enormous through the expansion of the abdomen as the eggs develop and is quite helpless. The workers feed and groom her and carry away her eggs.

It has been shown conclusively that termites depend on **protozoans** in the intestine for the digestion of the wood that they eat. Very few animals can digest cellulose, which is the chief compound in wood, but the protozoans do so and the termites utilize the products developed by the protozoans. This relationship is one of the finest examples of **symbiosis** among animals.

Because of their wood-eating habits termites sometimes do great damage to buildings. Their habit of building tunnels wherever they go and of remaining concealed in the wood where they work often results in their presence being unsuspected until the honeycombed timbers give way. When they once enter buildings they are not restricted to wood but damage papers, books, clothing, carpets and many other things. In regions where they are plentiful no timber in construction should be left in contact with the ground. Even a small contact may be a point of entry. Where timber must be exposed to attack it can be protected by impregnation with creosote, but the most effective type of construction demands masonry wherever contact with the ground must be made. Even in such structures termites may traverse several feet of masonry, building tunnels as they go, and may work through small cracks into the wooden parts of the building. Where termites have already entered, blocking their entrance and destroying the colony both inside the building and out with creosote or fumigants are usually effective methods of control. Special equipment and methods are available commercially for this work. (A.W.L.)

ISOSEISMALS. Lines of equal earthquake intensity according to one of the intensity scales. (R.M.F.)

ISOSEISMIC LINE. A line connecting all points on the surface of the earth where an earthquake has been determined to be of equal intensity. (See **Earthquakes.**) (R.M.F.)

ISOSTASY. A term proposed by C. E. Dutton in 1889 for the theory of **gravitational** balance between relatively broad, contiguous areas of different average altitudes or topographic relief. The term is derived from the Greek meaning equal standing (balance), and has been applied particularly to the isostatic equilibrium of the major topographical features of the earth—continents and ocean basins. Thus the continents are assumed to "stand high," relative to the ocean basins, because they are lighter (or less dense) material. Whenever any large segment of the earth's crust is out of balance with its surroundings, adjustment is assumed to take place by means of solid flow in a deep subcrustal zone. Since the surfaces of the continents are constantly being worn down by erosion, if it were not for isostasy, early in the geologic history of the earth all land areas would have been reduced to ocean level. The theory of isostasy was originally proposed to explain major problems in structural geology, and has been amply justified by **geophysical** and **geodetic** surveys. In the application of the theory there has been considerable disagreement between geophysicists and geologists as to the minimum areas of relief (topographic features) which may be subject to isostatic balance, especially in mountainous regions which are characterized by low angle **overthrusts** and consequent, horizontal translations of great thicknesses of the **lithosphere.** The general principle of isostasy has, however, been accepted by an increasing majority of geologists, geodesists, and geophysicists, and probably no other geophysical-geological theory is so firmly entrenched in geodetic, geophysical and geological literature. The most recent outstanding exponent of Isostasy was William Bowie (died, 1940). (R.M.F.)

ISOTHERMAL. Having the same temperature.

ISOTHERMAL ATMOSPHERE. Any layer of air in which the temperature does not vary with altitude is known as an isothermal layer; if the whole atmosphere were of constant temperature in the vertical it would be an isothermal atmosphere. (P.E.K.)

ISOTHERMS. Lines joining points of equal temperature. Isotherms can be drawn for any surface or cross-section. (P.E.K.)

ISOTOPES. **Chemical Composition.**

ITABRITE. A variety of **quartzite** rich in iron minerals. It is named from the type locality at Itabira, Brazil. (E.S.C.S.)

ITACOLUMITE. This is a **sandstone** with a peculiar flexibility which is due to the interlocking of its constituent grains, permitting a limited amount of distortion without fracture. The name is derived from *Itacolumi,* a mountain in Brazil. (E.S.C.S.)

ITERATED INTEGRALS. **Double Integrals and Triple Integrals.**

ITERATIVE IMPEDANCE. **Characteristic Impedance.**

IVORY. The dentine of teeth, a material similar to bone but harder and of different minute structure. It is deposited outside of the layer of cells that produce it in the form of small tubules extending toward the outside of the tooth.

The chief sources of ivory for commercial purposes are the tusks of various animals. Elephants' tusks have only a little enamel at the tip and are solid ivory except where the pulp cavity invades the base. The tusks of walruses have also been an important source of ivory, although they are inferior to elephant ivory. The material is used extensively for carved ornaments. (A.W.L.)

IZARD. Mammalia, Artiodactyla. A name applied to the **chamois** in the Pyrenees. (A.W.L.)

J

JABIRU. Aves, Ciconiiformes. The giant **storks** of South America, Africa, and Australia. (A.W.L.)

JACAMAR. Aves, Piciformes. South American birds (**Aves**) related to the woodpeckers. (A.W.L.)

JACANA. Aves, Charadriiformes. Shore birds (**Aves**) of South America, Africa, and the Oriental region. They have long legs and tail and very long toes. (A.W.L.)

JACARE. Caiman.

JACK. A jack is a portable device for lifting heavy loads through short distances by hand power. Power is applied manually to a lever or bar. The mechanism of the jack allows the operator to exert a great **mechanical advantage** and lift a weight many times that which would be possible unaided by the jack. The mechanical advantage is secured by a great reduction in motion, and consequently jacks are slow in action.

The requirement of being readily carried by hand from place to place necessarily limits the capacity which may be built into a jack. However, it may be built to lift several tons. The mechanical advantage of a jack may be secured by screw, lever, or hydraulic action. The screw jack has a threaded screw fitting to a nut which is a part of the base of the jack. The threaded portion is revolved by bars inserted in it, and is topped by a bearing plate, which presses against the load being lifted, and which rubs on the top of the jack as the latter is turned. In its usual form, the lever jack has a rack and pawl, the pawl being mounted on the end of a lever whose fulcrum point is very close to the pawl, thus giving a big mechanical advantage to any force exerted at the other end of the long lever. The hydraulic jack, which is even more powerful than the other two types, has a very small piston which is actuated by hand, and which forces oil into a cylinder where it can act against a much larger piston. This larger piston is connected to the lifting portion of the jack, and the mechanical advantage which is, roughly, the ratio of the areas of the large and small pistons, may be made as large as wanted. (F.T.M.)

JACKAL. Mammalia, Carnivora. An animal resembling the wolf and of similar habits. The common jackal, *Canis aureus,* ranges from southeastern Europe to Ceylon and into northern Africa, and the remaining species are African. Jackals are predators and scavengers. They also eat some fruits and occasionally damage sugar cane. (A.W.L.)

JACKDAW. Aves, Passeriformes. A small European crow, *Corvus monedula,* typically with a gray collar but also occurring in a wholly black form. Another species of **daw** occurs in Asia and the name jackdaw is applied to the great-tailed **grackle** in the southwestern United States. (A.W.L.)

JACKET. A jacket is a covering whose function is associated with retention or extraction of heat from that which it covers. The **cylinder** of a **steam engine** is sometimes covered with a wooden jacket whose purpose is to prevent heat loss from the cylinder. The jackets of **internal combustion engines** remove the heat from the cylinder. While some internal combustion engines are air-cooled, the majority are liquid-cooled, usually with water which is circulated in jackets which surround the cylinder head and sometimes extend the full length of the cylinder. These jackets may be cast on the cylinders when the latter are poured, or they may be made of thin sheet metal welded to the cylinder. The latter practice produces a lighter weight engine, but is much more expensive than the cast type water-jacketed cylinder. Small engines can have the water led into the jacket and conducted away from it by simple openings, but a more definitely controlled flow of cooling water is necessary for a large cylinder. In addition, other parts such as exhaust **manifolds,** and pistons, may be water-jacketed. About one-third of the heat of the fuel supplied to an internal combustion engine finds its way into the contents of the cooling jacket. (F.T.M.)

JACK-IN-THE-PULPIT. Aroids.

JACOBIAN. A Jacobian is a type of mathematical expression, named after the great German mathematician Karl Gustav Jakob Jacobi (1804–1851).

Let F_1 and F_2 be two **functions** of u and v. The **determinant**

$$J = \begin{vmatrix} \dfrac{\partial F_1}{\partial u} & \dfrac{\partial F_1}{\partial v} \\ \dfrac{\partial F_2}{\partial u} & \dfrac{\partial F_2}{\partial v} \end{vmatrix} = \frac{\partial F_1}{\partial u}\frac{\partial F_2}{\partial v} - \frac{\partial F_1}{\partial v}\frac{\partial F_2}{\partial u}$$

is called the functional determinant or Jacobian of F_1 and F_2 with respect to u and v. It is frequently denoted by $\dfrac{\partial(F_1, F_2)}{\partial(u, v)}$.

In general, if $F_1, F_2, \cdots, F_n$ are functions of $u_1, u_2, \cdots, u_n$, then the functional determinant or Jacobian of $F_1, F_2, \cdots, F_n$ with respect to $u_1, u_2, \cdots, u_n$ is defined to be the determinant

$$J = \begin{vmatrix} \dfrac{\partial F_1}{\partial u_1} & \dfrac{\partial F_1}{\partial u_2} & \cdots & \dfrac{\partial F_1}{\partial u_n} \\ \dfrac{\partial F_2}{\partial u_1} & \dfrac{\partial F_2}{\partial u_2} & \cdots & \dfrac{\partial F_2}{\partial u_n} \\ \cdot & \cdot & \cdots & \cdot \\ \dfrac{\partial F_n}{\partial u_1} & \dfrac{\partial F_n}{\partial u_2} & \cdots & \dfrac{\partial F_n}{\partial u_n} \end{vmatrix},$$

and is often denoted by $\dfrac{\partial(F_1, F_2, \cdots, F_n)}{\partial(u_1, u_2, \cdots, u_n)}$. (L.L.S.)

JADE. Jade is a general term for a compact green mineral substance much prized for ornamental purposes in China and Japan and to a less extent in the Western World. Jade is, properly speaking, either a compact **actinolite** called **nephrite,** a variety of **amphibole,** or jadeite, a **monoclinic pyroxene.** It is easily worked and many prehistoric implements have been found of this material in Mexico, Switzerland, France, Greece, and Egypt. The word jade is derived from the Spanish *pietra di hijada,* kidney stone, because it was supposed to be beneficial to diseases of the kidneys. Nephrite is derived from the Greek word for kidney, the allusion being the same as in the case of jade. (E.S.C.S.)

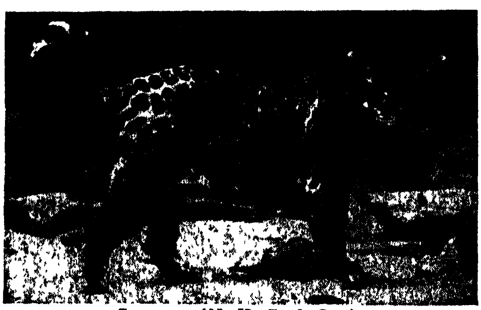
JADEITE. The mineral jadeite, essentially **sodium-aluminum silicate,** $NaAl(SiO_3)_2$, is a monoclinic **pyroxene** usually appearing in crystalline masses, or may be granular, fibrous, or compact. It has a prismatic **cleavage;** splintery **fracture;** hardness, 6 5–7; specific gravity, 3.3–3.5; luster, vitreous to pearly; color, various shades of green, bluish-green, greenish-white or almost white;

translucent to opaque. The processes that have acted to form this mineral are little understood both because of the confusion that exists between jadeite and **nephrite**, and the fact that the localities are not well known. Jadeite is found in Burma and China and has been reported from Mexico. It has probably resulted from the **metamorphism**, at great depths, of rocks rich in soda and aluminum, such as **nephelite syenites**. Its association in Burma with **serpentine** suggests its origin in more **basic igneous** rocks.

Jadeite is a tough and yet rather easily worked substance and has long been used for ornamental purposes. Evidence has been found in Europe, Mexico, Egypt, and elsewhere that it was used in prehistoric times for both ornaments and implements. The word jadeite has been formed by adding -ite to jade, the general term used for all green-colored tough compact stones that have been used as indicated above. (E.S.C.S.)

JAEGER. Aves, Charadriiformes. Birds closely related to the **gulls**, from which they differ in the elongate midd'e tail feathers. Four species nest in the Arctic regions and migrate into Europe, the southern United States, and even the southern hemisphere. One is antarctic and one lives on the west coast of South America. Also called skuas. (A.W.L.)

JAGUAR. Mammalia, Carnivora. A large South American cat, *Felis onca*, found chiefly in the jungles but also in open country. It is tan, marked with rings



Jaguar. (*N. Y. Zool. Soc.*)

and dots of black, resembling the leopard. The jaguar is larger than the leopard and differs in details of structure and markings. (A.W.L.)

JAGUARONDI. Mammalia, Carnivora. A small **cat**, *Felis jaguarondi*, of uniform brownish or blackish color. It ranges from northern Mexico to Brazil and Paraguay. (A.W.L.)

JAPANESE BEETLE. Insecta, Coleoptera. A small bronze-green **beetle**, *Pompillia japonica*, about three-eighths of an inch long, related to the May beetles. It is native to Japan and was first noticed as a pest in the United States about 1916. From New Jersey, where it first appeared, it has now spread about 500 miles westward. It attacks fruits, shrubs, forest and shade trees, and many crop plants, and the larvae damage the roots of grasses. The control of the pest is still a serious problem since sprays strong enough to kill the beetles injure many plants and trees. In cultivated lands the working of the ground kills the grubs, and strong sprays of **lead** arsenate (8 lbs. per 100 gal. of water) are effective against the adults on some fruits, shade trees, and shrubs.

In 1944 a new type of control became commercially available. It consists of a mixture of the spores of a milky-disease organism, *Bacillus popilliae*, and powdered talc. By spreading this material at 10-foot intervals in infested areas the disease, which kills the larvae of the beetles, is established much more promptly and effectively than through its natural spread. It is a very effective means of reducing the beetle population. (A.W.L.)

JARARACA. Reptilia, Sauria. A poisonous **snake**, *Lachesis jararaca*, which ranges from eastern Brazil to Ecuador and Peru. A **pit viper**. (A.W.L.)

JARGOON or JARGON. **Zircon.**

JARNO TAPER. **Taper.**

JAROSITE. The mineral jarosite is a **basic** hydrous sulfate of **potassium** and iron corresponding to the formula $K_2Fe_6(OH)_{12}(SO_4)_4$. It is formed in the outcrops of ore deposits during oxidation of **iron sulfides**. It is a **hexagonal** mineral with basal **cleavage**; is brittle; hardness 2.5–3.5; specific gravity 3.15–3.26; luster vitreous to dull; color, dark yellow to yellowish-brown; shining yellow **streak**; translucent to opaque. Jarosite was originally reported from and named for Barranco Jaroso in the Sierra Almagrera, Spain. It has been found in Bohemia, France, the Island of Elba, Siberia and Bolivia. In the United States it is found in Arizona, Colorado, Texas, New Mexico, Utah, Nevada, and South Dakota. (E.S.C.S.)

JASMINE OIL. **Volatile Oils.**

JASPER. This mineral normally occurs as a **red chalcedony**, the coloring matter being **hematite** or **limonite**. Other varieties of jasper are yellow, green, or dull blue. Jasper forms an important constituent of the hard iron ores of the Lake Superior iron ranges. (R.M.F.)

JASPILITE. A rock made up of alternating layers of **siliceous** material such as **quartz** or **chalcedony**, and red **jasper** or **hematite**. Jaspilites are often contorted and **brecciated** to a considerable degree, and are sometimes polished for ornamental use. (E.S.C.S.)

JAUNDICE (ICTERUS). A condition in which the bile pigments stain the skin, mucous membranes, tissues, and body fluids. It occurs commonly in many disorders and diseases.

Jaundice may be divided into three types: 1. Obstructive jaundice. This form accounts for about 85% of all cases and is seen when there is any obstruction of the bile ducts leading from the liver to the duodenum. (See diagram page 627.) The obstruction may be caused by gallstones within the ducts, inflammation of the duct wall, shutting off the flow of bile by swelling (cholangitis), tumor within the duct walls or causing pressure from without, scar tissue formation, or kinking, or spasm of the bile ducts. 2. Hemolytic jaundice due to excessive destruction of red blood cells with liberation of their pigments. (See **Hemolytic Jaundice.**) 3. Toxic and infectious jaundice. This occurs when the liver cells have been damaged by toxic substances, either chemical, virus, bacterial, or spirochaetal in nature. It is seen in poison from chloroform, phosphorus, and arsenic compounds and may occur with syphilis and several acute infections. It is also seen in Weil's disease, acute infectious **hepatitis**, and catarrhal jaundice.

Jaundice usually appears first as a yellow discoloration of the eyeballs. Gradually, the skin of the entire body becomes yellow, and may itch violently, especially in chronic jaundice. The urine varies from yellow to dark brown. The blood serum is bile-stained and in severe cases the clotting time of the blood is greatly prolonged so that bleeding is hard to control. The cerebrospinal fluid is usually not colored. The stools, when there is complete obstruction and absence of bile in the intestine, are clay-colored. With jaundice there

are usually mental depression, headache, and drowsiness. In severe cases there may be stupor or coma.

Other symptoms and signs depend on the disease causing the jaundice. (R.S.M.)

JAW. The assemblage of bones before and behind or above and below the mouth of a **vertebrate.** The lower jaw is movably articulated with the skull to work against the upper jaw for biting and chewing and both bear teeth in most species.

The earliest vertebrate jaws, as exemplified by the **sharks,** consisted entirely of cartilage and were not rigidly attached to the brain case. With the acquisition of an outer covering layer of dermal bones the upper jaw was firmly attached to the cranium and the primitive jaw **cartilages** receded in importance, although they, or the replacement bone superseding them, still served as the jaw joint. In the evolution of the mammals from the mammal-like reptiles a new jaw joint was formed, this time between dermal bones, and the old jaw joint became incorporated in the middle ear where it still functions as the joint between the malleus and incus. (A.W.L.)

JAY. Aves, Passeriformes. Birds (**Aves**) of several species related to the magpies and crows. Most jays live in the northern hemisphere but a few species occur in the Oriental region and northern Africa. They are noisy birds, often brightly colored, and sometimes interesting in habits, but some are too destructive of the eggs and young of other species and too quarrelsome to be desirable.

The blue jay, *Cyanocitta cristata,* is the most widely known of the North American species. More than a

Blue jay, *Cyanocitta cristata.* Blue above, with white bands on the wings. White below. A black band around the neck. Narrow black bars on wings and tail. A crest on the head.

dozen others occur in the western states where the Oregon jay, *Perisoreus obscurus,* and the Canada jay or whiskey jack, *P. canadensis,* are friends of campers. These species visit camps and human habitations freely in search of food. (A.W.L.)

JEJUNUM. That portion of the small intestine which extends from the end of the **duodenum** to the beginning of the **ileum.** The jejunum is about 8′ long and continues into the ileum without any line of demarcation. It occupies the upper and left part of the abdomen lying below the stomach and spleen on the left side. Its coils are freely movable and are connected with the posterior abdominal wall by wide folds of membrane (**peritoneum**) called the mesentery, through which run the blood and lymph vessels and nerves supplying it. (R.S.M.)

JELLYFISH. Scyphozoa. Coelenterata. Medusa.

JENNET. Mammalia, Artiodactyla. The female **ass.** (A.W.L.)

JENNY HANIVER. A curiosity resembling a misshapen human figure, made by variously distorting and decorating a **ray.** Made in the past by New England fishermen and sometimes found among collections of curios. (A.W.L.)

JERBOA. Mammalia, Rodentia. Small jumping animals of Asia and northern Africa. They resemble mice with long tufted tails and very long hind legs. The

Egyptian jerboa. (*N. Y. Zool. Soc.*)

small fore legs are not used in locomotion. The Asiatic jerboas have five toes on the hind feet and the African three. The most common Asiatic species is also called the alagdaga, *Allactaga indica.* (A.W.L.)

JET. The geological material, jet, is not a mineral in the true sense of the word. It is a hard and compact variety of lignite, coal-black in color. It can be easily polished and has been used for the manufacture of cheap ornaments. Jet is found in England, France, Spain, Germany, and the United States. (See also **Jet Propulsion.**) (E.S.C.S.)

JET ENGINE. Technically this term might include any device for propulsion which uses the reaction force obtained from the acceleration of a fluid stream (see **Jet Propulsion**). However, it is proposed to restrict the present treatment to combustion jets, wherein the reaction of a powerful jet of products of combustion expelled rearward from the engine is the source of propulsion. Present-day jet engines meeting this specification are classified as follows:

1. Gas turbine systems or turbo-jets.
2. Resonance ducts.
3. Aero-thermodynamic ducts (Athodyd).

All of these draw in air for combustion from the surrounding atmosphere, and it is in this respect that they differ from rocket motors.

Propulsion by jet action never becomes efficient unless the propelled body is moving at high speed. Airplanes furnish this condition, in some measure, as do also the so-called "flying bombs." In general, surface vehicles do not. Jet engine development therefore was nurtured in the aviation field, receiving great impetus from wartime demands for planes with lighter, more powerful engines, especially those well adapted to the high-speed range.

Gas Turbine Systems. One method of producing jet reaction is to impart a high velocity to the fluid by means of adiabatic expansion. But this necessitates a pressure drop. Since the discharge is back to the same atmosphere from whence the air was initially drawn, a means of compression has to be provided. Briefly, this system has a gas turbine driven compressor. Both centrifugal and turbine type (axial flow) compressors have been used. Between discharge from the compressor and entrance to the turbine, the air receives heat by the direct combustion in it of a suitable quantity of fuel. This increases the volume and temperature at constant pressure. The energy available is then sufficiently high so that the work of compression can be taken out of the gases by the turbine, with enough energy remaining to impart the high final kinetic energy and speed to the jet.

Fig. 1 shows the basic features of the turbo-jet engine. The single rotating shaft mounts the impeller of a centrifugal compressor and the wheel of a single stage

impulse gas turbine. Air, sometimes at subzero temperatures, is rammed into the engine cowling by the forward motion of the whole engine. It speedily finds the air in-

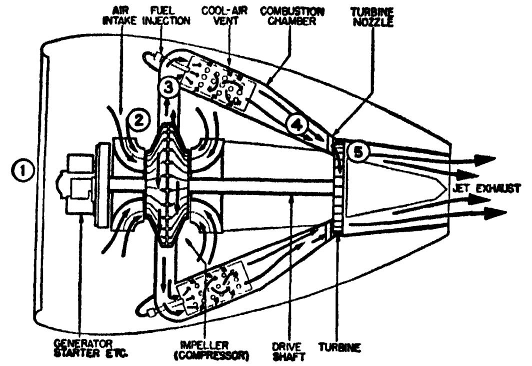


Fig. 1. Principle of the combustion gas turbine jet engine. (*General Electric Co.*)

take of the compressor and quickly is discharged in a compressed condition into the combustion chamber. Here fuel (kerosene) is burned in it in sufficient quantity to raise the temperature of the gases to say 1500° F. at the turbine nozzle. To obtain as complete combustion as possible, and to cool the chamber walls, the air-fuel ratio is temporarily reduced by feeding only part of the air through the burner. The remainder enters the combustion chamber through cooling vents. After partial expansion in the turbine nozzles the gas flows at high speed through the turbine blading, spinning the wheel at many thousand revolutions per minute. All the turbine output is used to drive the compressor; consequently only a portion of the available energy is consumed in this way. The gases emerge from the turbine wheel with considerable velocity and some positive pressure above final exhaust pressure. This is employed by the exhaust nozzle to raise the gases to the final jet speed by adiabatic expansion. It is seen that the compression and combustion process is devoted to preparing a flow of gas, composed of products of combustion and excess air, for adiabatic expansion through a nozzle. The gas turbine is merely incidental, a means of driving the compressor.

Theoretical considerations of energy and of momentum yield equations for thrust and efficiency based on engine speed u, jet speed v, and mass flow m. (See **Jet Propulsion.**) This approach has the virtue of simplicity but fails to include the factors which are responsible for whatever numerical value v may possess. With reference once again to Fig. 1, note that 5 stations along the line of flow of the fluid are selected as State Points in a description of the engine process from the thermodynamic viewpoint. State 1 is the free atmosphere at temperature T_1. The ram of air into the engine cowl is of the nature of a reversed and imperfect expansion of a gas jet. Borrowing an equation from **Jet, Gas,** with suitable subscripts for the case under consideration, the ideal ram pressure

$$P_2 = P_1\sqrt[z]{\frac{u^2z}{64RT_1} + 1}.$$

The relation $T_2/T_1 = (P_2/P_1)^z$, whose use was necessary in formation of the equation for P_2 from the gas jet equation, will also serve to determine the compressor intake temperature, for the actual ram pressure P_2 will be 80% to 90% of the ideal. Using symbols as follows,

$$W_c = \text{ideal compressor work} = \frac{RT_2}{z}\left[\left(\frac{P_3}{P_2}\right)^z - 1\right].$$

η_c, η_t = internal efficiencies of compressor, turbine.

R = 53.4 for air, nearly the same for gas turbine products.

$z = (c_p - c_v)/c_p$.

c_p, c_v = specific heats, constant pressure and constant volume.

h = enthalpy.

J = mechanical equivalent of heat.

The remaining steps in determining the magnitude of the final velocity, which call v, for a limiting T_4, are, based on a pound of air:

$$h_3 - h_2 = \frac{W_c}{J\eta_c} = c_p(T_3 - T_2).$$

This defines the temperature T_3 to be expected from a pressure ratio $\frac{P_3}{P_2}$. The combustion process which raises the temperature from T_3 to T_4 is essentially constant pressure, making the necessary heat addition $c_p(T_4 - T_3)$, although some adjustment might be made for a drop of pressure between points 3 and 4. Since all the turbine output goes to the compressor, the enthalpy at point 5 can be determined by $h_4 - h_5 = \frac{W_c}{J\eta_c}$ + energy required by the auxiliaries. Considering $T_{5'}$, the temperature at exit from turbine nozzle, and T_5, the temperature at exit from turbine blades,

$$h_4 - h_{5'} = \left[\frac{W_c}{J\eta_c} + \text{auxiliary energy}\right] \times \frac{1}{\eta_t} = T_4c_p - T_{5'}c_p.$$

Thus $T_{5'}$ is fixed, and also the pressure $P_{5'}(= P_5)$ from the polytropic relation $[P_4/P_{5'}]^z = T_4/T_{5'}$. The actual temperature drop from 4 to 5 is $\eta_t(T_4 - T_{5'})$. With P_5 and T_5 the final jet velocity is given by the jet equation (see **Jet, Gas**)

$$v = 8\sqrt{\frac{RT_5}{z}\left[1 - \left(\frac{P_5}{P_4}\right)^z\right]}.$$

To obtain good thermal efficiency the temperature T_4 needs to be as high as conditions permit. The cooling of these engines is therefore a critical feature of their design. Cooling air bled off the compressor is used to air-jacket many of the high-temperature regions. Air circulation through hollow turbine blades and other ingenious features has characterized these designs. Although not impressive in thermal efficiency, these pure jet engines are capable of powering airplanes of higher speed than the propeller type engines whose propeller blades are the first part of the airplane to be affected by compressibility.

A new type of power plant has been developed, having both propeller and jet output. Designed primarily to drive large high-speed military transports and bombers, this gas turbine with propeller is designed for installation in the wings of multi-engined aircraft or in the nose of a single-engine plane. A diagram of it shows that the air rams into the nose of the engine through ducts

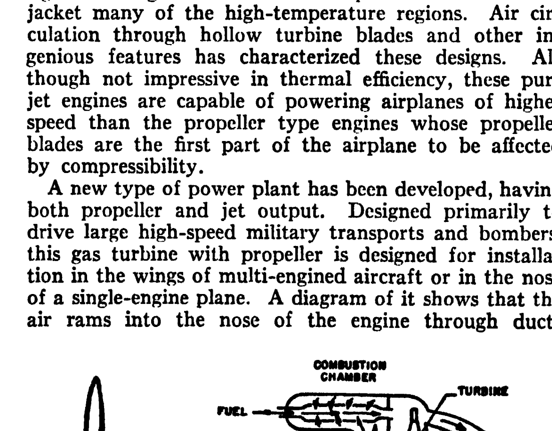

Fig. 2. G-E propeller drive gas turbine. (*General Electric Co.*)

opening forward. This air is compressed by axial flow units in the forward part of the engine and then is forced into combustion chambers. There fuel is injected and burns intensely. This raises the temperature and velocity of the gases, which then, with great energy, strike

the buckets of the turbine wheel. The turbine, spinning more than 10,000 times a minute at a temperature over 1500° F., absorbs the *major part* of the available energy in the gases.

The turbine powers the compressor and through reduction gears drives the propeller. Reactive thrust created by the energy remaining in the gases passing through the turbine wheel and discharging rearward is utilized in jet propulsion.

The power generated by these new units already is great and engineers see no basic difficulties in increasing the propulsive output of this type of gas turbine to almost any force visualized as necessary to drive the projected mammoth planes of the future.

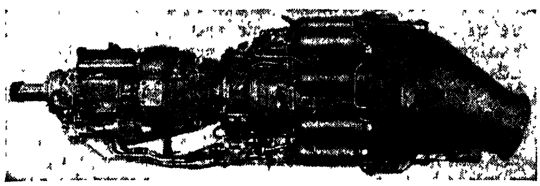

Fig. 3. The propeller-jet engine. (*General Electric Co.*)

The range of planes powered by gas turbines of this type will be extensive. At slow speeds and low altitudes, the gas turbine uses more fuel than a reciprocating engine cruising under similar conditions, but when operating at full power the turbine uses less fuel than a conventional engine operating at maximum power. The turbine functions most efficiently at high altitudes where the air is colder than at lower altitudes.

The speed limits on planes powered by the propeller-jet turbine are unquestionably the compressibility barriers that are reached by all propeller driven planes at speeds slightly exceeding 500 m.p.h.

Planes powered by these gas turbines may not reach the extreme high speeds attained by the pure jet propelled airplanes. However, while this type of gas turbine may not power the fastest planes, it will give ranges greater than may be possible with pure jet propulsion.

No complicated ignition or carburetion or timed injection system is needed on the combustion jet engine, but starting is more of a task as the compressor must be set spinning at high speed in order to initiate the cycle.

Resonance Duct Engine. In 1944 a new type of jet engine was introduced on a war weapon. Without touching on its value as a weapon, the technical features of its propulsion system are to be described. The "buzz bomb," or V-1, to mention two of the names ascribed to this flying bomb, was an unmanned aircraft carrying an explosive charge which was detonated when the bomb crashed at the end of its 100 to 200 mile flight. Gyro stabilizing and other controls which could be pre-set guided it to the target. By far the most interesting thing about this weapon was the jet engine that propelled it. Although possessing poor thermal efficiency, it was extremely light weight, simple, and inexpensive to construct, just the features needed for the expendable nature of its use. The principle of the "intermittent duct engine" is explained by Fig. 4. The duct itself is a long

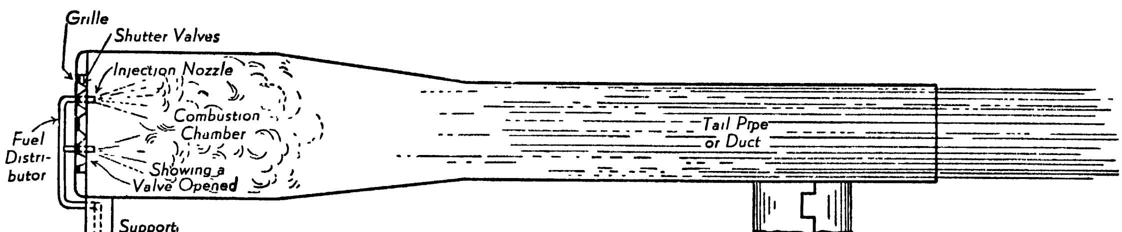

Fig. 4. Schematic diagram of the resonance duct jet engine.

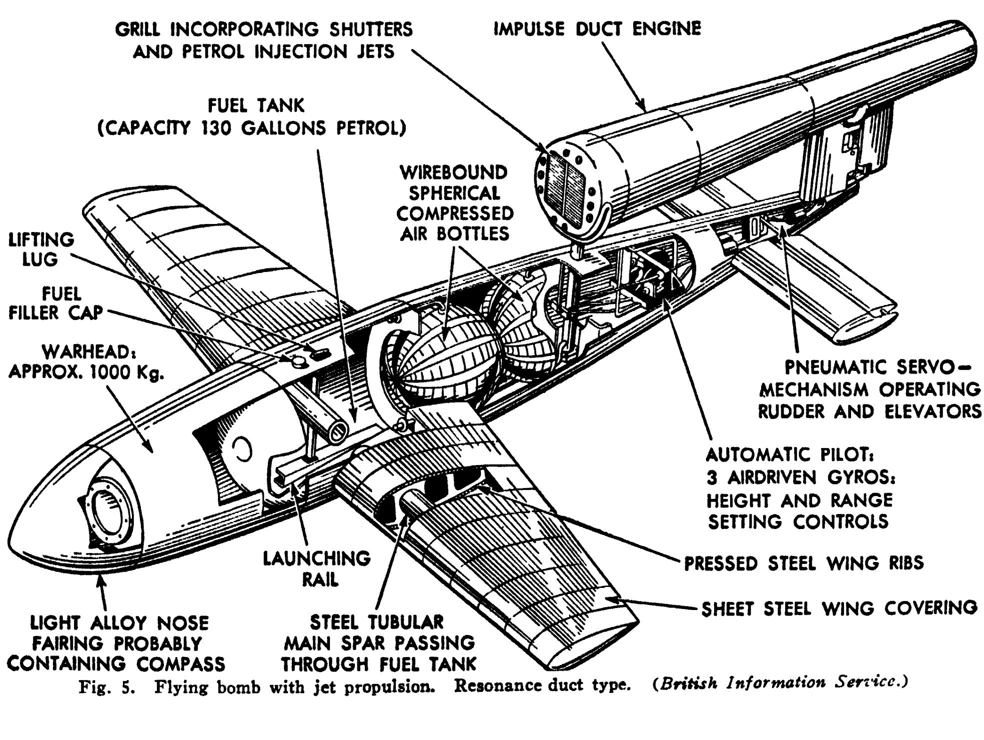

Fig. 5. Flying bomb with jet propulsion. Resonance duct type. (*British Information Service.*)

tube (11 ft.) enlarged at the forward end to serve for the combustion chamber. Across the front is a grill equipped with large numbers of thin spring steel flap valves which will open inward to allow air to enter, but will close when fuel burning in that air raises the combustion chamber pressure. Following each explosion a sound wave and column of gases travel down the duct and a partial vacuum is induced behind the grill. So more air enters, mixes with fuel that is sprayed into the chamber continuously, and explodes. These explosions follow each other in rapid sequence. Rates of 40 cycles per sec. have been mentioned. The ignition is by electric spark. However, after the combustion chamber is hot, ignition is continued by residual flame. The duct must be of the correct length to harmonize the explosion impulse waves with the natural period of oscillation of the grill valves. The source of thrust is, of course, the change in momentum of the gases shooting rearward out of the duct.

The flying bomb, which was able to make something like 300 m.p.h., is shown in Fig. 5, on page 815. Because of the low thermal efficiency, about 1 gal. of gasoline for each mile to be covered is required. This is carried in a fuel tank from which it is forced by compressed air pressure into fuel jets located in the front grill. A big disadvantage of this engine, and one which ultimately prevented its becoming a decisive weapon, was the trouble of getting it started. It had to be projected at about 250 m.p.h. from a long launching track before the resonance action could begin to function. This rendered the launching sites large targets vulnerable to enemy counter action. Some of these flying bombs were carried aloft by bombers and launched in flight. Although they were effective only against large targets, if equipped with television transmission in the nose, and perfected for longer ranges, they might offer a major and serious offensive threat.

Athodyd. This simple continuous jet engine is known to have been the subject of considerable wartime research, but the results have not appeared as yet. Not that the aero-thermodynamic-duct principle is new. On the contrary, it has been a subject for thought and debate for at least three decades. But its field of usefulness seems to lie in speed ranges only now being approached in aviation.

The device is a nozzle set into a well streamlined body containing fuel tanks and a system for injecting the fuel into the combustion region. It is not self-starting. If fuel is injected and ignited with the duct stationary, the exhaust will blow out of the duct in both directions, for there is nothing there to cause it to do differently. But when the duct is in motion at high speed, the air ram into the front end will block the possibility of exhaust there unless it is attempted to burn the fuel too rapidly. The thrust is theoretically

$$F = \frac{\rho u^2}{2}(A_m - A_1)$$

where ρ = mass density of the air.
u = duct speed.
A_m = mouth area.
A_1 = entrance area.

The $(A_m - A_1)$ term must be limited in magnitude because of certain thermodynamic and aerodynamic considerations, and large thrusts must necessarily imply high speeds, which enlarge the magnitude of dynamic pressure $\rho u^2/2$. Power is proportional to the product of thrust and velocity, which makes it proportional to u^3. Thus we find Athodyd to be a device suitable only for high speeds, but its power, insignificant at conventional speeds, rises mightily as those high speeds (thought to be near the speed of sound) are approached. The ideal efficiency is 100%, but whether that can be approached in an actual case depends on whether the duct design permits a decent amount of combustion to occur before the jet carries out of the duct. (F.T.M.)

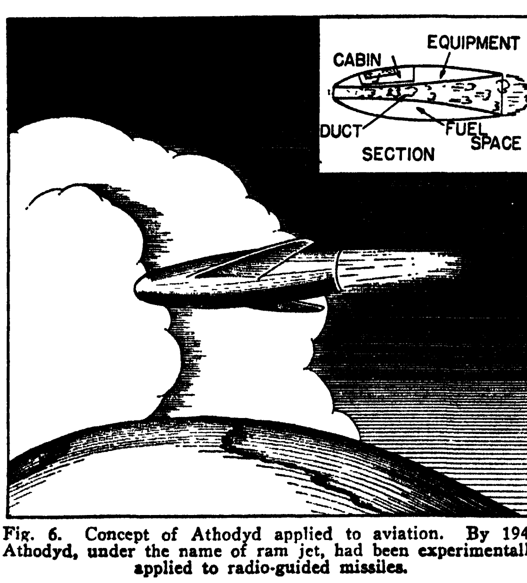

Fig. 6. Concept of Athodyd applied to aviation. By 1946 Athodyd, under the name of ram jet, had been experimentally applied to radio-guided missiles.

JET, GAS. As gas is a compressible fluid, the velocity attained in a jet cannot be evaluated from Bernoulli's principle. If one uses adiabatic expansion from P_1 to P_2 in a properly shaped nozzle, the ideal velocity of the gas jet is:

$$v = 8\sqrt{\frac{RT_1}{z}\left[1 - \left(\frac{P_2}{P_1}\right)^z\right]} \text{ ft. per sec.}$$

R and z are characteristics of the gas, R being the common gas constant (i.e., 53.4 ft. per degree for air), and z being $(c_p - c_v)/c_p$ wherein the c's are specific heats, B.T.U. per lb. per degree, at constant pressure and constant volume.

z = .286 for air under 1000° F.
z = .23 to .28 for products of combustion of fuels.

T_1 is the absolute temperature at pressure P_1.

Although gas jets have not been in common use heretofore, rocket propulsion and other uses of gas jets may serve to focus more attention on this subject. (See **Jet Propulsion.**) (F.T.M.)

JET PROPULSION. Jet propulsion, as commonly practiced, is reaction propulsion. In other power plants where both action and reaction exist, it is the action that is sought for use, and the reaction claims attention chiefly on account of the need for providing anchorage or support. But jet propulsion *uses the reaction.*

Principles governing jet propulsion belong in the field of dynamics. Classical dynamics rests upon the three Newtonian Laws, the third of which is the law of action-reaction. It states that for every action there is an equal and oppositely directed reaction. When a bridge rests on a pier and presses down against it with a force derived from the weight and load of the bridge, the pier simultaneously exerts an upward thrust of like magnitude against the bridge. This upward force is the "reaction." Jets which are accelerated out of a stationary nozzle produce a reaction on the nozzle that would drive it backward from the jet were it free to move. Where arrangements are made to use this jet reaction it can become a propellant for vehicles, bombs, etc.

Consider the case of a jet discharged from a body attached to a car, as shown by Fig. 1. It may be imagined that the source of this jet is a large sky-

rocket. If the car is light weight and equipped with anti-friction bearings, one can readily imagine that it would be accelerated forward speedily upon ignition of

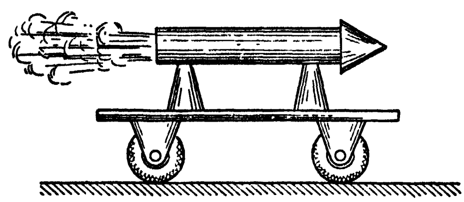

Fig. 1. Simple reaction propulsion.

the rocket. Now many may possess a feeling that this, in some way, is because the jet from the rocket pushes against the air; something in the manner of gas in an engine cylinder pushing against the piston. They may be surprised to learn that the rocket would use its fuel even more efficiently if operated in the absence of an atmosphere—as in the outer regions of space.

When the rocket contents burn, the products are expelled at high velocity and a forward thrust is imparted to the rocket case. If a constant rate of discharge of m slugs per sec. is assumed, and v is the velocity of discharge, relative to the rocket, which takes place through the nozzle mouth at section aa, Fig. 2, then a reaction

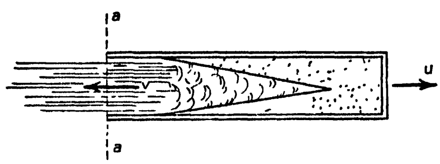

Fig. 2. Thrusting rocket.

force is set up which is caused by the momentum change suffered by m. This force is mv. Due to the rocket's symmetrical shape, the air pressure acting externally on it is balanced save for the area at aa and an equal parallel area at the closed end of the rocket body. Let P_m be the gas pressure at aa, A the area there, and P_a atmospheric pressure. The net static pressure is $A(P_m - P_a)$ acting with mv.

$$F = mv + A(P_m - P_a) \text{ gross rocket thrust.}$$

The net thrust would require air drag to be deducted from this force, also a gravitational component in some cases.

If the nozzle expands the jet to atmospheric pressure $P_m = P_a$ then $F = mv$. This is often cited as the thrust equation of true rockets. The same can be obtained from an energy analysis. The original kinetic energy of mass mt, t being time, and the realized heating value Q that creates the velocity v in that mass are, together, equivalent to the thrust work Fut plus the residual energy existing at the final absolute speed of $v - u$. Written symbolically,

$$\tfrac{1}{2}mtu^2 + \tfrac{1}{2}mtv^2 = Fut + \tfrac{1}{2}m(v - u)^2$$

this becomes, as before,

$$F = mv.$$

The efficiency of propulsion for a fixed jet velocity, v, and variable rocket speed, u, is given by the equation

$$\eta = \frac{2uv}{v^2 + u^2}.$$

Hence it appears that, theoretically at least, the thrust remains constant, but efficiency of use of the energy developed by combustion increases with u until it becomes 100% when $u = v$, thereafter falling off as u is increased above v.

In a jet engine the fuel is carried in the vehicle which the engine propels, but oxygen is secured by taking in air from the surrounding atmosphere. As very high air-fuel ratios are employed in combustion jet engines, a good approximation, with simplifying features, is to neglect the mass of the fuel and consider that heat only is added to the air passing through the engine.

A much simplified diagram of the engine in Fig. 3 is illustrative of jet propulsion in any fluid which may

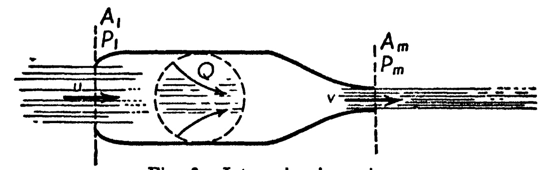

Fig. 3. Jet engine inversion.

somehow or other be accelerated as it passes through the engine. Although, in reality, the engine moves forward through a stationary fluid with a velocity of u, it is sometimes convenient to "invert" the relative velocities and consider the engine at rest in a fluid stream moving at velocity u past it. The region enclosed by the dotted boundary contains whatever means may be employed to accelerate the fluid flow from u to v. For example, this would consist of the compressor, burner, and exhaust nozzle of a turbo-jet airplane engine. Or it would be the fuel injection and combustion apparatus of the Athodyd which is a simple but intriguing jet engine using only air ram for compression.

Jet propulsion is secured as follows from the combustion jet engine. Let m be the mass per sec. of the air involved. As seen in Fig. 3, air rammed into the entrance scoop comes to rest, producing a ram pressure at the entrance of P_1. After fuel heat Q is added to it there is an expansion producing velocity and causing a jet to be expelled from the mouth of the nozzle at velocity v relative to the engine. Let P_m be the gas pressure at exit, A_m the area of the nozzle there, A_1 = area of entrance, and P_a = atmospheric pressure; then the thrust $F = mv - mu + (P_mA_m - P_1A_1) + P_a(A_1 - A_m)$.

When the engine is in motion through still air the energy it receives in t time is Fut. The residual, or unused, energy is $\tfrac{1}{2}mt(v - u)^2$. Efficiency being useful energy divided by useful energy plus losses,

$$\eta = \frac{Fut}{Fut + \tfrac{1}{2}mt(v - u)^2}.$$

Monographs by different authors are found to interpret this equation differently, depending on their assumptions regarding the PA terms of the expression (above) for thrust F. Assuming that $P_m = P_1 = P_a$, ideally,

$$\eta = \frac{2(uv - u^2)}{v^2 - u^2}.$$

In the case of Athodyd the engine action is principally an expansion of gases at constant (ram) pressure, making $v = u$ and causing A_m to exceed A_1.

No mechanical means of compression is furnished. If Athodyd has a speed of u, a dynamic pressure increment ΔP can be built up in the Athodyd body by air ram. Fuel is burned so that a velocity v equal to u will exist at the mouth. Since $v = u$ no momentum change is involved and thrust is derived from static pressure. The equation given above for F becomes $F = \Delta P(A_m - A_1)$ when $P_1 = P_a + \Delta P = P_m$ and $v = u$. As residual velocity $(v - u)$ is zero, the efficiency of Athodyd, operating under the assumed conditions, is 100%.

The thrust of the compression jet engine is mv at standstill, and decreases by the term m as velocity is increased. Athodyd has zero thrust until some dynamic pressure $\frac{\rho u^2}{2}$ exists.

It has been proposed that marine vessels, in particular submarines, be propelled by the reaction obtained by im-

parting a high velocity to a quantity of water taken in through a lengthwise duct, then discharged rearward.

Some cases illustrating reaction propulsion are:

1. The skyrocket.
2. War rockets (Bazooka, etc.).
3. Liquid fuel rockets (V-2).
4. Jet engines for airplanes.
5. Resonance jet (Buzz bomb). (F.T.M.)

JET, STEAM. A jet of steam is produced by the expansion of steam from a higher to a lower pressure. Almost always, the character of expansion is a close approximation of the adiabatic at constant entropy since nozzles neither impart nor remove heat from the steam flowing through them. The nozzle may be carefully shaped based on the theory of compressible flows through nozzles, or it may be a crude nozzle such as a small bored hole in a plate. The less perfect the **nozzle,** the lower the steam jet velocity will be and the more uncertain the jet direction. Steam is so light in weight per unit volume and its jet velocity usually so large that the effect of gravity on the path of the jet is negligible, so the axis of the nozzle determines the position of the jet for a considerable distance from the nozzle mouth.

The ideal velocity of a steam jet resulting from an adiabatic expansion may be calculated from the principle of conservation of energy. If 1 lb. of steam in expanding through a nozzle (which it approached at a velocity of V_1) suffers a change of enthalpy of Δh B.T.U., and if conditions of expansion are ideal, namely, no friction, turbulence, over-or-under-expansion, or supersaturation (see **Supersaturated vapor**), the jet velocity V_2^2 will be:

$$V_2^2 = 224\sqrt{\Delta h} + V_1^2.$$

This is derived by equating the loss of enthalpy to a gain in kinetic energy. Actual jet velocity approaches closely the ideal.

Although of low density, steam jets may represent great power because of extremely high velocities which may be produced with moderate pressure drops. The power of steam jets is put to use in numerous ways. **Steam turbines** are machines for producing jet power, then absorbing it on blades which, in turn, produce power as a rotating torque at a shaft to which the blades are indirectly attached. Certain refrigerating apparatus uses steam jets for compression, as do also ejectors for evacuating air from regions of high vacuum. Steam jets are the source of power for **injector** pumps and are often used for blowing and cleaning operations. (F.T.M.)

JET, WATER. A jet is a rapidly moving fluid stream launched into space from a **nozzle, orifice,** or other mouthpiece. The velocity of the jet is obtained from a pressure drop in the fluid as it passes the orifice or nozzle. The water jet will attain a theoretical velocity of $\sqrt{2gh}$ ft. per sec. (g = acceleration of gravity) when it is produced by an effective pressure head of h ft. of water. The actual jet velocity is 1 or 2% less than the theoretical.

A jet of water discharged horizontally follows a downwardly curved path on account of the attraction of gravity. The path taken by a freely spouting jet, initially discharged in a horizontal direction under head h is closely approximated by the parabola $x^2 = 4hy$, in which y is the drop of the jet below the level of the nozzle at a distance x horizontally out from the nozzle.

A water jet of A sq. ft. cross-sectional area moving at v ft. per sec. contains energy at a rate equivalent to 566 Av^3 horsepower. To obtain this power from the jet a machine would have to bring the water to rest without friction or turbulence. Impulse **hydraulic turbines** recover about 70% of the available power by deflecting the jet with blades or buckets mounted on the rim of a rotating disk. The force acting on a blade which deviates a jet of water through a velocity change of Δv is $\frac{62.4\Delta v}{g}$ lbs. per cu. ft. of water per sec. flowing. Δv may be a change in magnitude, a change in direction, or both. (F.T.M.)

JETTY. A jetty is a form of hydraulic works employed to control currents, sand bars, and shoals for the benefit of navigation. These are structures of rock, concrete, piling, or brushwork, made in the form of a long narrow dyke, and placed in accordance with the particular requirements of the installation which might be control of silt through maintenance of current, or control of waves or currents which might tend to produce sand bars. Sometimes jetties are in pairs, one on each side of the current, to confine and direct it, though single jetties are also useful in certain locations. The most famous jetties of the United States are those of the lower Mississippi, which serve to maintain the ship channel through the Mississippi Delta. (F.T.M.)

JEWFISH. Pisces, Teleostei. The giant **sea bass,** *Stereolepis gigas,* a game fish of the California coast which reaches a weight of 500 lbs. The name is also applied to other fish. (A.W.L.)

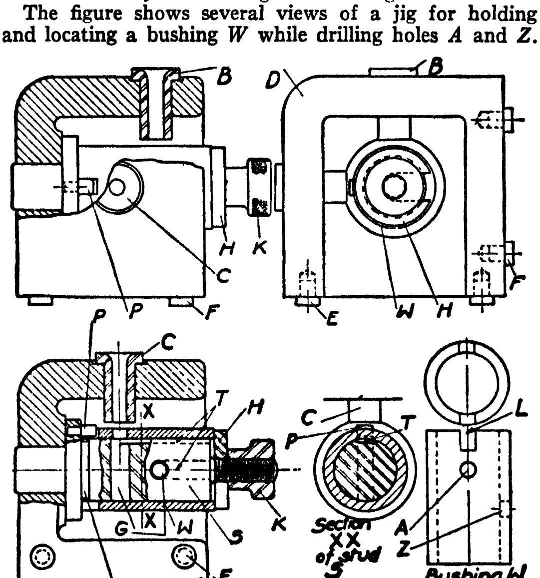
JIG BORER. A vertical-spindle boring machine for accurately boring and locating holes. It is similar in principle to an upright drill press, but is equipped with a table and a saddle similar to a milling machine so that perpendicular motion in a horizontal plane may be obtained for locating the work. The table and saddle may be positioned to within .001″ by means of accurate lead screws fitted with indicating dials, but for more accurate work end measuring rods are used to precisely position the work. A rotary indexing table which may be tilted to bore holes at various angles is also available. (See **Boring.**) (H.C.H.)

JIGGER. **Chigger.**

JIGGING. **Classification.**

JIGS AND FIXTURES. Jigs and fixtures are as important in modern manufacturing and mass production processes as cutting tools and machine tools. A jig is a device used in the manufacture of interchangeable parts to hold and locate the work and to guide the cutting tool. A fixture is a similar device, but is used only for holding and locating the work.

The figure shows several views of a jig for holding and locating a bushing W while drilling holes A and Z.



The jig has a cast iron frame *D* into which a hardened steel stud *S*, for supporting the work, is pressed. *S* has a large integral collar, with a chip recess *R* at its juncture with the body of the stud, into which a locating pin *P* is pressed. *P* fits the slot *L* in the work and serves to locate *L* with respect to *A* and *Z*. The work is held in place during the drilling operation by a horseshoe washer *H* and a knurled nut *K*. *K* is slightly smaller than the bore of *W* so that the work may be removed by giving *K* a fraction of a turn, taking off *H*, and sliding the work over *K*. The drills are guided by drill bushings *B* and *C* which are pressed into *D*. Drill bushings are made of tool or high-carbon steel, glass-hard, and lapped for a snug fit with the drill. They have a wide bell-mouth at the top so as to facilitate entry of the drill. The jig is supported on four feet *E* and *F* on each of two sides; the feet are made of case-hardened common steel and are pressed into holes in *D*.

In operation, the operator places a blank *W* on *S*, slips *H* in place and clamps *W* with *K*. He then places the jig on the drill press table resting on feet *F* and brings the drill down. If the jig is not perfectly aligned with the drill, the contact of the drill with the bell-mouthed hole in bushing *C* will move the jig sufficiently to permit entry. Hole *A* is drilled, the drill is withdrawn, and the jig is turned over so that it rests on feet *E*, and the drilling procedure is repeated for hole *Z*. The operator then removes the work and the cycle is complete. The stud *S* is provided with two grooves *T*, which permit easy removal of *W* even though the drilled holes have burrs resulting from the operation. The clearance holes *G* in the stud permit the drill to go completely through the wall of the bushing and provide a place for chips.

It is often more convenient and economical to purchase commercially available parts such as drill bushings, assembled clamping devices, skeleton drill jig frames, jig feet, and similar parts, and fabricate drill jigs by assembling these parts, rather than to completely build the entire tool. Several commercial jigs are available at present.

File jigs are used as templates for filing parts to shape and size. In its usual form, a file jig consists of a hardened steel plate with a beveled gauging edge, with some means for attaching the jig to the work. The operator locates the jig on the piece to be filed, clamps both in a vise, and files the part to the gauging edge. File jigs are employed for parts difficult to mill, and also in cases where the quantity of pieces required does not warrant the expense of a special milling cutter.

Milling fixtures are used for locating and holding work and are similar to drill jigs, but have no media for guiding the cutting tool. Fixtures are usually fastened rigidly to the table of a milling or boring machine; adjustment for position is generally made by moving the machine table.

Comparatively inexpensive milling fixtures can be made by fitting a milling machine vise with false or substitute jaw plates for locating and holding the work. The jaw plates supplied with the vise are removed, the false jaws substituted, and held in place with the jaw screws. When more than one part is to be held at the same time, equalizing or self-adjusting clamps are fitted to the false jaws. (H.C.H.)

JIMSON WEED. **Potato Family.**

JOINT, ANATOMICAL. In anatomy, a joint is a connection between rigid units of the **skeleton.** Joints are of two types, movable and fixed. The latter (synarthroses) provide for the formation of firm skeletal structures where more than one rigid part is involved, and movable joints (diarthroses) enable the separate divisions of the body and jointed appendages to act together as systems of levers, moved by muscles.

In the **arthropods** separate hard parts of the exoskeleton are known as sclerites. Since they are merely plates developed in a continuous tissue the flexible regions of the integument between them serve as connections. These joints are known as sutures and vary from well-marked and freely movable to completely obliterated unions. Where the principal sclerites of a segment unite along the sides of the body and between the sclerites of adjacent segments the unions are called conjunctivae. At the attachment of the segments of legs to each other and the articulation of legs and wings with the body the same principle prevails. The union of an appendage with the body is sometimes supplemented by small articular sclerites.

In the fixed joints of **vertebrates** the bones are united by tough **connective tissue**, including many white fibers which continue into the substance of the bone, or by a zone of cartilage (synchondrosis).

Movable joints of vertebrates develop in continuous tissue between the ends of the bones. The tissue splits to form a closed joint cavity filled with synovial fluid and surrounded by a connective tissue capsule. In this capsule a fibrous layer continues into the periosteum covering the bones. It is thickened in places to form the strong ligaments that bind the ends of the bones together. Folds or plates of fibrous tissue project into the cavity, forming articular disks and menisci, as in the knee joint. The entire cavity is lined with a looser layer of the capsule except at the ends of the bones, where articular cartilages are exposed to the **synovial fluid.** (See **Joint, Geological.**) (A.W.L.)

JOINT EFFICIENCY. This term refers to a strength ratio in connection with either riveted or welded joints. The joint efficiency is defined as the ratio of the strength of a section of the joint to the strength of an analogous section of solid plate. The joint efficiency, in pressure vessel design, usually requires an increase in the theoretical thickness of the plate which would otherwise be required for a seamless vessel. To illustrate, if the theoretical thickness of a seamless vessel, for a given set of conditions, is 1", the same vessel with a welded joint having an efficiency of 80% would require a wall thickness of $1\frac{1}{4}$". Welded joint efficiencies vary from 55 to 95%; riveted joint efficiencies from 45 to 95%. (H.C.H.)

JOINT, GEOLOGICAL. In geology, a joint is a fracture in a rock with no apparent relative displacement as in the case of a **fault.** Fractures are exceedingly common in all types of rocks and are frequently arranged in definite relation to each other, such as to produce joint systems more or less constant over considerable areas. Depending on the supposed cause of a given joint system the fractures may be described as tension joints, or compressional joints. In **igneous rocks** a set of joints may be developed by contraction during their period of cooling and solidification within the earth's crust. Igneous rocks, after complete solidification, may later have sets of tension or compression joints superimposed on the first set by the relief of pressure, due to the **erosion** of the overlying formation, or to insolation or frost action after the removal of the overlying formations. Joints are of great importance in quarrying and all operations which require the removal of bed rock. Well-jointed rocks are relatively easily taken out and split into smaller blocks for various constructional purposes. (See **Joint, Anatomical.**) (R.M.F.)

JOINTER. **Woodworking.**

JOINTWORM. Insecta, Hymenoptera. Small **insects** whose larvae work in the stems of grains and grasses, sometimes causing swelling at the joints or the forma-

tion of growths. Their work may weaken the stem and cause it to break. (A.W.L.)

JOIST. **Floor Beam.**

JOLY SCREEN. **Bench Photometers.**

JOMINY TEST. **Hardenability of Steel.**

JOULE. The M.K.S. absolute unit of **work** and **energy**, equal to one meter-newton, or to 10 ergs. It is roughly ¾ of a **foot-pound.** The "international joule" is defined in terms of the international **ampere** and the international **ohm.** (See **M.K.S. System; Watt.**) (L.D.W.)

JOULE'S LAW. The law commonly referred to by this name expresses the quantity of heat generated by a steady **electric current** as proportional to the **resistance** of the conductor in which the heat is generated, to the square of the current, and to the time of its duration: $H = KRI^2t$. If the resistance is in ohms, the current in amperes, the time in seconds, and the heat in calories, the constant K has the value $0.2388 \frac{\text{calories}}{\text{joule}}$. For example, an electric grill of 22 ohms resistance, operated at 110 volts, carries 5 amperes. In 10 minutes, therefore, the quantity of heat generated is $0.2388 \frac{\text{calories}}{\text{joule}} \times 22 \text{ ohms} \times 25 \text{ amperes}^2 \times 600 \text{ sec.} = 78{,}800$ calories; this amount would heat a gallon of water about 37° F. In electric power distribution systems much energy is wasted through heating of conductors, which, because of the form of the above equation, is often called the "RI^2 loss."

Another, although less familiar, law due to Joule states that in an ideal or perfect gas (see **Kinetic Theory** and **Ideal Gas Law**), the "internal energy" does not change during any process such as compression or expansion unless there is a change in temperature. That this statement is not strictly true of actual gases was demonstrated by Joule himself (see **Joule-Thomson Effect**). (L.D.W.)

JOULE-THOMSON EFFECT. A result observed in the so-called "porous plug experiment," performed by Joule and Thomson (Lord Kelvin) in 1852. Some years earlier (1844) Joule had tried liberating a compressed gas into a vacuum. He sought for a possible cooling of the gas as a whole as the result of work against intermolecular forces, but found none.

This was probably because his thermometer was not sufficiently sensitive. With Kelvin he later arranged an apparatus to pump gas slowly and steadily through a plug of cotton, carefully insulated against thermal conduction. The gas, before entering the plug, was maintained at strictly constant pressure and temperature, the energy being furnished entirely by the pump and not at the expense of the internal energy of the gas. Hence, unless there were other energy transformations than that involved in working against the constant (atmospheric) pressure beyond the plug, the gas merely served as a means of conveying energy from the pump to the outer atmosphere and should not change temperature at all, even though it expanded during its passage through the plug.

But in most cases there was a slight fall of temperature, proportional to the pressure difference on the two sides of the plug; with hydrogen at ordinary temperatures there was a slight rise of temperature. The cooling is taken to mean that expansion of a gas usually involves work against intermolecular attraction. Why hydrogen shows the opposite effect is not so clear; it is possibly due to an intermolecular repulsion. At higher temperatures, hydrogen behaves like other gases, while at sufficiently low temperatures and high pressures other gases behave like hydrogen. The data obtained from these experiments have served to give the exact relation between the standard gas thermometer scale and the Kelvin thermodynamic scale. (See **Temperature Scales.**) (L.D.W.)

JOURNAL BEARING. **Bearings.**

JULIAN DAY. In making calculations involving long intervals of time the use of the **calendar** date and hours, minutes, and seconds introduces both confusion and ambiguity. To avoid these difficulties astronomers have adopted a system of chronological reckoning using merely the mean solar day as a unit. According to a system first proposed in 1582, at the time of the adoption of the Gregorian Calendar, a date is expressed as the number of days elapsed since the beginning of an arbitrary "Julian Era," January 1, 4713 B.C. On this system of reckoning the use of hours, minutes, and seconds is eliminated by expressing the instant of occurrence of an event as a decimal part of a day, the day being assumed to begin when the mean sun is at upper culmination (mean noon) at Greenwich, England. On this system of reckoning an event which occurred at 2 hr. 43 min. 34.6 sec. P.M., eastern standard time, on January 24, 1937, would be recorded as occurring at J. D. (Julian Day) 2,428,558.32193. The Nautical Almanacs of the various governments give tables for converting any date to the proper Julian day number. (W.K.G.)

JUMPING HARE. Mammalia, Rodentia. A burrowing animal, *Pedetes caffer,* of the South African deserts. Its fore quarters are much like those of rabbits and the ears are long, but the tail is long and bushy like that of a squirrel and the hind legs are much larger proportionately than those of rabbits. It runs on the hind legs alone. (A.W.L.)

JUMPING MOUSE. Mammalia, Rodentia. Small mouse-like **rodents** with very large hind legs and long tail. They differ from the kangaroo mice in the absence of cheek pouches. Several genera, one Asiatic. Related to the jerboas of the Old World. (A.W.L.)

JUMPING PLANT LOUSE. Insecta, Homoptera. A small sucking **insect** which lives on plants. Family Chermidae. The numerous species include several of economic importance, among them the pear-tree psylla. Spraying with kerosene emulsion or nicotine sulfate is recommended as a check for this insect and the adults may be destroyed in winter by scraping off and burning the rough outer bark of the trees. The cylindrical galls on the leaves of hackberry trees are caused by another species. (A.W.L.)

JUMPING SHREW. Mammalia, Insectivora. Small African animals of several species, all with prolonged snouts and large hind legs. (A.W.L.)

JUNCO. Aves, Passeriformes. *Junco.* Small North American birds (**Aves**) of several species, mostly colored in shades of gray and white. They breed chiefly in colder regions and in higher altitudes, migrating to the

Junco. *Junco hyemalis.* Slate gray above and on the throat and breast. Belly white. Outer tail feathers white.

valleys and to more southern latitudes, although they thrive even in cold winters. (A.W.L.)

JUNE BUG. Insecta. A common name for the **May beetles**, large brown scarabaeid beetles whose larvae are the common white grubs of the garden. Applied along Lake Erie to the May flies. (A.W.L.)

JUNGLE FOWL. Aves, Galliformes. Wild game birds (**Aves**) of India and other parts of the Oriental region. One species, the red jungle fowl, is ancestral to the domestic game cock and resembles it in color. The jungle fowls are supposed also to be remotely ancestral to all domestic fowls. (A.W.L.)

JUPITER. (See tables of planetary data, page 1109.) Jupiter, the "giant planet," is the fifth of the major **planets** in order of distance from the sun. Whether we consider bulk or mass, Jupiter is truly a giant planet, for it is larger than all of the other planets combined in both of these characteristics, having a volume more than 1300 times that of the earth and a mass nearly 317 times the earth.

In spite of its great distance from the sun, the huge surface area and high **albedo** reflect a large amount of sunlight, with the result that the planet appears as one of the brightest objects in the night sky, being exceeded only by the **moon** and **Venus.** In a telescope Jupiter is a most interesting object, showing a distinct flattening at the poles of rotation, and reddish bands parallel to the planet's **equator.** With a large **telescope** and moderately high **magnifying power** a wealth of detail may be seen on the surface. Most of these markings are only semipermanent and drift about over the surface to a considerable extent.

The rotation period of the planet has been determined from these surface features and found to be the most rapid of all of the major planets, completing one rotation in slightly less than 10 hours. The rotation period varies with **latitude** on the planet, being the most rapid at the equator and diminishing toward the poles.

The semipermanent character of the surface features, the variation in rotation period in different latitudes, the high reflecting power, and the low mean density (0 242 that of the earth) indicate that the planet probably has a relatively small solid core, surrounded by a very thick layer of **atmosphere.** The characteristics of this atmosphere have been the subject of a large amount of research, particularly within recent years. The modern results all indicate that the atmosphere consists largely of ammonia and methane. The temperature of the surface of the planet is too low to be accurately measured, but theoretical studies, based on the distance of the planet from the sun and its reflecting power, indicate that the temperature is in the vicinity of 133° K. (−207° F.). At temperatures of this value and under the calculated pressure of the atmosphere the ammonia gas would be in unstable condition and would be continually condensing and evaporating. This leads to the conclusion that the semipermanent markings seen on Jupiter may well be clouds of droplets of ammonia.

Jupiter has 11 known **satellites,** four of which are easily visible with a pair of field glasses. The watching of the constantly changing apparent positions of these objects as they revolve about Jupiter forms an interesting program for those possessing moderate telescopic equipment. These four satellites were probably the first celestial objects ever "discovored," having been found by Galileo shortly after he completed his first telescope and applied it to astronomical observations in 1610. In size and mass the so-called Galilean satellites are comparable with our own moon, the inner two having diameters very close to that of our own moon while the outer two are half as large again. The planes of the orbits of these inner satellites are so nearly in the plane of the orbit of Jupiter that they pass within the shadow of the planet or cast a shadow on the surface of the planet at practically every revolution. Observations of the times of eclipse or **occultation** of these Galilean satellites led to the first determination of the finite velocity of light. The other seven satellites of Jupiter are too small and faint to be observed except with the largest telescopes, and even with such instruments the outer four can only be observed photographically. Their motions are subject to tremendous **perturbations** by the inner satellites and the analysis of their motions forms a complicated problem in celestial mechanics which has never been completely solved. The three outer satellites revolve about the planet in **retrograde** sense. (W.K.G.)

JUPURA. **Kinkajou.**

JURARA. Reptilia, Testudinata. The giant **tortoise,** *Podochemis expansa,* of the Amazon River basin. (A.W.L.)

JURASSIC PERIOD. A major subdivision of the **Mesozoic Era** of the geologic time-scale. Type locality, the Jura Mountains, Switzerland. The formations of this system were first studied in the south of England by William Smith, the father of **stratigraphy,** and the period was named by A. Brongniart in 1829. The Jurassic period began approximately 150,000,000 years ago and lasted for 40,000,000 years. In North America the formations of this system are best exposed on the Pacific Coast, where they occur both in the Rocky Mountain and Pacific **geosynclines.** No upper Jurassic strata are known to occur in eastern North America. **Aeolian** "Red Beds" of Early and Middle Jurassic age occur in the western interior and are especially well exposed in the Colorado Plateau. Marine Jurassic formations occur in the Arctic, also Africa, South America, Australia, New Zealand, Asia, the Himalayas, and Japan. The principal economic products of Jurassic age are: **gold** (Sierra Nevada), **coal,** and lithographic **limestone** from Solenhofen, Bavaria. Plant life during this period was essentially like that of the Triassic. Among the marine invertebrates the **pelecypods** and **cephalopods** are the most important fossils. Sharks and the modern type of fishes were abundant. The complete adaptive or radial evolution of the reptiles (Saurians) during this period is proved by the fossil skeletons of Ichthyosaurs (fish lizards), Plesiosaurs (marine lizards), Teleosaurus (ancestral crocodile), Pterosaurs (flying reptiles) (see **Fossil Reptiles**); and a number of terrestrial herbivorous and carnivorous **dinosaurs,** such as Diplodocus, Stegosaurus, Ceratosaurus, and Allosaurus. Perhaps the most famous fossil of this or any other geologic period is Archaeopteryx, the "missing link" between the reptiles and the birds. Severe crustal deformations occurred near the close of the Jurassic, especially in the Cordilleran region, with the birth of the Sierra Nevada and the Cascade Mountains. These mountain-building movements, which typify the close of the Jurassic Period in North America, are referred to as the Sierra Nevada Revolution. (R.M.F.)

JUTE. Jute is a fiber obtained from *Corchorus capsularis* and *Corchorus olitorius* (Tiliaceae), largely grown in India. The plants are woody, sparsely branched annuals growing 10–12′ in height, with ovate **leaves** and yellowish-white flowers. The phloem fibers are developed in the inner bark. In India the plant is grown mainly in the rich soil of river valleys, and cultivated by human labor. Harvesting, also by hand, is done 4 or 5 months after planting. The plants are pulled up, the roots and tops removed, and the stems tied in bunches and immersed in water for 2 or 3 weeks, during which time "retting" occurs, so that the fibers separate more or less easily from the remaining tissues. The stalks, still in water, are then pounded with mal-

lets, rinsed thoroughly, and wrung until the non-fibrous material is removed. After this the fibers are hung up to dry. The fibers are yellowish-white and lustrous, soft and without great strength. It is the cheapest textile fiber in use today and is used in immense quantities, cotton alone outranking it. The chief use is in the manufacture of burlap, from which are made sacks used in packing potatoes, sugar, grain, etc. Burlap is also used as a backing for linoleum. Cheap brown twine is often made from jute. The principal drawbacks to an even wider use of jute are its brittle nature, lack of durability, and lack of resistance to moisture. Nevertheless, about ¾ of a billion pounds are used annually in the United States. (R.M.W.)

JUVENILE WATER. Geyser.

K

K SERIES. **X-Ray Spectra.**

KAGU. Aves, Gruiformes. A bird (**Aves**), *Rhinochetus jubatus,* of the island of New Caledonia, related to the sun bittern. It is about the size of a domestic fowl with longer legs and beak and a long drooping crest. (A.W.L.)

KAGUAN. **Flying Lemur.**

KAKA. **Parrot.**

KAKAPO. **Parrot.**

KAKAR. **Muntjac.**

KALIUM. **Potassium.**

KALONG. Mammalia, Chiroptera. The Malayan fox **bat,** *Pteropus,* largest of all bats, with a wing spread of 5′. (A.W.L.)

KAME. Irregularly shaped mounds and depressions associated with **terminal moraines.** A kame topography is usually the result of a rather mixed set of glacial conditions, including both stratified and unstratified **drift,** and frequent **kettle holes.** One peculiarity of the term is that it is never used for a single mound or depression but rather to designate the character and origin of the general kame type of topography found only in glaciated regions. (R.M.F.)

KANGAROO. Mammalia, Marsupialia. Pouched mammals of Australia and adjacent islands. The typical kangaroos, *Macropus,* have large hind legs and a strong tail. They sit upright and move by springy leaps, not

Kangaroo.

touching the front feet to the ground. The largest kangaroos reach a height of more than 6′ and a weight of 200 lbs.

Moderate and small-sized members of the group which resemble the true kangaroos in form are called wallabies. The rock wallabies, *Petrogale* and *Peradoreas,* differ in the slender tufted tail and the hare wallabies, *Lagorchestes,* are small animals with an evenly furred tail.

Tree kangaroos, *Dendrolagus,* have the hind legs only moderately large and the tail long and evenly furred. They are arboreal, as the name suggests.

The Australian rat kangaroos and the Tasmanian jerboa kangaroo resemble the animals for which they are named, although one of the rat kangaroos has a bushy tail.

All of these animals eat vegetation and some cause severe damage to crops. (A.W.L.)

KANGAROO RAT. Mammalia, Rodentia. Burrowing **rodents** of the western United States with long tufted tail and long hind legs. Related to the pocket mice and kangaroo mice. Several genera. (A.W.L.)

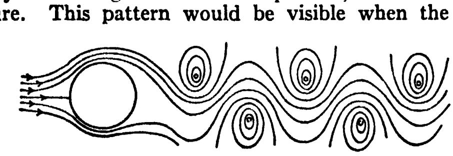
KANKA. A local Indian term for stone, which has been applied by some geologists to **concretions** of **calcium** carbonate that occur in otherwise unconsolidated sediments or **alluvium.** (R.M.F.)

KAOLINITE, KAOLIN. Kaolinite is the most common of a group of hydrous **silicates** of **aluminum** which result from the breaking down by weathering of mineral aluminum silicates such as the **feldspars, nephelite,** etc. Kaolinite when pure corresponds to the formula $H_4Al_2Si_2O_9$, and occurs in white, clay-like masses. Impurities may cause various colors or tints. Microscopic study shows kaolinite to be **crystalline** and **monoclinic;** it is also found, very rarely, in **hexagonal** scales. It has a perfect basal **cleavage;** is flexible but not elastic; hardness, 2–2.5; specific gravity, 2.6–2.63; luster, pearly to dull; color, white when pure, as described above, but may be yellow, red, blue, or brown; translucent to opaque. Kaolinite is a mineral of widespread occurrence, well distributed throughout the world. The finest kaolinite locality in Europe is said to be in France, from whence the clay is obtained for porcelain ware. Cornwall and Devonshire in England supply large quantities of this mineral. In the United States Pennsylvania, Virginia, Colorado, Georgia, and South Carolina contain deposits of kaolinite. The word kaolin or kaolinite is said to be a corruption of a Chinese word *kauling,* the name of a locality where this mineral is found. Kaolinite is very important commercially in the manufacture of china and pottery. (E.S.C.S.)

KAPOK. This is a downy substance obtained from the inside of the seed-pods of several species of trees known as silk-cotton trees. Its principal use is in pillows and mattresses and some types of life preservers. Java produces a large part of the marketed crop. (R.M.W.)

KARAKUL. The short, tightly curled wool of lambs of certain Asiatic breeds of domestic sheep. The lambs are killed very young to secure the most curly wool. The pelts are known as astrakhan or karakul, the latter term applying especially to those of better quality. (A.W.L.)

KÁRMÁN VORTICES. Within a certain range of **Reynolds number** the vortices in the wake of a **bluff body** are arranged in a definite pattern, as shown in the figure. This pattern would be visible when the body



was moved through fluid at rest. If the fluid moves past a stationary body, the observer must move with the fluid in order to see these vortices. The vortices

persist some distance downstream of the body, being finally dissipated by internal friction. At higher Reynolds numbers they disappear and the flow becomes completely irregular.

Although others had previously observed and studied the vortices, it remained for Th. Von Kármán to explain them as the only stable arrangement the vortices could assume within a limited range of Reynolds number. (F.T.M.)

KARYOLYMPH. Cell.

KARYOPSIS. Grass Family.

KARYOSOME. Cell.

KATABATIC WINDS. Cold-air drainage downhill toward lower terrain. In desert ravines katabatic winds locally reach high velocities. (P.E.K.)

KATABOLISM. Metabolism.

KATACLASTIC. Cataclastic.

KATAMORPHISM. Anamorphism.

KATER'S PENDULUM. Kater devised a number of rigid **pendulums** for comparing the accelerations of gravity at different places on the earth. Any pendulum of fixed length, carried from place to place, will swing in periods inversely proportional to the square root of the value of this acceleration, g, at the respective stations. Therefore if the pendulum has been timed at a station at which the value of g is accurately known, its period at any field station gives at once the value of g at that station.

Kater's best known pendulum is reversible, being provided with two knife edges, facing each other, and carefully adjusted to be at conjugate points with respect to each other. It follows that when such a pendulum is accurately timed, and the distance between the two knife edges accurately measured, the value of g can be calculated by using the formula for the period T of an ideal simple pendulum: $T = 2\pi\sqrt{\frac{l}{g}}$, or $g = \frac{4\pi^2 l}{T^2}$. When this is applied to the Kater's pendulum, l is taken as the distance between the knife edges. Such a pendulum can thus be used for absolute gravity measurements. (See **Gravitation and Gravity.**) (L.D.W.)

KATYDID. Insecta, Orthoptera. Large winged **insects** with long hind legs formed for jumping and very long slender antennae. They belong to the family of long-horned **grasshoppers.** The true katydid is found throughout the United States east of the Rockies and sings normally in three syllables which have been interpreted as ka-ty-did. Other insects of a different subfamily are commonly called katydids because of their similar appearance and habits. All of these insects are bright green and have leaf-like wings. A pink form of the katydid occasionally appears. (A.W.L.)

KAURI GUM. Resins.

KEA. Parrot.

KEBER'S ORGAN. Paired glandular organs of **bivalve** mollusks which serve as accessory organs of excretion. They are associated with the wall of the **pericardial cavity** or of the **auricles.** (A.W.L.)

KEEP-ALIVE. Mercury-Arc Tube.

KELP. Algae.

KELVIN SCALE. Thermometry.

KENNELLY-HEAVISIDE LAYER. Ionosphere.

KENOTRON. This is a high-vacuum diode rectifier **tube.** The tube contains a hot **cathode,** either filament or indirectly heated type, and an **anode.** Since electrons are emitted by the cathode and may be drawn to the anode when the latter is positive but the reverse process cannot take place, the tube will pass current in only one direction, hence serves as a rectifier. These tubes are extensively used for rectifying high-voltage alternating currents to produce high-voltage direct currents. They are used for the rectifiers in radio **receivers** as the noise introduced by gas-filled rectifiers would be objectionable. They are also used at high voltages where gas-filled tubes are not suitable because of **arc-back** difficulties. At intermediate voltages (up to a few thousand) the gas-filled rectifier is more generally used as it is more efficient. (L.R.Q.)

KEPLERIAN LAWS OF PLANETARY MOTION. After years of labor in attempting to develop a theory of planetary motion which would satisfy the accumulation of planetary positions determined by Tycho Brahe, Johann **Kepler** decided to abandon the superstition that the circle is the only perfect curve and hence must be followed by the planets. In the early part of the 17th century he announced three fundamental laws of planetary motion which satisfied Tycho's observations. These laws may be stated as follows:

1. Each planet moves in an ellipse with the sun at one focus.
2. The radius vector of each planet passes over equal areas in equal intervals of time. (The law of areas.)
3. The square of the period of revolution of a planet about the sun is proportional to the cube of the mean distance of the planet from the sun.

When first published, the laws were without theoretical foundation, being empirically derived from observational data. They created a tremendous stir and were declared heretical since they abandoned the circle as the only possible path for a planet. About 50 years later **Newton** was able to show that the laws are a direct consequence of motion under the action of the **law of universal gravitation.** It has also been shown that all types of **orbital motion** are characterized by these Keplerian laws.

The harmonic law as first stated by Kepler was independent of the masses of the bodies involved, but Newton was able to show that the masses are actually involved and obtained a more rigorous expression for it. Assume M_1 to be the mass of one body, M_2 to be the mass of the other, R to be the mean distance between the two bodies, P the sidereal period of revolution of one about the other, and K a numerical constant involving the constant of universal gravitation and we have: $K(M_1 + M_2) = \frac{R^3}{P^2}$. The masses of the planets are all inappreciable in comparison with the mass of the sun, and accordingly the expression $K(M_1 + M_2)$ is virtually a constant when considering the motions of the planets about the sun. In cases such as **binary star** orbits, and motions of **satellites** about primaries, the rigorous expression of the harmonic law is of immense value in the determination of masses of celestial objects.

While the development of the theory of relativity has necessitated slight modifications in the original laws of planetary motion, nevertheless, together with the law of universal gravitation, they form the basis upon which the entire structure of celestial mechanics and related fields rests. (W.K.G.)

KERATIN. A chemically complex material of which horns, nails, claws, hoofs, and the scales of reptiles, birds,

and mammals are formed. Hair and feathers also contain much keratin. It is present in the external layers of the skin, where it develops by the transformation of clear granules of keratohyalin of lower layers. (A.W.L.)

KERATOPHYRE. The name given by Gümbel, in 1874, to **felsitic** and **porphyritic** rocks resembling **hornfels**, and which occur in the Bavarian Alps. Later the use of the term was restricted to **porphyries** and **porphyrites** but differing from them by the abundance of **anorthoclase** instead of either **orthoclase** or the soda-lime feldspars. The term has also been restricted to rocks of this type which are pre-Tertiary in age. (R.M.F.)

KERATOSA. **Demospongiae.**

KERNITE. **Colemanite.**

KEROGEN. **Oil Shale.**

KEROSENE. **Hydrocarbons.**

KERR ELECTRO-OPTICAL EFFECT. **Electric and Magnetic Double Refraction.**

KERR MAGNETO-OPTICAL EFFECT. **Magneto-Optical Rotation.**

KESTREL. Aves, Falconiformes. A falcon of Europe and Asia. The common species is also called the windhover and a smaller related species is known as the lesser kestrel. (A.W.L.)

KETENES. **Aldehydes, Ketones, and Related Compounds.**

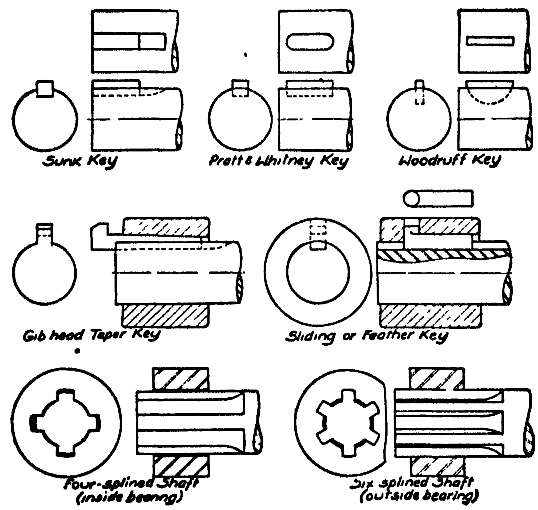
KETO-FORM. **Tautomerism.**

KETONES. **Aldehydes, Ketones, and Related Compounds.**

KETTLE HOLE. During the melting stages of the continental glaciers of the **Pleistocene Period** large masses of ice were imbedded in the stratified **drift**. The melting of these huge ice blocks resulted in the slumping of the loose material to form well-defined and steep-sided depressions. These depressions may be as much as 100′ deep and a mile or more in diameter, often containing small lakes, whose surfaces represent the level of the ground water in the surrounding glacial sediments. (R.M.F.)

KEUPER. **Copper-bearing shales.** (See **Triassic.**)

KEY. A machine element for preventing relative rotation. The sunk key is the commonest form, and must be carefully fitted to prevent rotation in the keyway, and consequent crushing or deformation. The Pratt and Whitney, or drop-seat key is applicable to conditions where the hub must move on the shaft and key, but the keyway must be end-milled. The Woodruff key fits in a semi-circular recess in the shaft, and automatically adjusts itself in instances where both the hub and shaft are tapered. The gibhead taper key will prevent both axial and rotative motion, since it is driven into place against a tapered keyway in the hub. It is usually equipped with a head, as shown, to permit withdrawal when required. The feather key is employed to prevent relative rotation but permits axial motion. It may be demonstrated that the axial force necessary to move a hub along a keyed shaft is twice as great when one key is used as when two or more keys are used. For this reason, and on account of strength considerations, multi-splined shafts are employed where shafts or hubs must move axially under load. Modern production methods have made it possible to machine both shaft and hole with comparative ease. (H.C.H.)



KEYING. This is the process of breaking up the telegraph currents or radio signals into the dots and dashes of the particular code used for transmission of intelligence. The keying may be done automatically by means of a prepared tape or other mechanism, or it may be done manually. There are two principal types of hand-operated keys, the conventional telegraph key consisting of a lever moved down by the hand and up by a spring and thus making and breaking the contacts, and the semi-automatic key or "bug." This latter is a sidewise operated device which is thrown to one side to transmit dashes, the length of the dash being determined by the time it is held in the dash position, and thrown to the other side to transmit the dots, these being transmitted automatically by the key mechanism and the number of dots being determined by the time the key is held to the dot position. This semi-automatic key is capable of faster operation, is less tiring to the operator and in the hands of a skilled operator transmits better formed characters than the conventional key. In telegraph circuits the keying consists of opening and closing a d-c circuit or of changing the polarity of the d-c circuit (see **Telegraphy**). In radio telegraph transmission keying is accomplished by interrupting the radio-frequency signal at some point in the **transmitter**, preferably at an intermediate or **buffer amplifier**. For break-in keying, i.e., where the receiving operator may operate his transmitter and interrupt the sending operator when desired, **oscillator** keying is used. This gives rise to some frequency shift unless the circuit is carefully designed. In any type of radio keying care must be exercised to prevent key clicks or slurring of the code characters. Key clicks are interfering signals in nearby receivers and are caused by spurious frequencies generated when the key makes and breaks the circuit too sharply. This may be avoided by introducing lag circuits (resistance, capacitance and inductance in various combinations) in the keying circuit. These lag circuits will destroy the sharpness of the code if overdone, however, so they must be adjusted for a compromise between key clicks and slurred characters. (L.R.Q.)

KEYWAY. **Key.**

KIANG. Mammalia, Perissodactyla. A wild ass, *Equus hemionus*, of Tibet and Mongolia, also called the kulan. (A.W.L.)

KIDNEY. The kidneys are the major organs of the **excretory system.** They are solid, glandular structures, lying on either side of the spine opposite the lumbar vertebrae. Their main functions are (1) the elimination of waste products, toxic materials, basic and nonvolatile acid radicals; (2) the maintenance of a constant volume of circulating blood and the regulation of the fluid content of the body as a whole; (3) the regulation of osmotic pressure relationships of the blood and tissues (see **Osmosis**); and (4) the maintenance of the optimum concentration of certain individual constituents of the plasma.

A kidney is composed of a **cortex**, or outer layer; medulla, or middle layer; and pelvis, the funnel-shaped sac which is continuous with the **ureter.** There are thousands of functioning units or nephrons in the kidney; these are made up of a glomerulus, **Bowman's capsule** (see **Renal corpuscle**) and convoluted, descending, ascending, and collecting tubules. The latter drain into the kidney pelvis. The glomerulus acts as a filtration mechanism and allows the passage of **plasma** deprived of its protein from the blood into the lumen of the tubules. Some 100 liters of plasma filter through the glomeruli each 24 hours. Since only 1.5 liters of urine are excreted daily, 98.5 liters of fluid must be reabsorbed. The tubules exert a selective action on the various materials present in the filtrate, reabsorbing almost completely substances like sugar, chloride, sodium, and bicarbonate, which are necessary to the body economy, and excreting waste substances like urea, creatinine and sulfate. Whether or not the tubules in addition secrete certain substances has not yet been established.

The kidneys are subject to a variety of disease conditions. Inflammation (**Nephritis**), infection (**pyelitis** and **pyelonephritis**), congenital defects, **tumors,** and stones are the more common. (D.M.H.)

KILLDEER. Aves, Charadriiformes. A North American **plover,** *Oxyechus vociferus,* named for its call. Breeds throughout temperature North America and winters as far south as northern South America. (A.W.L.)

KILLED STEEL. Steel deoxidized by aluminum, ferrosilicon, ferrotitanium, etc., so that there is little or no evolution of dissolved gases during cooling in the mold. Ingots of killed steel are relatively free from **blowholes** but have a large central shrinkage cavity or **pipe** unless a chamber of heat-insulating brick, called a hot top, is used to keep the top of the ingot molten and to feed the shrinkage cavity with molten metal.

Compared with **rimming** and semi-killed steels, killed steels are generally finer grained and tougher. In the case of low-carbon **drawing** grade sheets, killed steels are "non-aging"; that is, after **temper rolling** the tendency to form **stretcher strains** is permanently eliminated. (R.H.H.)

KILLIFISH. Pisces, Teleostei. Small fishes (**Pisces**) of fresh and salt water. The family Cyprinodontidae is known as the killifish family, and in it the genus *Fundulus* contains the typical killifishes. The common killifish is also called the mummichog. (A.W.L.)

KILOGRAM. Originally the kilogram was dependent upon the **gram** as the standard unit of **mass** in the **metric system.** The kilogram was simply 1000 grams, and the gram, in turn, was defined in terms of the centimeter and the density of water. Now, however, the kilogram is the standard, and the gram is defined as one-thousandth part of it. The primary standard kilogram is the mass of a cylinder of platinum kept in the archives of the French government at Sèvres. It was constructed with the object of duplicating and perpetuating the original gram in a form practicable for use; unfortunately, it was made too large by about 28 parts in a million. (See **Liter.**) (L.D.W.)

KILOWATT. A unit of **power**—defined as 1000 watts —which ordinarily serves as the commercial measure for electrical power. Electrical power of one kilowatt used steadily for one hour involves an energy consumption of one kilowatt-hour. A kilowatt is equal to about 1.34 hp. (F.T.M.)

KIMBERLITE. The name applied to a mica **peridotite** which occurs at Kimberley and other places in South Africa, the source of rich deposits of **diamonds.** These valuable **gem stones** were originally found in the decomposed kimberlite which, being colored yellow by limonite, was termed "yellow ground." Deeper workings disclosed the less altered rock, kimberlite, which the miners call "blue ground." (E.S.C.S.)

KINEMATICS. The physics of abstract motion, without regard to forces or bodies of matter, which are treated under **Mechanics.** Two aspects need special consideration: the motion of points and the motion of rigid figures. Whatever system of space coordinates is found simplest may be used, and may be transformed from one system to another as desired.

The motion of a point is completely specified by giving each of its three rectangular coordinates (for example) as a function of the time; that is, by writing its "equations of motion":

$$\left.\begin{aligned} x &= f_1(t), \\ y &= f_2(t), \\ z &= f_3(t). \end{aligned}\right\} \qquad (1)$$

In many cases the information represented by these equations is supplied only indirectly in the statement of a problem. For example, an expression may be given for the component of the linear **velocity** or the linear **acceleration,** as a function of either the time or the distance. In such case a differential equation is first obtained. Thus if it is specified that the X-component of the acceleration is constant and equal to a, the differential equation is

$$\frac{d^2x}{dt^2} = a; \qquad (2)$$

and the corresponding equation of (uniformly accelerated) motion is its solution,

$$x = \tfrac{1}{2}at^2 + v_0t + x_0, \qquad (3)$$

in which the integration constants x_0, v_0, stand respectively for the initial distance (value of x when $t = 0$) and the initial velocity. By eliminating t from the equations of motion (1) three geometric equations may be arrived at, one in x, y, one in x, z, and one in y, z, any two of which determine the path of the moving point in space.

Again, if the Y-component of acceleration is proportional to the coordinate y and of opposite sign,

$$\frac{d^2y}{dt^2} = -k^2y, \qquad (4)$$

may be written in which k^2 is a positive constant. The solution of this is

$$y = A \sin kt + B \cos kt, \qquad (5)$$

which is a general equation of **simple harmonic motion.**

A rigid 3-dimensional figure has six **degrees of freedom.** These require six equations of motion, which may, for example, express the three components of linear motion of the centroid of the figure with respect to the three rectangular axes, and the three components of angular motion or rotation about the same three axes. In such a case it is often convenient to use the notation

of vector analysis. It may be shown that any motion of a rigid figure is at any given instant equivalent to a linear motion of its centroid in some definite direction, plus a rotation of the figure about some definite axis through the centroid.

The laws and equations of kinematics are of constant service in problems of **kinetics.** (L.D.W.)

KINESCOPE. This is a **cathode ray tube** used as the picture tube in a **television** receiver. The signal representing the picture intensity is fed to the **grid** of the electron gun so the intensity of the beam varies with the intensity of the original scene. This variable beam is swept back and forth, up and down by deflecting voltages impressed on the deflecting plates and synchronized with the scanning of the camera tube (see **Iconoscope** and **Image Dissector**). The beam of electrons then hits the fluorescent end screen of the tube and reproduces the scene being televised. (L.R.Q.)

KINETIC ENERGY. The most obvious way in which a body can manifest **energy** is to be in motion. Experience impels us to get out of the way when we see a rapidly moving, massive object approaching. We know that the more massive it is, and the faster it moves, the more work (and the more damage) it will do when it strikes. A simple course of reasoning based on **Newton's laws of dynamics** leads to the formula $E = \frac{1}{2}mv^2$ for the kinetic energy (in absolute units) of a mass m moving with a speed v. Thus a stone of mass 100 grams moving with a speed of 1000 cm. per sec. has $\frac{1}{2} \times 100$ g. $\times 1000^2$ cm.²/sec.² = 50,000,000 g. cm.²/sec.² (or ergs) of kinetic energy. When the moving body is brought to rest by a force of average value f, and continues to move a distance, d, after this force is applied, it does an amount of work, fd, equal to its kinetic energy $\frac{1}{2}mv^2$. If d is very small, f must be large. Thus, if the stone in the above example were stopped in a space of 0.01 cm. (as in striking a hard obstacle), we should have 0.01 cm. $\times f$ = 50,000,000 g. cm.²/sec.², or f = 5,000,000,000 g. cm./sec.² (or dynes), which is equivalent to 5100 kilograms or more than 5.6 tons.

The kinetic energy of a body rotating with angular speed ω (radians per sec.) about an axis for which its moment of inertia is I, is $E = \frac{1}{2}I\omega^2$; or $2\pi^2In^2$, where n is the number of rotations per sec. The theory of **relativity** gives slightly higher values for the kinetic energy, but the differences are negligible except for very great speeds. (L.D.W.)

KINETIC THEORY. Many phenomena formerly attributed to unknown or hypothetical forces are now known to be due to the invisible motions of small particles, molecules, atoms, or electrons. Notable among these are gas and **vapor pressure, evaporation,** and **diffusion of fluids.**

Gases expand indefinitely when released, not because of repulsion between the molecules as formerly supposed (though the **Joule-Thomson effect** under certain conditions may involve this), but because the molecules are in rapid motion and do not stop unless they collide with something. Air is not "forced" out through a tire puncture; only those air molecules pass out which, in their aimless wanderings, happen to encounter the opening. Molecules also pass in from the outside; but since there are several times as many per unit volume inside as outside, many more pass out than in. This continues until, a statistical equilibrium being reached, the air inside is no more dense than that outside, and the tire is "flat." The rapidity with which this takes place emphasizes the speed of the molecular motion and the relative insignificance of the "internal friction" opposing it.

What appears to be a steady pressure is due to the incessant impacts of the gas molecules on any surface exposed to them. If n molecules of equal mass m are released in an enclosure of volume v, and if their speeds are $u_1, u_2, \cdots, u_n$, it is easy to show that the average pressure set up by these impacts, neglecting the effects of collisions and gravity, is

$$p = \frac{m}{3v}(u_1^2 + u_2^2 + \cdots + u_n^2). \qquad (1)$$

This may be written

$$p = \frac{1}{3}\frac{nm}{v}\frac{\Sigma(u^2)}{n};$$

or since nm/v is the gas density ρ, and $\Sigma(u^2)/n$ is the mean square molecular speed $\overline{u^2}$,

$$p = \tfrac{1}{3}\rho\overline{u^2}. \qquad (2)$$

This relation gives the mean square speed as $\overline{u^2} = 3p/\rho$; which is the square of the effective speed, corresponding to average kinetic energy. From this it may be shown that the average speed is

$$\bar{u} = \sqrt{\frac{8p}{\pi\rho}}, \qquad (3)$$

easily determined since p and ρ are measurable. (See **Maxwell Distribution Law.**) Again (1) may be written

$$pv = \tfrac{2}{3}(\tfrac{1}{2}mu_1^2 + \tfrac{1}{2}mu_2^2 + \cdots + \tfrac{1}{2}mu_n^2) = \tfrac{2}{3}E; \qquad (4)$$

in which E is the total kinetic energy of linear motion of the molecules. From this it follows that the absolute temperature T of the gas bears a constant ratio to this total kinetic energy, and hence to the average translational kinetic energy of the molecules. (See **Ideal Gas Law.**)

Further analysis shows that when gravity is considered, the pressure in an undisturbed pure gas of uniform temperature, at an elevation h, is given by

$$p = p_0e^{-3gh/\overline{u^2}} \qquad (5)$$

in which p_0 is the pressure at the zero of elevation. This is a form of Laplace's "law of atmospheres," useful in barometric altitude determinations.

A quantity much used in kinetic theory is the "mean free path," which is the average distance traversed by a molecule between collisions. There are ways of calculating this and also the effective diameters of molecules, and these data lead to many conclusions as to frequency of collisions, rate of diffusion, etc. (See **Brownian Movement.**) (L.D.W.)

KINETICS. This branch of physics deals with the effects of forces or of torques upon the motions of material bodies. There are separate articles on **Kinematics, Dynamics of Rotation, Moment of Inertia, Power, Centrifugal Force, Precession, Orbital Motion, Pendulums,** etc. The basis of this subject, so far as the classical theory is concerned, consists in **Newton's laws of dynamics,** which may be extended to include **d'Alembert's principle** of kinetic equilibrium.

The motions of a particle or of a rigid body may be either "free" or "constrained"; that is, it may be at liberty to move in any manner in obedience to the applied forces or torques, or there may be present material barriers which limit its linear motion to a certain path or surface, or its rotation to a certain axis Thus a projectile or a planet is free to travel and to rotate as it will; but a railway train must follow a fixed track, and a grindstone must revolve, or a **pendulum** must swing, about a fixed axis. These latter cases may be dealt with by considering that the barriers offer opposing forces or torques in equilibrium with those components tending to cause motion against them, and by treating as "effective" only those components acting in directions in which motion is permissible.

A simple problem of this type is that of a block of mass m sliding without friction down an inclined plane inclined at an angle α (see figure). Its weight mg (in which g is the acceleration due to **gravity**) is resolved into

components f and p, along and perpendicular to the plane, only the former of which is effective. This force $f = mg \sin \alpha$, acting on the mass m, gives it the constant

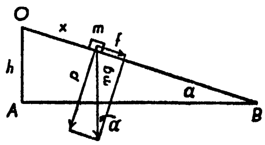


Fig. 1.

acceleration $a = f/m = g \sin \alpha$. Therefore the motion of the block along OB is expressed by

$$x = \tfrac{1}{2} g \sin \alpha \cdot t^2 + v_0 t + x_0, \tag{1}$$

in which $x = Om$, x_0 is the initial value of x, and v_0 is the initial velocity (see **Kinematics**). An interesting problem of constrained motion is to determine in what path from O to B the block would slide down in the least time; it turns out to be not a straight line, but a **cycloid**.

Many kinetic problems are greatly simplified by applying the conservation of **energy** principle. Thus for any path, the final speed of the block starting at O and sliding to B is $\sqrt{2gh + v_0^2}$, where h is the vertical height of O above B. This may be shown by using (1), as an equation of pure kinematics, with $x_0 = 0$ and $x = OB = h/\sin \alpha$. It is necessary first to solve the equation, which now takes the form

$$\frac{h}{\sin \alpha} = \tfrac{1}{2} g \sin \alpha \cdot t^2 + v_0 t,$$

for t, obtaining as the (positive) root

$$t = \frac{\sqrt{v_0^2 + 2gh} - v_0}{g \sin \alpha}. \tag{2}$$

Then the final speed is $V = at + v_0 = g \sin \alpha \cdot t + v_0$, which, using the value of t from (2), gives

$$V = \sqrt{2gh + v_0^2}. \tag{3}$$

But let us now use instead the fact that the kinetic energy at B is equal to that at O plus the loss of potential energy in descent through height h, which is mgh. The kinetic energy at O and at B are, respectively,

$$E_O = \tfrac{1}{2} m v_0^2, \quad E_B = \tfrac{1}{2} m V^2;$$

so that

$$\tfrac{1}{2} m V^2 - \tfrac{1}{2} m v_0^2 = mgh. \tag{4}$$

Solution of this gives at once

$$V = \sqrt{2gh + v_0^2},$$

which is the same as (3). The most significant feature of this is that the solution is here reached without considering the nature of the motion at all. Indeed, if a simple pendulum is pulled aside until the ball is at an elevation h above its lowest level and then given a push with initial speed v_0, it will attain the speed given by (3) as it descends to that lowest level; though no algebraic equation corresponding to (1) can be derived to describe its motion on the way down. The problem has thus become one of energetics rather than of kinematics.

Problems involving impacts or collisions are best handled by means of the principles of conservation of momentum and conservation of energy. In this way, for example, it may be shown that if an elastic sphere A strikes centrally a stationary elastic sphere B of greater mass, B will take part of the energy and momentum and A will rebound; if A and B are of equal mass, B will take all the energy and momentum and A will stop; while if A is more massive than B, B will take part of the energy and momentum and A will continue more slowly in its original direction.

By the use of d'Alembert's principle, problems of kinetics become equivalent to problems of statics. In case a body or a system is in frictionless, uniform rectilinear motion, in which there are no accelerations, classical dynamics introduces no element of the problem due to the motion; the situation is exactly as if the system were at rest. But with accelerations there develop what may be called "inertia forces," namely, the reactions opposing the forces causing the accelerations. If there is appreciable friction, that factor enters also as another opposing force.

Suppose a heavy boat is at rest in the water, in static equilibrium. Its mass is $m = 5000$ kilograms. A tow line begins pulling on the boat. When, at the end of 30 sec., the boat has attained a speed of 0.6 meters per sec., the force of water friction on the boat is 3 kilograms. It is desired to find the tension in the tow line at that moment.

We take the direction of motion as positive and let the required tension be f. The reaction force of inertia is negative and in gravitational units is equal to ma/g, where a is the acceleration. We then have the equation of equilibrium,

$$f + \text{inertia force} + \text{friction force} = 0$$

or

$$f - \frac{5000 \text{ kilograms} \times 0.02 \text{ meters/sec.}^2}{9.8 \text{ meters/sec.}^2} - 3 \text{ kilograms} = 0,$$

from which $f = 13.2$ kilograms. The last two force components enter just as if the boat were at rest and two other ropes were pulling backward on it, one with a force of 10.2, the other with 3 kilograms. The same principle applies, using vector addition, when the forces concerned are not collinear. (L.D.W.)

KINETOGENESIS. An evolutionary theory of E. D. Cope which assumes that animal structure is shaped by mechanical stresses due to movement. In relation to length of limb, stresses along the axes of the bones are supposed to have lengthened them whether these stresses were due to repeated impact against the ground as in the hoofed animals or to stretching as in the arms of the primates. (A.W.L.)

KING CRAB. **Xiphosura.**

KINGBIRD. Aves, Passeriformes. A large North American **flycatcher.** The most common species is found from the Atlantic to beyond the Rockies and is called the **bee martin** and tyrant flycatcher as well as the kingbird. This species and the several others found in the West and South are noisy and quarrelsome birds. (A.W.L.)

Kingbird, *Tyrannus tyrannus.* Dark slaty-gray above, with a concealed orange spot on the top of head. White below. Tail black, with a white band across the tip.

KINGFISHER. Aves, Coraciiformes. Birds (**Aves**) of many species, mostly with strong sharp beaks used for catching fish. Some species eat insects and reptiles more than fish and have broader beaks, hooked at the tip. One of the species, *Dacelo gigas*, with a broad beak lives in Australia and the Papuan Islands and has been named from its peculiar call the laughing jackass. Kingfishers are found on every continent. (A.W.L.)

KINGLET. Aves, Passeriformes. Very small birds (**Aves**) related to the gnatcatchers. The two North

American species are the golden-crowned, *Regulus satrapa,* and the ruby-crowned, *Corthylio calendula.* Both are grayish and olive with a bright crown patch. In the golden-crowned kinglet this patch is orange in the male and yellow in the female, and is concealed. In the ruby-crowned it is bright red and is exposed. It occurs only in the male. The goldcrest and firecrest of Europe are related species. (A.W.L.)

KINGSBURY THRUST BEARING. This is a special type of **babbitted** bearing for supporting large rotating masses, such, for example, as the principal bearing of a vertical shaft hydroelectric turbine. Very small frictional losses with large bearing pressure and high velocities are made possible by dividing the bearing surface into a number of pivoted segments which tilt in such a way as to scrape a wedge of oil between them and the rotating collar against which the bearing is mounted. (F.T.M.)

KINKAJOU. Mammalia, Carnivora. An animal, *Cercoleptes caudivolvulus,* related to the raccoons, which resembles the common cat slightly in appearance and has a long prehensile tail. It is yellowish-brown in color. The species ranges from central Mexico to Brazil. Also called jupura. (A.W.L.)

KINORHYNCHA. Minute worms, not exceeding 1 mm. in length, which live in sand and mud on the ocean floor. The body is made up of rings but the internal organs are unsegmented. They progress by thrusting out and retracting the head and sometimes adjacent segments.

The relationships of these animals are uncertain. They are sometimes included in the phylum **Rotifera** as a separate class. One order, Echinodera, is recognized. (A.W.L.)

KIPPER. A European name for the breeding male of the Altantic **salmon.** A cured (Yarmouth) herring. (A.W.L.)

KIRCHHOFF'S LAWS OF NETWORKS. Two laws relating to electric networks carrying steady currents. The general case is that of n points or junctions, each one of which is connected with each of the $n - 1$ remaining points by a conductor containing a source of electromotive force. Kirchhoff's two statements are as follows:

1. If conductors forming part of a network carrying a steady current meet at one point, the sum of the currents flowing toward the point is equal to the sum of those flowing away from it; or the algebraic sum of all the currents in these conductors is zero.

2. Starting at any one of the junctions of such a network and following any succession of the conductors which form a closed path, around either way to the starting point, the algebraic sum of the products formed by multiplying the resistance of each conductor by the current through it is equal to the algebraic sum of the electromotive forces encountered on the journey. (In this reckoning, we call all currents moving with us positive, and all electromotive forces tending to cause such currents positive.)

Maxwell has set forth a general method of calculating the currents and the relative potentials of the junctions when the resistances and electromotive forces in the several branches of a network are given. For a network of n points, this method involves the solution of $n - 1$ simultaneous, first-degree equations. The work is often simplified, however, by the circumstance that some of the conductors or some of the electromotive forces are absent. (L.D.W.)

KIRCHHOFF'S LAW OF RADIATION. Thermal Radiation.

KIROUMBO. Aves, Coraciiformes. A peculiar bird (**Aves**) of Madagascar and several similar species of other Pacific islands. Related to the rollers. (A.W.L.)

KISSING BUG. Insecta, Hemiptera. A name applied late in the 19th century to a supposedly deadly **bug** which was said to bite human beings about the face. It probably applies to some of the large predacious bugs of the family Reduviidae, commonly called **assassin bugs.** One species known as the big bedbug enters houses and sucks human blood, inflicting a painful but by no means dangerous wound. (A.W.L.)

KITCHEN MIDDEN. Primitive refuse pile of shells of edible **mollusks,** bones and implements, dating from the **Paleolithic** to the present. (R.M.F.)

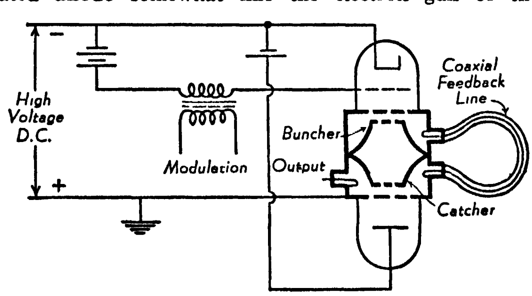
KITE. Aves, Falconiformes. Large birds (**Aves**) of prey related to the eagles. They are found on all continents. Three species, the swallow-tailed kite, *Elanoides forficatus,* white-tailed kite, *Elanus leucurus,* and Mississippi kite, *Ictinia misisipiensis,* occur in North America. (A.W.L.)

KITTIWAKE. Aves, Charadriiformes. *Rissa.* Marine birds (**Aves**) of the far north, resembling gulls. One species lives in the north Pacific and a second in all polar seas of the north. (A.W.L.)

KIWI. Aves, Apterygiformes. *Apteryx.* Stoutly built flightless birds (**Aves**) of New Zealand. The several species are all about as large as domestic fowls. They have strong legs, a long curved beak, slender hairlike feathers, and rudimentary wings which are concealed by the plumage of the body. (A.W.L.)

KLIPSPRINGER. Mammalia, Artiodactyla. A very small African **antelope,** *Oreotragus oreotragus.* It is an active and agile animal which inhabits rocky and mountainous country. The males have very short horns. (A.W.L.)

KLYSTRON. This is an electron **tube** of the velocity-modulated type used in **ultra high frequency** circuits. At these extremely high frequencies (measured in terms of hundreds or thousands of megacycles) the conventional **vacuum tubes** become useless because of lead and electrode inductance and capacitance, and transit-time effects, so a radically different approach is necessary. The klystron is one solution of the problem. This vacuum tube consists of a **cathode, grid** and perforated **anode** somewhat like the electron gun of the



Modulated klystron oscillator.

cathode ray tube (however, here the electrodes are grid-like structures rather than the cap with a single hole) followed by two **cavity resonators** separated a calculated distance and finally a collector. All electrodes except the collector have grid-like surfaces so the electrons can pass on through them. The beam of random-velocity electrons passing through the grid is accelerated by the positive potential applied to the first resonant cavity structure, causing this structure to serve

as an anode. These electrons pass through the grids into the cavity which is called the buncher. Here the standing waves in the cavity act on the electrons and cause them to change speed so they arrive at the second cavity, called the catcher, in bunches (having passed out of the first into a field free space and then into the second through the grids in the sides of the cavities). Here the energy of the electrons is absorbed by the field and contributes to the useful output and normally supplies also the driving energy for the buncher. The electrons then pass on to the collector and return to the cathode. By proper adjustment of the voltages and spacings of the cavities the circuit may be made to oscillate or amplify as desired. A circuit of a modulated klystron oscillator is shown. (L.R.Q.)

KNEE BRACE. **Bent.**

KNEE TOOL. **Turret Lathe.**

KNOT. In **navigation,** the term knot is used as an abbreviation for the phrase "**nautical miles** per hour." The use of this term started during the period when the **log** chip and line were used to determine the speed of a ship through the water.

It should be clearly understood that the word itself indicates a speed and, if a ship is moving through the water at a speed of 15 nautical miles per hour, the speed of the ship relative to the water is 15 knots. This should never be expressed as "15 knots per hour" since such a phrase means that the ship has an **acceleration** of 15 nautical miles per hour per hour.

The term knot is used for speed by the U. S. Navy and Merchant marine for both air and seaborne ships. It is also used by the ocean-going vessels of nearly all other nations. Because of the fact that the nautical mile is, by definition, closely related to angular measure on the surface of the earth, the knot is a far more convenient speed unit for use in **dead-reckoning** problems than is the statute **mile** per hour. (W.K.G.)

KNURLING. The process of forming a series of fine ridges upon the periphery of a circular part such as a screw head or knob to facilitate its rotation by hand, although knurling is often done for a purely ornamental effect. Knurling may consist of small, closely spaced ridges which are either at an angle to the axis of the surface of revolution or parallel with it like the milled edges of a coin. A knurling tool generally has a pair of rolls with diagonal teeth inclining in opposite directions, which are pressed against the unhardened work and rotate with it, thus forming small diamond-shaped projections on the surface of the work. (H.C.H.)

KOALA. Mammalia, Marsupialia. *Phascolarctos.* A curious pouched **marsupial** mammal of eastern Australia. It is much like the toy teddybear in appearance and is sometimes called the native bear. An arboreal animal. (A.W.L.)

KOEL. Aves, Cuculiformes **Cuckoos** of the Oriental and Australian regions. (A.W.L.)

KOHL-RABI. **Brassica.**

KOLM. The term applied to highly bituminous "coal-like" lenses which occur in the lower **Paleozoic,** alum-shales of Sweden. The ash of this "coal" contains a relatively high content of the **radioactive minerals** which have been used to determine the age of the formations in which they occur. (R.M.F.)

KONZI. Mammalia, Artiodactyla. An African **antelope** belonging to the hartebeest group. (A.W.L.)

KORIGUM. Mammalia, Artiodactyla. An **antelope** of central Africa, also called the Senegal antelope. One of the hartebeest group. (A.W.L.)

KORIN. Mammalia, Artiodactyla. A central African **antelope,** one of the gazelles. (A.W.L.)

KORSAKOFF'S PSYCHOSIS. **Ethyl Alcohol.**

KOSTINSKY EFFECT. A photographic effect discovered by the Russian, Kostinsky (1906). It was found that if two areas of high density, e.g., star images, are close together the restraining by-products formed in the process of development retard the development of the adjacent portions of the images so that the distance separating the two images is greater than is actually the case. The effect assumes considerable importance in astronomical photography. It is more marked with developers such as pyro which are greatly restrained by the oxidation products formed in development and less so by metol-hydroquinone, diaminophenol, and paraminophenol. (C.B.N.)

KRA. Mammalia, Primates. The crab-eating **macaque,** *Macacus cynomolgus,* a monkey of the Oriental region. (A.W.L.)

KRAIT. **Crait.**

KRENNERITE. **Sylvanite.**

KRYPTON. Symbol: Kr. Atomic number: 36. Atomic weight: 83.7. Density: 3.708 grams per liter, 0° C., 760 mm., or 2.87 when air is 1.00. Melting point: −157° C. Boiling point: −152.9° C. (**Isotopes:** page 290.)

Krypton is a colorless, odorless gas, of negative chemical properties with ordinary materials. Discovered by Ramsay and Travers in 1898, in ordinary air to the extent of 1 part krypton in about 1,000,000 air. (R K.S.)

KUDU. Mammalia, Artiodactyla. African **antelopes** of two species, the common, *Strepsiceros strepsiceros,* and the lesser kudu, *S. imberbis.* The males have long spiral horns. (A.W.L.)

KUMQUAT. **Citrus Fruits.**

KUNDT CONSTANT. **Faraday Effect.**

KUNZITE. **Spodumene.**

KURTOSIS. Kurtosis is a property of a distribution or **probability function** depending on its height or peakedness at the **mean** combined with the property of having a long or short tail at the extremities of the distribution. A measure of kurtosis is $\alpha_{4:x} = \frac{\mu_{4:x}}{\sigma_x^4}$, where $\mu_{4:x}$ is the fourth central **moment,** σ_x is the **standard deviation** of the distribution. If $\alpha_{4:x} = 3$, the distribution is said to be mesokurtic, if $\alpha_{4:x} > 3$ leptokurtic, if $\alpha_{4:x} < 3$ platykurtic. If a probability function is represented by a Type A **Gram-Charlier series,** consisting of terms up to and including $\phi^{(4)}(t)$, and if $\alpha_{4:x} > 3$, then such a function has a higher ordinate at the mean than the **normal curve.** Under the same conditions if $\alpha_{4\cdot x} < 3$, the distribution has a lower ordinate at the mean than the normal curve. If the distribution function is not representable by a Gram-Charlier Type A series, then $\alpha_{4:x} > 3$ does not guarantee that the distribution will have a higher peak than the normal curve. In the normal curve $\alpha_{4:x} = 3$. In Fig. 1 we have $\alpha_{4:x} > 3$, and $\alpha_{4:x} = 3$. In Fig. 2 we have $\alpha_{4:x} < 3$, $\alpha_{4:x} = 3$. (L.A.A.)

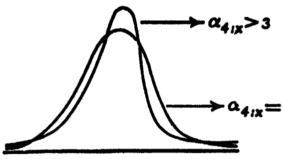


Fig. 1.

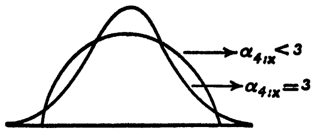

Fig. 2.

KYANITE. The mineral kyanite is an **aluminum silicate,** corresponding to the formula Al_2SiO_5. It is **triclinic,** and has a good **cleavage** parallel to the **macropinacoid.** Its hardness varies considerably, depending on the crystallographic direction from 5 to 7.25; specific gravity, 3.56–3.67; luster, vitreous to pearly; color, commonly blue to white, but sometimes gray to green or nearly black; transparent to translucent. Usually found in long-bladed crystals or columnar to fibrous structures. Kyanite is found in such **metamorphic** rocks as **gneisses** or mica **schists.** Of the many European localities for fine specimens might be mentioned the Ural Mts., Russia; Czechoslovakia; Austria; Trentino, Italy; the St. Gotthard region, Switzerland; and France. In the United States: Chesterfield, Massachusetts; Litchfield, Connecticut; and Gaston County, North Carolina, have furnished fine specimens. Kyanite derives its name from the Greek work meaning *blue,* in reference to the delicate blue of the inner portions of the bladed crystals. (E.S.C.S.)

L

L SECTION. This refers to an elementary section of a network such as a **filter** where the components are connected in the form of an L, i.e., one component in series with one side and the other in shunt across the two sides of the circuit. (L.R.Q.)

L SERIES. X-Ray Spectra.

LABARIA. Reptilia, Sauria. A poisonous South American **snake** belonging to the pit vipers. It ranges from eastern Brazil north into the Guianas. Related to the jararaca. (A.W.L.)

LABIUM. 1. A lip or lip-shaped structure. 2. The posterior element of the insect's mouth parts, derived from a pair of jointed appendages.

The labium consists typically of three segments with a pair of appendages called labial palpi. The basal segment is the submentum, the next segment the mentum, and the terminal segment the ligula. The ligula is sometimes complex, consisting of a median glossa, sometimes very long, and two basal lobes known as paraglossae of very variable size. The labial palpi arise from the base of the ligula and consist of four segments or less. In some species the palpus is attached to a distinct part called the palpiger. (A.W.L.)

LABOR (CHILDBIRTH). The process of separation of the mature or nearly mature **fetus** and **placenta** from the interior of the **uterus** and its expulsion from the mother.

The first stage of labor begins near the end of the tenth lunar month after conception. The onset of labor is marked by the appearance of cramp-like pains in the lower abdomen, which gradually increase in frequency and severity. The pains are due to muscular contractions of the uterus which brings about dilation of the **cervical** opening of the uterus in the **vagina.** At this time there may be a little blood with the vaginal discharge—"the show." After the pains have continued for a variable time—usually 12–15 hours—there is a gush of considerable fluid from the vagina due to rupture of the membranes, "bag of waters," with escape of the amniotic fluid.

A short time after the rupture of the membranes the second stage of labor begins. The labor pains increase in severity, frequency, and duration. During this stage the child passes from the uterus through the dilated cervix and vagina to the outside world. The **umbilical cord** is severed at this time. The second stage of labor usually lasts about 2 hours in the first pregnancy. In succeeding pregnancies the time is usually shorter.

After the birth of the child the third stage of labor begins. At first the labor pains cease, the uterus contracts and becomes much smaller. After a few minutes contractions begin again and the placenta (afterbirth) is expelled. This last procedure may be completed by the obstetrician. Considerable blood may be lost during this stage.

Normal labor varies in duration for the three stages, depending on the size of the child, size of the mother's pelvis, and the character of muscular contractions. The three stages usually take about 18 hours—16 for the first, 2 hours for the second, and 15–30 minutes for the third stage. The birth of the first child usually takes 6 hours longer for the three stages.

Labor is sometimes prolonged in primiparous women over 35 years of age because of the loss of elasticity and distensibility of the cervical tissue.

The complications of labor are obstruction due to disproportion between the size of the fetus and the size of the pelvis, and poor muscular contractions of the uterus. The use of obstetrical forceps may be necessary to aid the progress of the child. Other complications are hemorrhage, premature separation of the placenta, **eclampsia,** and rupture of the uterus. (R.S.M., D.M.H.)

LABRADORITE. Feldspar.

LABRUM. The anterior or upper element of the insect's mouth parts. It is not derived from jointed appendages like the other mouth parts and is usually a simple flap, movably attached to the front of the head. (A.W.L.)

LABYRINTH. Stuffing Box.

LABYRINTHODONTS. Fossil Amphibia.

LACCOLITH. An intrusive, **igneous rock** mass which has been injected along the bedding plains of **sedimentary** formations in such a way as to dome the overlying strata. Typical laccoliths have been fed by **dikes** and are mushroom-shaped with symmetrical domes and flat floors. Because of the mechanics involved in their origin, laccoliths are formed in the upper portion of the **lithosphere** where the static pressure of the overlying formations is not too great to prohibit their local uplift by the intruded **magma.** (R.M.F.)

LACERTILIA. Reptilia.

LACEWING. Golden-Eye.

LACING BAR. Compression Member.

LACINIA. Maxilla. Also a movable appendage of the **mandible** of some isopod **crustaceans,** the lacinia mobilis. (A.W.L.)

LACQUER. Pigments; Paints; Varnishes; Resins; Nitrocellulose; and Paints.

LACTAMS. Aminoacids, Polypeptides, and Proteins.

LACTIC ACID AND LACTATES. Lactic acid alpha-hydroxypropionic acid ($H \cdot C_3H_5O_3$ or $CH_3 \cdot CHOH \cdot COOH$) is a colorless liquid, melting point 18° C., boiling point 122° C. at 15 mm. pressure, miscible with water, alcohol or ether in all proportions. **Calcium** lactate, on account of its solubility characteristics (10 grams per 100 grams cold water and very soluble in warm water) is of importance in the separation and recovery of lactic acid. Calcium lactate plus dilute **sulfuric** acid yields lactic acid plus calcium sulfate, and the latter may be separated by **filtration.** Lactic acid may be obtained by **evaporation** of the filtrate in **vacuum.** Lactic acid, when heated at atmospheric pressure, changes to lactide; when oxidized cautiously, changes to pyruvic acid; when heated with dilute sulfuric acid yields **acetaldehyde** plus **formic acid.** Lactic acid may be obtained (1) by the fermentation of **lactose,** "milk sugar" (thus accounting for the presence of lactic acid in sour milk), **sucrose,** molasses, **glucose,** starch (corn starch, potato starch) in the presence of **calcium** carbonate forming calcium lactate, from which lactic acid is obtainable, (2) by reac-

tion of glucose and **sodium** hydroxide solution under proper conditions, (3) by reaction of sodium hydroxide solution and alpha-chloropropionic acid, (4) by reaction of acetaldehydecyanhydrin and water. The physiological formation of lactic acid in the animal organism is responsible for the fatigue of muscles.

The following are esters of lactic acid:

Methyl lactate ($CH_3CHOHCOOCH_3$), boiling point 145° C.

Ethyl lactate ($CH_3CHOHCOOC_2H_5$), boiling point 154° C.

Lactic acid is used in the textile and farming industries, and in certain food industries, e.g., pickles, essences. (See **Isomerism** and **Stereoisomerism.**) (R.K.S.)

LACTIDES. **Acids, Carboxylic and Related Compounds.**

LACTIMS. **Aminoacids, Polypeptides, and Proteins.**

LACTONES. **Acids, Carboxylic, and Related Compounds.**

LACTOSE. **Carbohydrates.**

LACUNAR TISSUE. A tissue peculiar to **echinoderms.** It occurs in strands containing associated spaces which serve as circulatory channels. Unlike true blood vessels these spaces have no epithelial lining. (A.W.L.)

LADLE. **Foundry Practice.**

LADY BUG. Insecta, Coleoptera. Small oval **beetles,** strongly convex and with relatively small legs. The common name applies chiefly to the more common red species, marked with black and white, but the family Coccinellidae to which they belong contains many others. (A.W.L.)

LADY'S-SLIPPER. **Orchid Family.**

LAGOON. **Barrier Beach.**

LAKE HERRING. Pisces, Teleostei. Fresh-water **herrings** of several species, all important food fishes. Also called **ciscoes.** These fishes occur in the Great Lakes and many smaller bodies of water. They include the most important commercial species of the Great Lakes fisheries. (A.W.L.)

LAKES. **Dyes.**

LAMARCKIAN THEORY. A theory of organic **evolution** first expressed in 1809 by the French scientist, Jean Baptiste Lamarck. Lamarck formulated two principles, first that use strengthens and develops an organ and that disuse weakens it and causes it to become atrophied, and second that the results of use and disuse are inherited and so influence the development of a species through a succession of generations. The first of these principles is abundantly proved, while the second is not true.

In discussions of evolutionary theory since Darwin's work was published the term acquired characters has become synonymous with the organic changes which Lamarck emphasized and the inheritance of acquired characters, or Lamarckian evolution, has been generally discredited. Closer perusal of Lamarck's work, however, indicates that he emphasized the reaction of the organism to environmental conditions as a source of change. The results of this reaction are not inherited as such, but whether the reaction in one generation adds to the capacity of the next generation for similar reaction is neither proved nor disproved, hence the Lamarckian theory still has a valid place in organic evolution. (A.W.L.)

LAMBERT. **Brightness.**

LAMBERT PROJECTION. The Lambert modified conformal conic **projection** (commonly known as the Lambert, and sometimes as the Gauss conformal) has been used for many years in the construction of **maps.** Within the past decade this projection gained rapidly in favor for use in constructing **charts** for air navigators.

The projection is actually a mathematical type, but may be quite accurately described as a **conical projection,** differing from the simple conical in that the cone is not tangent to the earth's surface, but cuts it on two **latitude** parallels known as standard parallels. This type of projection is particularly valuable for portraying large longitudinal areas, e.g., the entire United States. The **graticule** of the Lambert chart shows parallels of latitude as concentric circles centered at the nearer pole, and the meridians of **longitude** as straight lines converging on this pole. From simple geometric considerations it is obvious that the meridians and parallels must be perpendicular. The angle of convergence of the meridians, and therefore the radii of the parallels, depends upon the distance of the nearer pole from the center of the area.

The great advantage of the Lambert projection is that the scale of distance is uniform, for all practical purposes, all over the chart. To indicate the accuracy of this statement consider the Lambert projection on which the series of aeronautical charts of the United States are constructed by the Coast and Geodetic Survey. The standard parallels for these charts are N 45° and N 33°. The scale of distance, if considered as unity on the standard parallels, is 0.994 at the central parallel, expands to 1.010 at the extreme north boundary of the United States, and to 1.023 at the tip of Florida. Comparing the Lambert with the **Mercator** distance scales we find that if we consider the Mercator scale as unity at N 39°, the scale at the northern limits of the United States is 1.154 while at the tip of Florida it is 0.846.

The non-orthogonal graticule of the Lambert chart is a distinct disadvantage for general navigational problems since neither the **rhumb** line nor the **great circle** is straight. However, the uniformity of scale is of such great advantage that air navigators have begun to use this type of chart even in preference to the Mercator, particularly when navigating in good visibility over land or where good **radio aids** are available. A straight line between two points on a Lambert chart is referred to as a Lambert line. Since the meridians on the graticule are convergent this will not be a rhumb line. However, the distance measured along this line will be less than that along the rhumb line and only slightly greater than the great-circle distance between the two points. This line is frequently used by aviators during conditions of good visibility. The standard procedure in using the Lambert line is to draw a straight line on the chart and pick out conspicuous landmarks separated by about 25 miles. Then follow the rhumb line indicated by measurement of the angle between the Lambert line and the meridian nearest the starting point. This will lead you to a point some distance from the first landmark but within visibility. From this first landmark a new heading is adopted for the second, and so on to destination. In case a rhumb line is desired for the entire route, the Lambert line is drawn as before and the course measured from the meridian half-way between the point left and point to be arrived at. This rhumb line will appear as a curve on the Lambert chart, but can be laid down by

any one of a number of standard methods with sufficient accuracy for the selection of landmarks.

The convergence of the meridians prevents the use of the Lambert chart for graphical solution of dead-reckoning problems, and introduces difficulties in plotting **lines of position** obtained either by radio **bearings** or by celestial observation. The ease with which such problems can be solved on the Mercator chart seems to cast doubt on the statement to the effect that "the Lambert Chart will completely supersede the Mercator for all navigational purposes." (W.K.G.)

LAMELLA. In botany the **middle lamella** is the compound layer composed of the primary walls and the cement-like intercellular substance which occurs between the primary walls of two cells. From this layer is obtained **pectin** which is added to concentrated fruit juices in the preparation of jellies. The term lamella is also applied to each of the concentric growth layers in large starch grains.

In zoology the term lamella is used with two common meanings. It may be: 1. A thin leaf or plate, such as a lamella of bone. 2. A flat plate formed by the fusion of **ctenidial filaments in the bivalve** mollusks. Two lamellae united by bridges of tissue form a gill through which water circulates under the influence of ciliary action in the persisting open spaces. This form of gill is the source of the name **Lamellibranchiata** applied to the class containing these animals. (R.M.W., A.W.L.)

LAMELLAR VECTOR. Irrotational Vector.

LAMELLIBRANCHIATA. The bivalve mollusks, a class of the phylum **Mollusca** including the **clams, mussels, oysters, scallops** and related species. Many of these animals are valuable for food, and pearls and mother-of-pearl are produced by them. The class is also named Pelecypoda.

Bivalve mollusks differ from other members of the phylum in the following characters: 1. The body is transversely compressed. 2. The **mantle** forms two lobes extending down along the sides of the body. In most species these lobes unite at the posterior end to form two passages, an upper excurrent and a lower incurrent siphon. Currents of water carry food and oxygen into the mantle cavity through the lower opening and a current bearing wastes passes out of the upper. 3. Each mantle fold secretes a valve of the shell formed of calcareous matter covered outside by a horny periostracum and inside by nacre, commonly called mother-of-pearl. The two valves of the shell are joined by a hinge ligament and the articulation is strengthened in some species by interlocking teeth. 4. The gills are thin plates on each side of the body in most species. They are formed of united ctenidial filaments. 5. The foot is a muscular wedge-shaped protuberance at the anterior end of the body.

All bivalves are aquatic. Most species creep slowly by thrusting the foot into the muddy or sandy bottom but some propel themselves by jets of water squirted from the siphons or forced from the mantle cavity by rapidly closing the valves. The species vary from fresh water forms about ⅛″ long to giant marine shells more than a yard long.

The class is divided into four orders:

Order Protobranchiata. Gills in the form of small leaflets, two rows on each side of the body. Marine species.

Order Filibranchiata. Marine **mussels, scallops,** etc. Gills composed of filaments united only by ciliary junctions.

Order Eulamellibranchiata. Gill filaments united to form continuous plates. Fresh-water **clams** or **mussels,** marine clams, **oysters, shipworms,** etc.

Order Septibranchiata. Gills replaced by a horizontal partition between the upper and lower divisions of the mantle chamber. A few marine species.

(See also **Clam, Mussel, Mother-of-Pearl, Pearl,** and **Oyster.**) (A.W.L.)

LAMINAR FLOW. Turbulence.

LAMINARIA. Algae.

LAMINATION. A discontinuity in a plane parallel to the surface of a sheet, strip or plate of any metal. Laminations may vary considerably in size and distribution. Common causes of laminations are shrinkage cavities resulting from the solidification of metal **ingots** and less frequently gross segregations of nonmetallic **inclusions** that may be trapped in the ingot when the metal solidifies.

In most electrical machinery there are certain iron core parts which are subjected to an alternating flux, hence they will have alternating voltages induced in them. These voltages give rise to circulating currents which represent a loss and consequent heating of the machine. These currents are known as eddy currents and the loss is commonly called eddy current loss. To reduce this loss to a minimum the core parts which have alternating flux are laminated, i.e., composed of thin sheets of magnetic material, each insulated from the other. This breaks the circuit for the eddy currents into many very small ones so the induced voltages will be too small to produce appreciable currents. Often the laminations are varnished for insulation but frequently the natural oxide scale is depended upon to perform this function. As the frequency goes up the laminations must be made thinner if the loss is to be kept down. Thus at audio frequencies the laminations are much thinner than at commercial power frequencies and at **radio frequencies** (iron cores can only be used at the lower radio frequencies) the magnetic material is powdered and mixed with a binder to give the effect of extremely thin laminations. (See **Metamorphism** and **Lava.**) (R. S. BURNS, L.R.Q.)

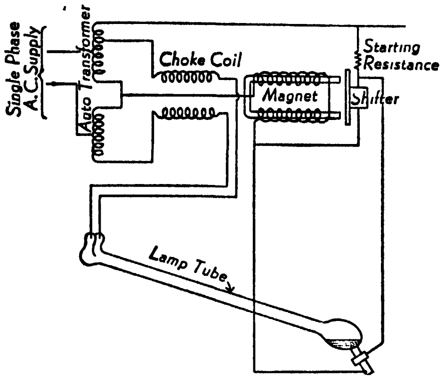
LAMMERGEIER. Vulture.

LAMP, ELECTRIC. The principal electric lamps are the **arc lamp**, vapor lamp, the incandescent resistance lamp and the fluorescent lamp. The common vapor lamps in use now are the mercury-vapor, giving a bluish-green light, and the sodium lamp, giving a yellow or orange light. Other gases are used for special purpose lamps such as advertising displays where a wider range of colors is desirable. The Cooper-Hewitt lamp is the oldest commercial form of vapor lamp and makes use of a mercury pool **cathode.** As with all types of vapor lamps the light is produced principally by the recombination of the vapor ions and electrons, the gas being ionized by the passage of an electric current through it. (See **Discharge.**) The mercury liquid is contained in the vapor lamp in a state of high vacuum. When the tube is cold it is necessary to strike an arc by tilting the tube until an electrode dips in the pool of mercury. The accompanying figure shows the principle of the electrical connections of a single-phase, a-c Cooper-Hewitt lamp.

A recent development is the high-pressure mercury-vapor lamp. These lamps, in conjunction with a high reactance **transformer,** are self-starting without any tilting or moving mechanism and have a higher efficiency than the low-pressure Cooper-Hewitt lamps.

The quality of light from the mercury-vapor lamp is bluish-green in color, and has a tendency to distort the colors of objects viewed in it. However, this light is good for industrial purposes, as it permits small details to be more easily seen by workmen than does

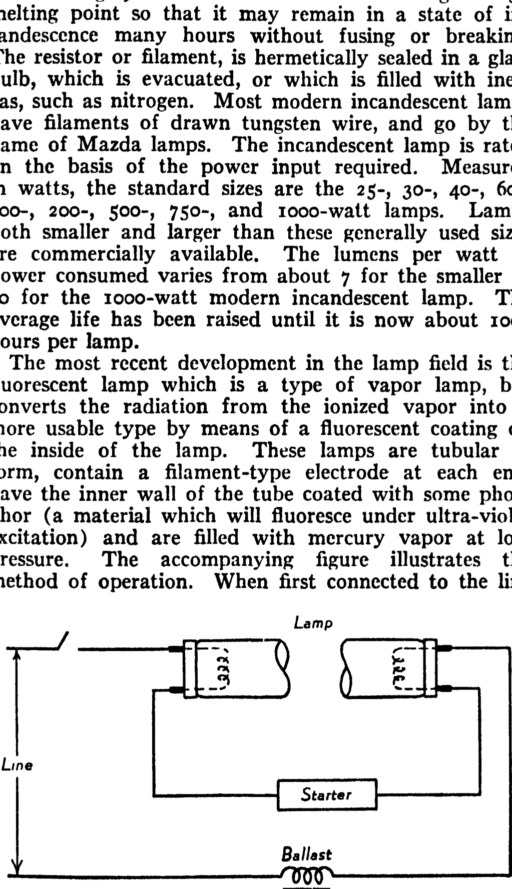
white light. On account of the intense light delivered by the mercury vapor lamp, fewer units are necessary for adequate lighting of large manufacturing areas.



Mercury vapor lamp.

In the ordinary incandescent lamp, light is emitted from a highly heated resistance wire having a high melting point so that it may remain in a state of incandescence many hours without fusing or breaking. The resistor or filament, is hermetically sealed in a glass bulb, which is evacuated, or which is filled with inert gas, such as nitrogen. Most modern incandescent lamps have filaments of drawn tungsten wire, and go by the name of Mazda lamps. The incandescent lamp is rated on the basis of the power input required. Measured in watts, the standard sizes are the 25-, 30-, 40-, 60-, 100-, 200-, 500-, 750-, and 1000-watt lamps. Lamps both smaller and larger than these generally used sizes are commercially available. The lumens per watt of power consumed varies from about 7 for the smaller to 20 for the 1000-watt modern incandescent lamp. The average life has been raised until it is now about 1000 hours per lamp.

The most recent development in the lamp field is the fluorescent lamp which is a type of vapor lamp, but converts the radiation from the ionized vapor into a more usable type by means of a fluorescent coating on the inside of the lamp. These lamps are tubular in form, contain a filament-type electrode at each end, have the inner wall of the tube coated with some phosphor (a material which will fluoresce under ultra-violet excitation) and are filled with mercury vapor at low pressure. The accompanying figure illustrates the method of operation. When first connected to the line



Fluorescent lamp connections.

the filaments heat and emit electrons. After a short time interval the starter opens and high voltage appears across the electrodes, causing the vapor to break down into a self-maintaining **discharge.** This discharge is rich in ultra-violet radiation which excites a visible radiation in the fluorescent coating of the tube. The ballast limits the current to a safe value since the discharge is not inherently self-limiting. The color of the light may be controlled by the type phosphor used for coating the lamp. The efficiency is much higher than incandescent lamps, for example, a 40-watt fluorescent lamp will produce about the same number of lumens as a 150-watt incandescent lamp. The better control of color of light and the better efficiency are causing a widespread change-over to this type lighting in many applications.

One of the most striking developments of the present century has been the growth of electric lighting. The reason for this growth is to be found in the multiple advantages of electric lighting over other methods of illumination. Principal advantages might be summarized as follows:

1. Convenience in use.
2. Adequate illumination, eliminating physical handicaps resulting from eye-strain.
3. Safety from fire hazard of oil and gas lights.
4. Artistic lighting units made possible by the use of electricity. (F.T.M., L.R.Q.)

LAMP SHELL. **Tongue Shell; and Invertebrate Paleontology.**

LAMPREY. **Cyclostomata.**

LAMPROPHYRE. An old group term originally proposed by Gümbel and later redefined by Rosenbusch to include **basic** dike rocks of **porphyritic** texture whose phenocrysts are **femic** minerals such as **augite, hornblende** and **biotite.** The term is derived from the Greek meaning glistening, and referring particularly to the abundant biotite which occurs in the particular variety of Lamprophyre called **Minette.** (R.M.F.)

LANCELET. **Cephalochordata.**

LANCEOLATE. Shaped like a lance; that is, narrow and tapering to a point, as in lanceolate leaves. (R.M.W.)

LAND BREEZE. At night air in contact with land cools, and that in contact with water does not. When sufficient difference in temperature arises between the land and the sea air, there springs up a breeze flowing off-shore from cold land onto warm water. This wind is known as the land breeze. Its basic cause lies in the fact that constant pressure and density surfaces intersect and form a solenoidal field; the resulting circulation tends to bring the density surfaces parallel with the pressure surfaces. (P.E.K.)

LAND SUBDIVISION. The standard system of subdivision of lands for legal and other purposes is that employed in the United States land subdivision system, which involves the location of subdivisions with regard to a set of principal axes. In this system the units of subdivision are the township and the section. The origin is the intersection of a true parallel of **latitude** called the base line, and the true **meridian** called the principal meridian. Some 35 of these origins have been established and wholly, or in part, govern surveys in most of the states of the Union, outside the original 13 colonies. Secondary axes are established at intervals of 24 miles north and south of the base line, and east and west of the principal meridian. These divide the area into quadrangles bounded by meridians and parallels. The meridians are each 24 miles long, but while the southern bounadry of each quadrangle is 24 miles in length, the northern boundary, in the northern hemisphere, is less than 24 miles, due to the convergence of meridians. These 24-mile boundaries are termed standard parallels and guide meridians. The parallels are, of course, continuous, but the meridians, with the exception of the principal meridian, are broken at the parallels. On the other hand, the parallels are curves, and the meridian lines are straight.

Each of these quadrangles is divided into 16 parts by north and south range lines at 6-mile intervals, and by east and west township lines at 6-mile intervals. The area enclosed by range lines and township lines is slightly less than 36 square miles. It would be 36 square miles except for the convergence of the range lines which are meridional in nature. Beginning with the eastern side of the township, the sections are laid off by section lines north and south and east and west, at 1-mile intervals. Thus there are 36 sections in a township, each of which is 1 mile square except on the westerly edge, where, due to the convergence of the meridional section lines, the sections will have a latitudinal dimension of less than 1 mile with the deficiency being greater in the northern sections than in the southern.

The base line and principal meridian are used for legal descriptions of all sections whose survey relates to their origin. Any given township may be located by giving it a range number east or west from the principal meridian, and a township number north or south from the base line; for example, range 6 East, township 7 South. The section lines divide each township into 36 sections, which are numbered consecutively from east to west in the first tier, west to east in the second, and so on, beginning with number 1 in the northeast corner, and ending with number 36 in the southeast corner. (F.T.M.)

LANDING, AIRCRAFT SYSTEMS. Blind Landing.

LANDING GEAR, AIRPLANE. The structure which supports an airplane in contact with land is called its landing gear. As here interpreted, the term is applicable only to airplanes intended to operate normally from land surfaces, although others have considered "landing gear" to include the understructure of float-type **seaplanes.**

The components of all landing gear are (1) wheels (alternately skis for snow), (2) structural connection between wheels and airframe, and (3) some means of reducing the shock of landing. Modifications sometimes found include brakes, retraction, fairing, steering.

The method of airplane support by the landing gear is often classified as *conventional* or *tricycle.* The "conventional" designation is used to indicate a type, formerly in general use, at a time when usage of the tricycle type is rapidly increasing and it threatens to become the conventional type of the future. Both types support the airplane at three points, two of which are furnished by main wheels located close to the airplane center of gravity, while the third (the auxiliary wheel) is at the tail in the conventional type, and at the nose in the tricycle type. The wheels are always located so that the resultant of airplane mass acts inside an imaginary triangle joining the three wheels. Both types are shown in Fig. 1 in normal rest position. In a range of normal landing attitudes the main wheels touch first, followed by a rotation (caused by weight and inertia forces acting through the center of gravity (C.G.) bringing the tail or nose wheel, as the case may be, in contact with the ground. (See **Landings, Airplane.**) Proponents of tricycle gear claim simpler and less exacting landing technique, better attitude for pilot (and passengers) during taxiing and take-off, and more braking action allowable without "nosing-over." However, nose-wheel supports (usually rectractable) have been heavier and more complicated than tail wheels, and often more difficult to accommodate in the fuselage if retractable. Also, shimmy of the nose wheel has been difficult to overcome. Tricycle landing-gear design is more easily accomplished where the engines are wing-mounted than for nose-mounted single-engine designs.

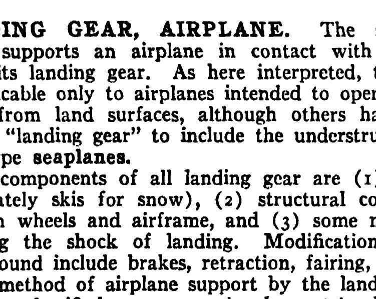


Fig. 1. Method of support.

The structure which extends between airframe and wheel is all-metal, necessarily of strong construction since it may be required to resist dynamic loads (see **Load Factor**) of 2 or 3 times the airplane dead weight. The material is often alloy steel tubing, steel, and magnesium castings. Loads on the landing-gear structure arise not only from the normal reaction between wheel and ground, but also from horizontal sidewise forces caused by landing with side drift, and torque created by use of brakes.

These loads are carried by a variety of structures in different airplanes; however, all may be classified as (1) tripod, (2) full cantilever, or (3) semi-cantilever. The tripod type has the greatest rigidity, but the most aerodynamic drag. Also, it is not very well suited for retraction designs. The full cantilever types shows better aerodynamic performance, but tends to be heavier than the truss type for the same rigidity. Large bending moments are imposed on the fuselage-landing gear joint. Semi-cantilever types have been widely adopted for retractable gear for the reason that the retraction arm may also constitute a brace for the main load-carrying strut. All three types are diagrammed in Fig. 2, with shock absorption and retraction omitted. Shock absorption is needed to make good landings smooth and comfortable for passengers, and to ease the strain on the airframe of a poor landing. (See **Shock Absorber.**) The common hydraulic shock-absorber requires that the strut containing it change in length during the action. This motion is much easier to incorporate in the tripod gear where only axial loads exist than in cantilever types where bending is also present. Torque arising from use of brakes is resisted by the two rigid struts of the tripod gear, but must be carried by some special torque member in cantilever designs. A torque shears (Fig. 3) is often used to maintain wheel alignment.

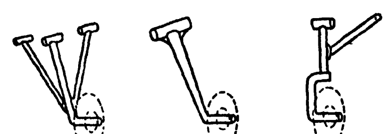

Fig. 2. Structural types (without shock absorption).

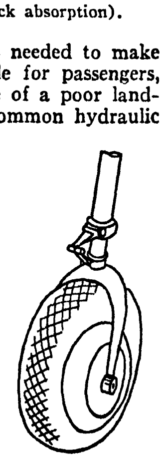

Fig. 3. Torque shears for cantilevered gear.

A further classification of landing gear may be: (1) fixed, (2) retractable. For many years all land planes had fixed landing gear, usually of the tripod type. These had the advantages of simplicity, ruggedness, and reliability, but did expose a parasitic area to air action, resulting in an aerodynamic drag. At low airplane speeds (say below 100 m.p.h.) the landing-gear drag

is not of great importance and fixed landing gear imposes no great penalty on performance. Parasitic drag increases as the square of air velocity, so the effect mounts rapidly with increase of air speed once it begins to be noticeable. To achieve high speeds (200–600 m.p.h.) retraction of all parasitic surfaces into a streamline fuselage or nacelle is a practical necessity. At moderate speeds considerable reduction of required engine hp. will partly compensate for the trouble of including retractable landing gear. Engine power varies about as the cube of air speed, so to raise a flight speed from 110 m p.h. to 130 m.p.h. would require 65% more power unless drag can be reduced by retraction and other means. All high-speed airplanes now have retractable gear, while at the other extreme, several small airplanes for private use have been able to make speeds of 120–140 m.p.h. on 80 to 100 engine hp. with retractable gear, whereas formerly barely more than 105 m.p.h. would be expected on this power.

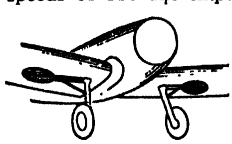

Fig. 4. Typical retraction single-engined airplane.

On single-engine airplanes, main wheels are retracted into the fuselage or into the wings, generally the latter. Retraction into the engine nacelle is common on multimotored designs. In any event, the problem of retraction requires mechanical ingenuity for successful solution, since the necessary space is always hard to find, and certain interior structural members will need to be cleared. Some of the motions employed are:

1. Sideways into the wing or wing center section. When extended, the retraction member serves as a lateral brace.

2. Backwards, with a 90° rotation of the landing-gear strut, so that the plane of the wheel will be horizontal and it will retract into the lower surface of a wing. Where this is actuated by a brace, the brace is longitudinal when the gear is extended.

3. Backwards or forwards into nacelle with a jack-knife action on the main strut. This is necessary where (as on bombers) the strut is long and simple rotation would land it outside the available retraction region. Some of these mechanisms are quite complicated. (Fig. 5.)

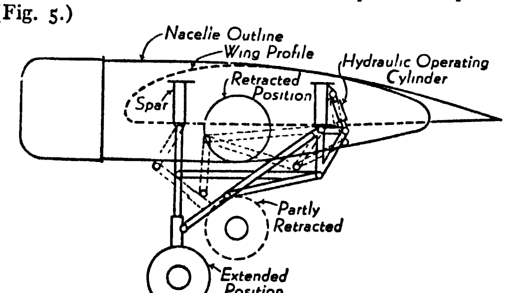

Fig. 5. Retraction mechanism.

Operation of retraction mechanism by the pilot is by remote control since ordinarily the gear is accessible to neither pilot nor crew member. Systems employed are hydraulic, electric, and mechanical. Hydraulic systems operate from engine oil pressure through control valves accessible to the pilot. The ultimate power motion is the stroke of a plunger in or out of a double-acting oil cylinder. Electric systems are, of course, controlled by switches and generate power either by motor or solenoid. Light-weight motors operating nut and thread actuators are common types of final drives.

Pure mechanical systems are seldom used for actuating landing gear as they are slow in action (hand-cranking by pilot, etc.), but they are sometimes installed as an emergency measure.

Retractable landing-gear installation is further complicated by the need of the following components:

1. Indicating mechanism to assure the pilot that the wheels are in correct "down" position before he lands. The gear is rarely visible from the control cabin.

2. Locking mechanism to lock the jointed landing gear in its extended position.

3. Limit stops on power supply to prevent heavy stresses acting on the structural members after being extended or retracted.

4. Automatic landing-gear well doors to open when gear is actuated for lowering, and close after gear is retracted. These doors are mainly to "fair" over the opening for aerodynamic reasons.

The wheels are generally cast from aluminum or magnesium alloy, and consist of little other than the

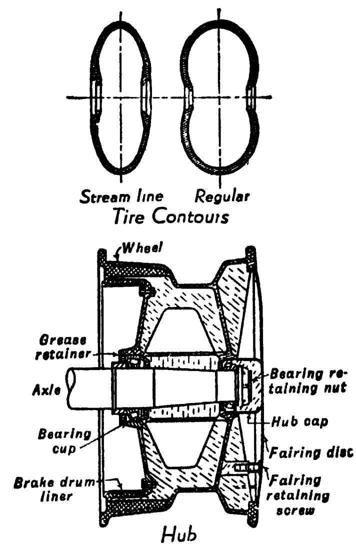

Fig. 6. Airplane wheel.

hub, on which the tire and tube are mounted, and inside of which are located wheel bearings and brake drum. Several different designs of brake shoe have been used. Small airplanes frequently have brakes actuated by cable from the brake pedals. This is not satisfactory for large brakes nor for retractable wheels, these being generally hydraulic in action. A typical hydraulic braking system would consist of a reservoir to hold the brake fluid and compensate for any slight leaks in the connecting lines, a master cylinder to build up the system pressure, and a wheel cylinder whose piston actuates the brake shoe. The master cylinder piston can be actuated directly from the brake pedals or (as on some of the large airplanes) by hydraulic or electric servo-motor. Wheels are individually braked to aid in controlling ground loops and to facilitate taxiing downwind.

Tires for airplanes are of the pneumatic tube and casing type similar to automobile tires, except that the ratio of contour diameter to rim diameter is much greater. Wheels are constructed for both drop-center and removable-flange methods of mounting tires. Streamline tires are made for use on fixed landing gear where careful external streamlining is attempted. (F.T.M.)

LANDINGS, AIRPLANE. Obviously, every airplane flight must be terminated by a landing. The landing maneuver has as its object the transfer of the airplane weight from wings to wheels in such a way as to produce the minimum practical impact and deceleration. As this may be done in a variety of ways, both expertly and inexpertly, producing variations in load

factor and requiring variable techniques, various types of landings will be described individually.

The difference between the landing of a helicopter (or airship) and an airplane is that the airplane is always required to exceed a certain minimum forward speed in order to obtain the necessary sustension. This is called the stalling speed, and is an important factor to be taken into account in landing maneuvers. Until the time when the wheels are to be put in contact with the ground, this speed must be exceeded, otherwise the airplane will begin to fall in an uncontrolled way. At the stalling point the **angle of attack** has its maximum value, and the attitude of the airplane for horizontal flight is nose high, whereas, progressively, at speeds higher than the stall the nose lies closer to the horizontal. It will be seen, then, that for horizontal flight at decreasing velocity the attitude of the airplane must be increased towards the nose high position until it reaches the angle of stall at minimum flying speed. Further deceleration will be followed by a stalling of the airplane, due to the weight exceeding the existing lift on the wing.

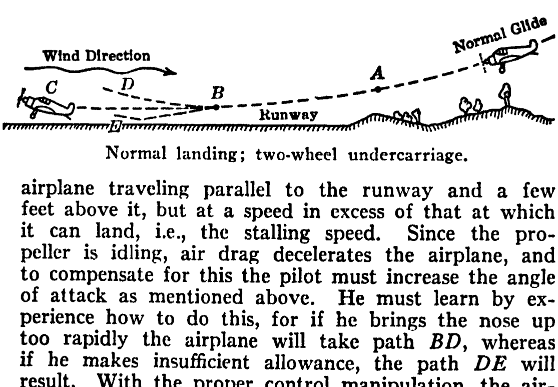
Landing techniques will also vary with types of undercarriage. The two principal types are the two-wheel (tail wheel not counted) and the tricycle. The two-wheel undercarriage has the wheels placed slightly ahead of the center of gravity. The weight of the airplane, therefore, will be borne principally by these wheels, but partly by a tail wheel or skid located at the aft end of the fuselage. Initial contact of the two wheels would be followed by a natural rotation of the airplane around the point of contact with the ground until the tail wheel rested on the ground; however, if wheel brakes were heavily applied, the deceleration might set up sufficient inertia forces to overbalance the deadweight moment and nose the airplane over in a crash. An attempt to prevent this by locating the wheels far forward of the center of gravity will cause the airplane to be "tail heavy," which would result in its being inconvenient to handle on the ground, and to have undesirable take-off characteristics. Usually the undercarriage structure is made of sufficient length that the attitude of the grounded airplane is approximately that for the stalling angle for horizontal flight.

Although for many years the two-wheel undercarriage was standard, latterly three-wheel, or tricycle, undercarriages have received general approval. The center of gravity is slightly ahead of the two main wheels in this arrangement, hence their initial contact with the ground rotates the airplane into nose-down position, bringing the nose wheel into contact with the ground. Brakes may then be applied heavily without danger of nosing over. Other advantages of this system are that the angle of attack and the lift are automatically decreased upon contact with the ground, thus eliminating a tendency to regain an airborne condition if the landing speed is unduly high, and the attitude of the plane is more conducive to good visibility and control during taxiing.

The nature of an airplane landing is such that a *runway* of 1000′ or more is required for a normal landing. As the safest landings are made *into* the ground wind, airports will usually have a number of runways so that the pilot of the approaching plane may select a direction into or nearly into the wind for a landing. An airplane with a landing speed of 50 m.p.h. in still air would land at 30 m.p.h. into a 20 m.p.h. wind, whereas the landing speed would become 70 m.p.h. downwind. Furthermore, control of the airplane during the landing run is far simpler for upwind landings; in fact, there is practically no control downwind unless the airplane is equipped with individual wheel brakes. Hence downwind landings are generally taken to be the mark of ignorant, inexperienced, or rash pilots, except in light ground winds with airplanes of high landing speed.

Prior to the beginning of the landing maneuver, the airplane must be put into an approach to the runway. This maneuver varies not only with the size and type of airplane, but also with the individual policies and preliminary training of the pilot. Some prefer to make a long (1 mile or more) straight-away approach during which the airplane is put in its normal glide attitude and corrections are made for side drifting; however, pilots of light airplanes usually prefer a short right-angle approach with the expectation of making their final turn in the direction of the runway not much more than ¼ mile from its beginning. Arguments in favor of the short approach are that position relative to the landing area may be more accurately gauged, and more readily corrected if defective, thus decreasing the likelihood of gliding past the runway before achieving a landing (over-shooting), or failing to reach the runway (under-shooting). These possibilities loom large on airports with short runways, and with pilots of moderate experience or ability. Large airplanes, such as transports, are flown by pilots whose experience and abilities are of a high order. They are operated from airports with lengthy runways, and are a type of airplane for which the low-altitude maneuvers necessary in a short approach are not recommended. Hence long approaches are the rule in their operation.

Normal Landing—Two-wheel Undercarriages. The approach maneuvers place the airplane a few hundred feet from the end of the runway in a normal glide the horizontal projection of which coincides with the axis of the runway. The *normal glide* is unaccelerated flight at a speed of 5–15 m.p.h. above the stalling speed. The angle of glide depends on the drag of the airplane (**parasite drag** and **aspect ratio**), and the pilot's use of flaps or other drag-increasing action such as fish-tailing, slipping, etc. The angle also depends on the ground wind, being steeper the higher the wind. As the airplane approaches to within 30–50′ of the ground in this glide, the pilot will use his controls to deflect the **elevator**, thereby leveling the direction of flight, as shown by the arc AB, Fig. 1. This will leave the



Normal landing; two-wheel undercarriage.

airplane traveling parallel to the runway and a few feet above it, but at a speed in excess of that at which it can land, i.e., the stalling speed. Since the propeller is idling, air drag decelerates the airplane, and to compensate for this the pilot must increase the angle of attack as mentioned above. He must learn by experience how to do this, for if he brings the nose up too rapidly the airplane will take path BD, whereas if he makes insufficient allowance, the path DE will result. With the proper control manipulation, the airplane will arrive at the point C at the stalling attitude and the stalling speed, whereupon it will settle. In a normal landing the wheels are within 2–3′ of the ground when this **stall** occurs, and the airplane settles smoothly and naturally into a "three-point landing." If the pilot has misjudged his altitude, and the wheels are perhaps 10–20′ from the ground when the stall begins, the airplane can achieve considerable vertical velocity before contact with the ground, with shock which will usually cause structural damage. This is called a *pancake landing,* and is a sign of inept piloting, except that an expert might elect to pancake an airplane when making an emergency landing into a forest.

Normal Landing—Tricycle Undercarriage. Up to the point B of Fig. 1, the tricycle-equipped airplane would be flown in a manner similar to that of one with a two-

wheel undercarriage. From *B* on, the maneuver would be different. Instead of holding the airplane off the ground while it was losing speed, it would be flown into gentle contact with the ground along a path something like *BE*. As the main wheels touch the runway surface the weight of the airplane would cause the nose to drop until the nose wheel also touched the surface. This will cause a decrease in angle of attack and wing lift so that there will not be a tendency for the airplane to become airborne again even though it has a speed in excess of stalling. With this undercarriage the airplane will be brought to a fast stop by heavy use of the brakes.

Cross-Wind Landing. When airplanes must be landed on a runway where the wind is not parallel to the axis of the runway, the cross component must be allowed for, or the airplane will land with some side drift which may overstrain the undercarriage, cause a wing tip to touch the ground surface, blow out a tire, or one of several other mishaps. The lighter the wing loading of the airplane, the more vulnerable it is to cross winds during landing. There are two methods for making a smooth cross-wind landing. One is to lower the windward wing slightly when approaching the runway, thus slipping the airplane sidewise into the wind just enough so that the path over the ground is maintained in a straight line in the same direction that the airplane is headed. Just before contact the wings are leveled with the ailerons, although in case of a strong cross wind it may be desirable to land with the windward wing low, i.e., on one wheel. The other method is to head into the wind slightly, but with wings horizontal. The airplane can then be caused to maintain a straight line down the runway, but it will not be headed in its direction of motion. Just before contact the airplane is ruddered rapidly so as to head it in the direction of its motion, this being necessary because normally the main wheels are not of a castering type. There are other variations, and often a pilot will use a combination of methods.

Belly Landing. Emergency landings of airplanes equipped with retractable undercarriage are sometimes, by the choice of the pilot, made with the wheels retracted. This is usually done where the emergency landing area looks soft or irregular, or where the distance available for landing run is quite limited. The airplane is landed on the under side of the fuselage. The center of gravity is low, and the frictional drag with the ground high. These are both of advantage in preventing a serious crash, and belly landings often can be accomplished with but minor damage to the fuselage.

Power Landing. Power landings are made with throttle partly open, and the propeller delivering an appreciable thrust. Two types of power landings will be described, viz., the two-wheel landing and the power stall landing. When landing in a high wind, it is inadvisable to throttle the engine. The approach to the landing is not made with a normal glide, but with the use of some amount of the engine power. This improves the control and allows the pilot to combat unexpected gusts better. The airplane is flown into contact with the runway in the position for level flight, and, if possible, taxied into the lee of a windbreak or to where airport personnel may help with the ground handling. During such taxiing the tail should not be allowed to come down, that is, the **angle of attack** should be kept low. The power stall landing is used in order to land with minimum forward speed, when landing on muddy or swampy ground, or in snow. It is also a customary method of "landing" seaplanes at night. In a power stall landing the airplane is headed into the wind with the throttle partly closed and speed reduced by raising the nose slightly until settling begins. The rate of settling is controlled by the use of the throttle, which should not be reduced to the point where the rudder and elevator begin to feel ineffective. In the night landing of a flying boat, this attitude is maintained until the boat strikes the water. The crew has knowledge of the progress of the landing operation from a sensitive altimeter which will note the height from the water, and from the rate of climb meter, which will show also the rate of descent. Airplanes with wheel undercarriages when brought to a power stall landing in daylight are generally landed with the throttle closed a few seconds before actual contact is made. Pilots must always be cautioned on the manner of terminating a power stall approach if it is desired to resume a normal glide. Full power must be employed, and the angle of attack reduced very gradually, otherwise there may be a decrease of angle of attack disproportionate to the speed. (See **Airplane Speeds; Airplane; Controls, Airplane Flight.**) (F.T.M.)

LANDSCAPE MARBLE. A British popular and trade term for **argillaceous limestones** of Liassic (lower **Jurassic**) age quarried near Bristol, England, and characterized by a tree-like pattern. (R.M.F.)

LANGUR. Mammalia, Primates. *Semnopithecus.* A group of Old World **monkeys** characterized by slender build and by extremely long tails. The legs are longer than the arms. They eat principally the leaves and young shoots of trees. Langurs live only in Asia and some of the East Indian islands.

Among the species of langurs that bear distinctive names are the hanuman, lutong, douc, negro monkey, leaf monkeys, bear monkey, white monkey, and purple-faced monkey. (A.W.L.)

LANIER EFFECT. A photographic effect observed by A. Lanier (1896) involving the acceleration of development by the addition of potassium iodide to the developer, or by bathing the plate or film in a solution of potassium iodide before development. The effect is more marked with developers of low reduction potential, particularly hydroquinone, and is hardly apparent with developers of high reduction potential. (C.B.N.)

LANTERN FLY. Insecta, Homoptera. Any member of the family Fulgoridae, which differs from the related leaf hoppers and other families in having the antennae inserted at the sides of the head. The North American species are small but one giant Brazilian species has a wing spread of six inches. A large prominence on the head of this species was once said to be luminous, hence the name lantern fly has persisted although none of these insects is actually luminous. (A.W.L.)

LANTHANUM. Symbol: La. Atomic number: 57. Atomic weight: 138.92. Density: 6.15. Melting point: 826° C. No isotope, but of simple atomic form: 139. Type of compound: La_2O_3. Color of salts: Colorless. Discovered by Mosander in 1837. A member of the **cerium** sub-group of the rare earth metals. (R.K.S.)

LAP JOINT. **Riveted Fastenings.**

LAPILLI. During volcanic eruptions there may be thrown into the air quantities of melted rock which cools into solid fragments before it falls back on the earth. This material is classified roughly according to size. Fragments 2 or 3″ or more in diameter are called **bombs,** those of smaller size down to the dimensions of bird shot are called lapilli, still finer particles are called volcanic ash or dust. Derived from the Latin *lapillus,* a little stone. (E.S.C.S.)

LAPIS LAZULI. **Lazurite.**

LAPLACE'S EQUATION. Laplace's equation is a type of partial differential equation of the second order

in three independent variables. In most of its many applications, these three variables represent 3-dimensional space coordinates, while the one dependent variable represents one of a number of physical point-functions fulfilling the condition expressed by the equation.

In **rectangular coordinates** (x, y, z), Laplace's equation takes the form

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2} = 0 \qquad (1)$$

where u is the dependent variable. The operator $\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$, often abbreviated ∇^2, is called the Laplacian.

In **cylindrical coordinates** (r, θ, z), the equation corresponding to (1) is

$$\frac{\partial^2 u}{\partial r^2} + \frac{1}{r}\frac{\partial u}{\partial r} + \frac{1}{r^2}\frac{\partial^2 u}{\partial \theta^2} + \frac{\partial^2 u}{\partial z^2} = 0; \qquad (2)$$

while in **spherical coordinates** (ρ, α, β), one of several forms is

$$\frac{1}{\rho^2 \cos\beta}\left[\cos\beta \frac{\partial}{\partial\rho}\left(\rho^2 \frac{\partial u}{\partial\rho}\right) + \frac{1}{\cos\beta}\frac{\partial^2 u}{\partial x^2} + \frac{\partial}{\partial\beta}\left(\cos\beta \frac{\partial u}{\partial\beta}\right)\right] = 0. \qquad (3)$$

Each of the three equivalent forms has its advantages in certain situations, but the rectangular form (1) is the one usually referred to when Laplace's equation is mentioned.

We shall here cite two familiar physical examples to which Laplace's equation applies; there are many others.

1. Consider a region of space in which there is an electric field (due to electric charges in the vicinity) but no free electricity, that is, no such **space charge** as exists in a vacuum tube in operation. At any point in this space there is an electric **potential**, which varies with the position of the point and is therefore a function of its coordinates. It is shown in electrostatic theory that if the potential is designated by u, it satisfies Laplace's equation in any of the forms (1), (2), or (3), whatever be the distribution of electric charges responsible for it. This fact makes it possible to trace the lines of force and equipotential surfaces in the region, by means of special solutions of Laplace's equation, called harmonic functions, which satisfy the "boundary conditions" imposed by the arrangement of the neighboring charges. As to which form of the equation is to be used, this depends upon which system of coordinates is most conveniently adapted to the shape and arrangement of the charged bodies.

2. If specified parts of the surface of a solid thermal conductor (such as a block of copper) are kept at different specified constant temperatures, heat will flow from the warmer toward the colder boundaries within the conductor. When this flow has become steady, the temperature of the conductor takes on a definite constant value at each point, dependent upon the location of the point. If the temperature is designated by u, it now satisfies Laplace's equation in each of its three forms, and the lines of flow and isothermal surfaces may be determined accordingly. A similar procedure is applied to potential in the steady flow of electricity through a metallic conductor. (L.D.W.)

LAPPING. The process of producing an extremely accurate, highly finished surface by means of a lap, which is a block charged with **abrasive**. Lapping reduces the possibility of wear on close-fitting running parts or on the surfaces of measuring equipment, by reducing the minute ridges and serrations left by machining and grinding operations to a more uniform bearing surface. Lapping may be done by hand or by machine. If a part is to be hand lapped to a final accurate dimension, a lap or mating form is made from a metal somewhat softer than the part to be finished. The surface of the lap is charged with a fine abrasive, or a small amount of abrasive mixed with grease, oil, or alcohol. A flat lap has a carefully-trued surface with a series of grooves in it. The lapping compound is smeared on the face of the lap and the work is rubbed over the face along an ever-changing path. The grooves in the face of the lap act as channels for any excess abrasive and oil. Very little pressure is used in order to eliminate the danger of scoring the work or stripping the lap. Hand lapping requires skill and time. The amount of material removed by lapping should not exceed .0002″ to .0005″.

A squaring lap is one in which the edge of the work is lapped at right angles to the bottom surface. A cylindrical lap is usually made of brass and is split and has a set screw so that the lap can be adjusted for wear. A helical groove of irregular lead in the surface of the lap serves as a channel for the abrasive and oil.

Mechanical lapping is analogous to hand lapping and is often the final stock-removing operation for sizing and finishing gauges and other commercial precision parts. Three types of lapping media are ordinarily used: bonded abrasives for the usual run of commercial precision work; metal laps and loose abrasive mixed with a lubricant for gauge manufacture; and abrasive paper or cloth, for crankshaft lapping.

For satisfactory precision lapping, the lap surfaces must be true planes. The process of generating true planes is very similar to the process of originating straight edges. Three laps are hand-scraped to a surface plate and one of the laps is then fastened to the table of a drill press. The second lap is placed on the first with a film of abrasive and oil between the contact surfaces. By means of a short-throw crank attached to the drill spindle, the upper lap is made to move in a circular eccentric path across the lower lap, which also causes the upper lap to rotate slowly about its own axis. This motion of the upper lap reduces the faces of both laps until they match. The first lap is then worked with the third, and then the second with the third, continuing until a true surface has been attained. Such laps may be used without any additional abrasive for finishing operations since the lap surface retains enough abrasive for this purpose. (See also **Gear Tooth Forming, Superfinishing.**) (H.C.H.)

LAPSE RATE. The rate at which temperature decreases or lapses with altitude. It is the vertical temperature gradient. Since temperature normally decreases with altitude in the troposphere, it is convenient to assign positive values to the rate of temperature change with altitude: Lapse rate, therefore, is defined as the rate of change of temperature with altitude and is positive when the temperature decreases. (P.E.K.)

LAPWING. Aves, Charadriiformes. *Vanellus.* Birds (**Aves**) of several species resembling the plovers in appearance and habits. They occur in Europe, Asia, Africa and the Americas. (A.W.L.)

LARAMIDE REVOLUTION. Cretaceous.

LARD. Esters.

LARK. Aves, Passeriformes. Song birds (**Aves**) of many species, confined to the northern hemisphere. The skylarks of Europe and Asia are the most famous members of the group because of the quality of their song. The common European species, *Alauda arrensis*, is established in Oregon and North America also has a native

species, the horned lark, *Otocoris alpestris*. The **meadowlark** is more closely related to the blackbirds and orioles. (A.W.L.)

LARKSPUR. Buttercup Family.

LARVA. An immature form of animals that undergo **metamorphosis** between emergence from the egg and the attainment of adult life. The larva is often very different from the adult.

The larvae of many invertebrates of **sessile habit**, such as the **sponges** and some **coelenterates**, are ciliated (**cilia**) organisms which swim about for a time before attaching themselves to the permanent support where they are to develop. In the two **phyla** mentioned the larva is little more than a ciliated **gastrula**. It is filled with solid endoderm in the coelenterates and is called a planula.

The **flukes** also begin life as a ciliated larva known as a miracidium. This form gives rise to more complex larvae called rediae and these in turn produce tailed larvae called cercariae. The cercaria is transformed into the adult. In the same phylum the tapeworms hatch as 6-spined hexacanth larvae and pass through a bladderworm stage before becoming adults.

Roundworms of many species pass through one or more larval stages in which they are worm-like but differ in habits and in some structural details from the adults.

Some of the segmented worms, **mollusks, echinoderms**, and **chordates**, hatch as complex larvae with localized zones of cilia for locomotion. The trochophore or trochosphere larva of **annelids** and mollusks has a ciliated alimentary tract with mouth and anus 90 degrees apart and a belt of cilia around the middle of the body. Larvae of echinoderms also have a bent alimentary tract but the cilia are arranged in one or more bands, sometimes of intricate form. These larvae bear various names: bipinnaria, auricularia, pluteus, of the starfishes, sea cucumbers and sea urchins and brittle stars, respectively, or collectively the dipleurula. The bipinnaria resembles the tornaria larva of **Balanoglossus**.

Among the **arthropods** the high development of metamorphosis is accompanied by great diversity of larval forms. In the class **Crustacea** these forms seem to represent previous evolutionary stages and are named after groups of the class whose adults they resemble. Among them are the Nauplius, Cypris, and Cyclops larvae and many others. A single individual may pass through several of these stages in the course of its development. Insects present an entirely different type of metamorphosis in which the larval characteristics appear to have been acquired later in the course of evolution than those of the adult, as an adaptation to special conditions (**Cenogensis**). In species with complete metamorphosis only the first immature stage is called the larva. In this stage butterflies and moths are called caterpillars, some of the beetles grubs, and many flies maggots. Species with less complex metamorphosis are called nymphs or naiads during development (in gradual and incomplete metamorphosis respectively).

(See also **Actinula, Ephyra, Glochidium, Hydratuba, Hypopus, Pilidium, Scyphistoma,** and **Veliger.**) (A.W.L.)

LARVACEA. The appendicularians. A class of minute marine animals belonging to the subphylum **Tunicata.** These forms have a trunk and tail and resemble the larvae of the tunicates. (A.W.L.)

LARYNGITIS. Inflammation or **infection** of the **larynx** occurring commonly as part of a general upper respiratory infection or as a complication of the common cold. Pulmonary **tuberculosis** is not infrequently complicated by tuberculous laryngitis. **Syphilitic** laryngitis is rare. **Croup** is a form of laryngitis. (D.M.H.)

LARYNX. The larynx or voice box is in the upper anterior part of the neck in front of the lower part of the **pharynx** and just above the **trachea.** It is composed of a series of cartilages adapted for phonation. The cavity of the larynx is divided into three compartments by two paired folds of **mucous membrane** stretching across it. These folds are the vocal cords. The two lower ones are the true vocal cords. They are set into vibration by currents of air which pass over them during breathing. In speaking, laughing, etc., the air currents are altered to produce different sounds. The pitch, volume of sound, and tautness of the vocal cords are under voluntary control, and are modified by voluntarily changing the force of the air current.

The larynx is subject to inflammation and infection (**laryngitis**), tumors (cancer) and trauma. Laryngeal **diphtheria** is a particularly fatal form of the disease. (See **Sound Production.**) (D.M.H.)

LASSO CELL. Colloblast.

LATENT PHOTOGRAPHIC IMAGE. The invisible, but developable, image formed on exposure of a light-sensitive emulsion to light is termed the *latent* image. Formerly thought (1) to consist of a subhalide, i.e., a silver halide containing less halide than the normal, or (2) a physical modification of the silver halide crystal, it is now generally considered to be composed of metallic silver adsorbed to silver bromide. This assumption is without direct experimental confirmation but is supported by much indirect evidence. It is well known, for example, that if the exposure producing a latent image is greatly increased a visible image is obtained. This suggests, although it does not necessarily follow, that the visible "print-out" image is a continuation of the same process which produces the latent image. Since the visible image, formed on prolonged exposure, is known to consist of metallic silver, it is evident that the latent image may also be regarded as consisting of silver. Furthermore, the latent image is destroyed by solvents of silver, such as nitric acid, or by strong oxidizing agents such as potassium permanganate or persulfate. Substances which reduce silver halide to silver produce a latent image; i.e., render an emulsion developable without exposure to light. Finally, no other explanation of the process of development fits the known facts so well as that which regards the latent image as consisting of a center, or nucleus, of silver on the grain of silver halide which serves as a center for the reduction of the entire grain to metallic silver by the developing agent.

While the latent image is generally regarded as consisting of silver, the mechanism by which silver is formed when light quanta are absorbed by the silver halide crystals of a photographic emulsion is not entirely clear.

According to one theory (Gurney-Mott) the quanta absorbed by the silver halide crystal produce free electrons which are trapped—or held—by the sensitivity centers. These sensitivity centers are small centers, or nuclei, of silver sulfide on the silver halide crystal and are formed during the digestion of the emulsion (see **Photographic Emulsions**) with heat or ammonia, as a result of a reaction taking place between substances normally present in the gelatin and the silver halide. As the electrons thus trapped are negatively charged, the sensitivity center acquires a negative charge and thus attracts positive charges. Therefore, silver ions, which bear a positive charge are drawn to the sensitivity center until its negative charge is neutralized. The sensitivity center then holds metallic silver bearing no free charge. The sensitivity center thus forms the nucleus on which the free silver constituting the latent image is built up.

Not all students of the subject, however, agree that the latent image consists of silver. Huggins, for example, suggests that the effect of exposure is to convert the cubic crystal, typical of the silver halides, into a crystal

of a different type, in fact of the type represented by zinc sulfide. His calculations suggest that the energy (light quanta) necessary for such a transformation is more nearly in accord with that required for the formation of a latent image than is the case if the result of exposure is to form metallic silver. This theory is of much more recent date (1943) than the other and less fully developed. (C.B.N.)

LATERAL. A force which acts on a structure or a structural member in a transverse direction is sometimes called a lateral load. The wind blowing upon the exposed surface of a **bridge** or building at right angles to its length or upon the stationary or moving traffic using the bridge constitutes one type of lateral load. The sway of a moving train on a bridge or the centrifugal force transmitted if the bridge is on a curve is a type of lateral loading. A moving crane supported on girders exerts a side thrust on the girders which may also be included in this classification.

Trusses and **girders,** which constitute the main load-carrying members of bridges, are not ordinarily designed to carry side loads of this nature, and consequently have very little strength in that direction. For this reason, the trusses or girders of a bridge are joined together in a horizontal plane by a system of lateral bracing composed of **struts** and diagonals. The diagonal members are known as laterals. This lateral bracing stiffens the whole bridge and opposes any sidewise **deflection** or vibration.

The term lateral is also used in connection with **sewerage** systems. Any sewer which serves the abutting property owners and in which each owner has an equal right is a common sewer. A lateral sewer is one which has no other common sewer flowing into it. (C.W.C.)

LATERAL BRACING. **Bridge.**

LATERAL LINE ORGANS. Sensory organs located on the head and in a line along the side of the body in the fishes (**Pisces**). They are unlike the sensory organs of terrestrial vertebrates but are supposed to perceive vibrations of low frequency. (A.W.L.)

LATERAL MORAINE. The **talus** or other material from the sides of a glacial valley accumulated upon the glacier and are carried away by it. Thus the mass of debris distributed along the lateral edges of the glacier is called a lateral **moraine.** In the case of valley glaciers which have disappeared, their former existence may often be proved by the traces of lateral moraines left along the sides of the valley. (R.M.F.)

LATERAL SEWER. **Lateral; Sewerage System.**

LATERITE. The sub-aerial decay of rocks in tropical regions, having a distinctly moist or rainy climate, results in the development of a residual, reddish, and usually sticky soil frequently containing **concretions.** The principal products of lateritization are the hydrated oxides of **aluminum** and **iron** either in the crystalline or amorphous form. If the concentration of iron oxide is sufficiently high the laterite may be valuable as an iron ore. If, on the other hand, the concentration of alumina is high the laterite may be valuable as an ore of that metal. (R.M.F.)

LATEX. Latex is a milky substance found in many plants. It is a complex emulsion in which such substances as **proteins, alkaloids, starches, sugars, oils, tannins, resins,** and **gums** are found. In most plants the latex is white; but in some it is yellow; in others, orange or scarlet.

The cells or vessels in which latex is found make up the laticiferous system. There are two very different ways in which this system may be formed. In many plants the laticiferous system is formed from cells laid down in the **meristematic** region of the stem or root. Rows of these cells are formed. The cell walls separating them are dissolved, so that continuous tubes, called latex vessels, are formed. This method of formation is found in the **poppy family;** in the rubber plant, *Hevea brasiliensis;* and in the Cichorieae, a section of the **composite family** distinguished by the presence of latex in its members. Dandelion, lettuce, hawkweed, and salsify are members of the Cichorieae.

In the **milkweed** and **spurge** families, on the other hand, the laticiferous system is formed in a very different way. Early in the development of the seedling latex cells are differentiated. As the seedling grows these latex cells grow, forming a branching system which extends throughout the plant. So in the mature plant the entire latex system results from the growth of a single cell or group of cells which were present in the **embryo.**

The laticiferous system is found in all parts of the mature plant, including roots, stems and leaves, and sometimes the fruits. It is particularly noticeable in the cortical (see **Cortex**) tissues.

Many functions have been attributed to latex. Some regard it as a form of stored food, while others consider it a sort of excretory substance in which waste products of the plant are deposited. To still others it is a substance which protects the plant in case of injuries, the latex exuding and drying to form a covering which prevents the entrance of harmful bacteria and fungi. Similarly it may be a protection against browsing animals, since in some plants it is very bitter, and in others, poisonous.

Many products useful and valuable to man are obtained from latex. First among these is **rubber,** obtained from the latex of many plants. **Chicle,** widely used as the base of chewing gum, is another latex product. So also is **opium,** with its many derivatives. (R.M.W.)

LATHE. A lathe is essentially a machine tool for producing and finishing surfaces of revolution. The machine is designed to hold and revolve work about an axis of rotation so that it may be subjected to the action of a cutting tool moving in a horizontal plane through the axis of the work. When the cutting tool moves in a longitudinal direction or parallel to the axis, the operation is known as turning; when it moves in a transverse direction, it is known as facing. In hand lathes for woodwork and some metal work, the cutting tool is guided by hand; in engine lathes the cutting tools are generally guided by the machine tool itself.

Figure 1 shows the front view of a wood-turning lathe. The rotating spindle carries a live or spur center

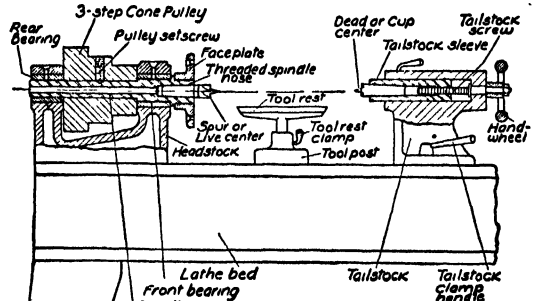


Fig. 1.

on which the piece to be turned is placed. The other end of the work is supported by and rotates on the non-rotating dead or cup center.

Many modern lathes have a motor built into the headstock with the spindle serving as the motor shaft. The lathe shown, however, is belt driven and has a three-step cone pulley which is driven from a counter-shaft cone pulley. The spur center fits in a tapered hole in the spindle which is hollow, so that the center may be removed by inserting a rod from the rear. The head-stock is fastened to the lathe bed and carries the bearings in which the spindle rotates.

The tailstock may be moved anywhere along the lathe bed and can be clamped in place at any point. The tailstock is keyed to the bed, however, so that the headstock and tailstock centers will always be in alignment. The tailstock carries a non-rotating sleeve, keyed to the tailstock, which may be advanced or retracted by means of the tailstock sleeve screw operated by the handwheel.

The dead center fits in a Morse Taper hole in the sleeve and may be removed by retracting the sleeve, thereby bringing the end of the tailstock screw against the rear of center and forcing it out. Major adjustment for work length is made by moving the tailstock and clamping it in position; subsequent fine adjustment to provide the proper bearing for the work is made by turning the handwheel. The sleeve clamp handle is used to clamp the sleeve after the center is adjusted to the work.

The tool post may be placed anywhere on the lathe bed and clamped in position; the tool rest is then adjusted for height and set either parallel to the work axis or in an angular position, and clamped by the tool rest clamp. In wood turning, the stock is centered and driven on the live center with a mallet. The dead center is brought up to approximate position by moving up the tailstock and clamping it. The tailstock sleeve is then adjusted and clamped so that the dead center is imbedded in the work (a small quantity of mineral oil having been previously applied to the center). The tool post is placed in position and clamped, and the tool rest is brought to the proper height and clamped.

The spurs on the live center cause the work to rotate. Cutting is performed by moving the tool towards the headstock so that the bearing will take the cutting thrust. An outside bevel gouge is generally used for converting the stock from its rough original shape to a cylindrical form. The skew or shaving chisel is used to obtain a smooth finish after roughing with the gouge. Scraping chisels are employed for both finishing cuts and for grooving and angular cuts. The cut-off or parting chisel is generally used for grooving work at various points to definite diameters to serve as a guide in turning, thus eliminating frequent measurement. Turning chisels are equipped with wooden handles. The handle is held in the left hand, and the right hand guides the cutting edge. The parting chisel, however, is held in the right hand while a caliper to check the groove diameter is held in the left hand.

The *engine lathe* is used for metal turning, and is essentially similar to the wood-turning lathe, except that it is fitted with a power-actuated carriage and cross-slide for clamping and holding the cutting tool. The headstock and tailstock of an engine lathe are similar to those on a wood-turning lathe, but the engine lathe tailstock rests on a saddle to which it is cross-keyed, so as to permit the tailstock center to be adjusted for alignment or misalignment with respect to the spindle center. The centers have 60° conical points to fit center holes in the work. Their shanks are fitted to self-holding tapers in the headstock spindle and tailstock sleeve. The live center is often left soft, but the dead center is hardened since the work rotates on it.

The carriage is supported on the lathe bed ways and can move in a direction parallel to the spindle axis. The front wall of the carriage is termed the apron which provides a support for the operating hand wheel and control levers. The cross-slide is mounted on the carriage, and can move at right angles to the spindle axis. It is operated by the cross-slide screw which turns in a nut fixed to the carriage. On the cross-slide is mounted a saddle in which the compound rest moves. The compound rest is similar to the cross-slide, except that it can be swung around at an angle. The compound rest slide is actuated by a screw which rotates in a nut fixed to the saddle. The tool post fits in a tee slot in the compound rest, and the tool holder is adjusted and supported by a rocker fitting in a concave ring, and clamped by the tool post screw.

For turning and facing, the carriage is driven from the headstock spindle by gearing or belting, through a feed shaft. For thread cutting, where a definite amount of carriage movement is required for every spindle rotation, a lead screw, geared to the spindle, is used for the motion of the carriage.

The size of a lathe is determined by the diameter and length of work that may be swung between centers. A 14″ x 54″ lathe, for example, will handle parts that are 14″ in diameter and 54″ long. Lathes of comparatively small swing are generally termed bench lathes. Gap lathes are large engine lathes with a space or gap in the bed at the headstock which will permit work to be handled, particularly in facing operations, that would exceed the capacity of the ordinary engine lathe of similar proportions. Very large lathes, particularly those employed in ordnance manufacture, are often made without legs with a bed mounted directly on a concrete base.

There are three important methods of holding and rotating work in engine lathes, which may be referred to as turning between centers; chuck work; and faceplate work. In turning between centers, the work is supported by the 60° conical points of the live and dead centers, turns with the live center, and on the dead center. The work must therefore have 60° center holes in each end, machined by using a pilot drill and a 60° countersink, or a center drill. (The function of the drilled hole is to insure contact on the sides of the conical hole and not at the extreme point.) The work is rotated by a lathe dog, illustrated in Fig. 2, which is clamped to the work by means of a set screw. The tail of the dog fits loosely in a slot in the lathe faceplate and turns with it. In many lathes, the faceplate *F* screws on the spindle nose. In modern heavy-duty lathes, the faceplate is seated and keyed on a standard tapered spindle nose, and is drawn on and held in place by a "pull-on" nut engaging external threads on the hub of the faceplate. Lathe chucks are held in the same manner.

Draw-in chucks and collets are used for bar work, and are designed to fit on the heavy-duty spindle nose if the live center is removed. The collets, which are of various sizes, fit in the chuck and are clamped with a removable key or wrench. Drawing in the spring collet forces its outer surface against the taper on the inside of the chuck; releasing the collet causes its jaws to open by their spring action. Bars of any length may be held in the chuck, extending entirely through the hole in the spindle if necessary. Collets for all standard sizes of circular rod are available as well as collets for hexagonal bar stock and cylindrical metric sizes.

Fig. 2 illustrates the essential operations in turning cylindrical work on a lathe. The work shown is a cylindrical bar of cast iron. The casting is about 3/16″ larger in diameter, and has been previously cut to a length of 1/16″ greater than the finished part. The first operation is not illustrated, and consists of centering each end of the casting and drilling center holes with a center drill. A bent-tail lathe dog is clamped to one end of the bar which is placed between the live and dead centers of the lathe. The lathe dog tail fits loosely in the slot in the faceplate and serves to drive the work. The dead center is lubricated with some substance such as white-lead and oil, and adjusted to the work by

turning the tailstock sleeve screw handwheel so that the work will rotate on the dead center without any perceptible looseness or "shake." The tailstock is then clamped. A straight-shank turning tool with an inserted tool bit is placed in the tool post and adjusted by means of the supporting rocker so that the tool point or cutting edge will be very slightly above center. The tool post screw is tightened so as to clamp the tool holder in place.

Fig. 2 shows the initial rough-turning operation about half completed. A cut sufficiently deep to get under the

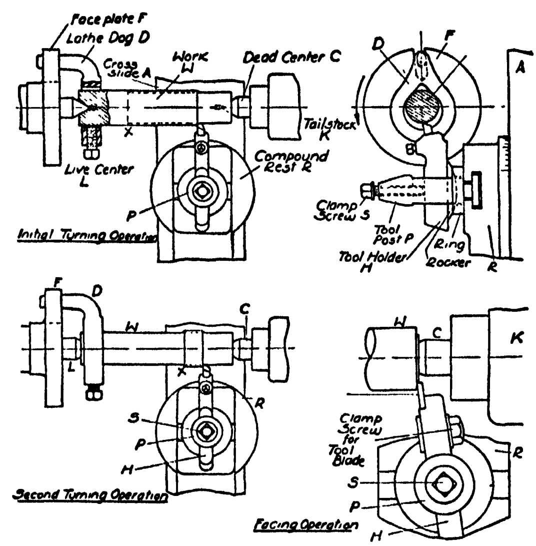

Fig. 2.

casting scale is taken, but at least .015" to .025" must remain for finish turning. The depth of cut is set by adjusting either the cross-slide or the compound rest, and the operator starts the longitudinal feed of the carriage by turning the carriage hand wheel. As soon as the operator observes that the feed and cut are satisfactory, he engages the power feed for the carriage, and the turning continues until point *X* is reached. At this point the lathe spindle rotation and the feed are stopped, the dead center is withdrawn, the work is removed from the centers, and the carriage is returned by hand to its position. The lathe dog is taken off the end of the bar and placed on the other end of the work which is then replaced between the centers, thus reversing the work end for end. Without disturbing the tool setting, the balance of the bar is then rough-turned as shown in the second turning operation. The second roughing cut is run slightly past point *X* to be certain that no ridge remains.

The same procedure is followed for the finishing cut. The tool is generally resharpened or stoned for this operation. A trial finishing cut is taken; this cut is just long enough so that the bar diameter may be measured, which may be done by using outside calipers, vernier calipers, or a micrometer, depending upon the degree of precision required. If the diameter is correct, the longitudinal power feed of the carriage are engaged, and a finishing cut is taken for about two-thirds of the length of the bar. The work is then reversed end for end, and the remainder of the bar length is finish-turned with the same tool setting. The finished surface on the second finishing cut is generally protected by inserting a piece of copper or brass between the work and the point of the lathe dog set screw.

After the cylindrical surface of the work is finished, the turning tool is removed, and a right-hand offset side tool is substituted. The carriage is set in the approximate position required for the end facing cut and clamped. The compound rest is set around at an angle and used to provide adjustment for the depth of cut. The cross-slide is employed to feed the tool towards the axis of the work, and is generally hand-operated because the distance to be traversed is so short. After one end is squared, the work is reversed between centers, the other end squared, and the bar brought to correct length. The facing or squaring operation generally leaves a burr at the center holes, which must be removed by filing at the bench. In some instances it is necessary to obtain a smoother finish than that provided by turning. In such cases finishing by filing and polishing with emery cloth may be resorted to. An ordinary single-cut mill file is employed for lathe work. When a filed finish is required, the operator generally turns the bar .0005" to .001" oversize for filing allowance. Too much filing may destroy the precision of the bar; too little will not permit the removal of the turned ridges.

In machining long bars of small diameter, the bar has a tendency to spring away from the cutting tool so that a truly cylindrical surface cannot be procured. For such work some form of auxiliary support other than the use of the centers is required. The follower rest is a support that is bolted to the carriage with bearing blocks that can be adjusted to fit the turned surface. Whenever the bar has several diameters so that a follower rest cannot be employed, a steadyrest may be used. In this case it is necessary to turn a small portion of the bar to size, which can generally be done by taking light cuts. The steadyrest is clamped to the lathe bed, and its bearing blocks are adjusted to the turned surface or "seat" on the bar. In this application the steadyrest acts as a center bearing, but is not as effective as the follower rest which provides a support immediately to the right of the turning tool, or practically at the point where the cutting force is exerted.

Tapered or conical work may be turned in the lathe by three methods. The first method necessitates setting-over the tailstock an amount equal to one-half the taper, based upon the actual length of the stock. The set-over method is not applicable to large tapers since the centers will not fit properly in the center holes. The taper attachment method is accurate but requires a taper-turning attachment on the lathe. In this method the clamping bolt for the cross-slide feed screw nut is removed so that the motion of the cross-slide is no longer controlled by its screw, but is guided by a block moving in the taper attachment guide. The tool adjustment and setting is effected by the compound rest. Another method of turning tapers, particularly large tapers, is to set the compound rest at the required angle, clamp the carriage in place, adjust and set the tool by using the cross-slide, and cut the taper by hand-feeding the compound rest.

Hollow cylindrical work is usually machined in a lathe by drilling and boring the hole while the part is held in a chuck; the work is then removed and driven or pressed on a mandrel, which is swung between centers to turn the exterior periphery and face the ends. The hole in the work may be bored by a boring tool held in the tool post, or drilled and reamed by taper-shank twist drills and reamers held in the dead center socket in the tailstock sleeve.

In thread cutting, it is necessary that the carriage advance a definite amount for every revolution of the spindle, which is accomplished by connecting the lead screw to the stud, an auxiliary shaft rotating at the same speed as the spindle, by spur gears. Engine lathes are equipped either with a change gear box or with loose gears, called change gears, to provide suitable speed ratios for the stud and the lead screw. If, for example, the lead screw has 6 threads per inch, and a 6-pitch screw is to be cut, the gears on the stud and screw should have the same number of teeth; if a 12-pitch thread is to be cut, the gear on the stud should have one-half as many teeth as the gear on the screw.

Since lathes are equipped with a limited number of change gears, it is often necessary to compound the gearing to cut special thread pitches.

Lathes are also used for boring brackets, frames, etc., that cannot be held in a chuck or on a faceplate; this may be accomplished by removing the compound rest, mounting the work on the cross-slide, and using a boring bar held between the lathe centers. Springs may be wound on a lathe by using a mandrel of suitable size, and using the lead screw to provide a constant lead for the spring. A special tool or wire holder to furnish the necessary tension on the spring wire is required. (H.C.H.)

LATIN SQUARE. The Latin square is a type of design used in the **analysis of variance.** Consider a table of r rows, r columns arranged in such a manner that each treatment occurs once and only once in every row and every column. The total sum of squares equals then the sum of squares among column **means,** among row means, and among treatment means. We are interested in testing the hypothesis that treatment means are equal, assuming the **variates** are **normally distributed** with common **variance** σ^2. The analysis of variance proceeds as follows:

Mean square among column means

$$r\frac{\Sigma(\bar{X}_c - \bar{X})^2}{r - 1} = V_c$$

Mean square among row means

$$r\frac{\Sigma(\bar{X}_r - \bar{X})^2}{r - 1} = V_r$$

Mean square among treatment means

$$r\frac{\Sigma(\bar{X}_t - \bar{X})^2}{r - 1} = V_t$$

Mean square due to error

$$\frac{1}{r - 2}\{(r + 1)V_T - V_c - V_r - V_t\} = V_e$$

Total mean square

$$\frac{\sum_{j=1}^{r}\sum_{i=1}^{r}(X_{ij} - \bar{X})^2}{r^2 - 1} = V_T$$

To test the hypothesis of equality of treatment means we compute **Snedecor's** $F = \frac{V_t}{V_e}$ with $n_1 = r - 1$, the **degrees of freedom** of the numerator and $n_2 = (r - 1)(r - 2)$, the degrees of freedom of the denominator. In this analysis $\bar{X}_c$ = mean of a column, $\bar{X}_r$ = mean of a row, $\bar{X}_t$ = mean of a particular treatment, Xij is the variate in the ith row and jth column, and $\bar{X}$ = mean of all the variates. The Latin square is an effective way of finding the causes of variation when there are 3 sources of variation and it is desired to eliminate the variation due to 2 of the sources of variation, the third source of variation generally called a treatment.

Latin squares are effective designs in agriculture and industry, particularly if the square consists of less than 10 rows and 10 columns. (See **Randomized Blocks.**) (L.A.A.)

LATITUDE. The celestial latitude of a point on the **celestial sphere** is the **spherical coordinate** measured from the plane of the **ecliptic** along a great circle passing through the object and the poles of the ecliptic.

Because of the fact that the earth is not a perfect sphere there are several different sorts of terrestrial latitude in use. In Fig. 1 we have $PEP'E'$ an **ellipse** representing a section of the earth in the plane of a **meridian.** C is the geometric center of the earth and the line COZ' is the line to the geocentric **zenith** of the point O. The angle ECO (φ') is the geocentric latitude of the point O.

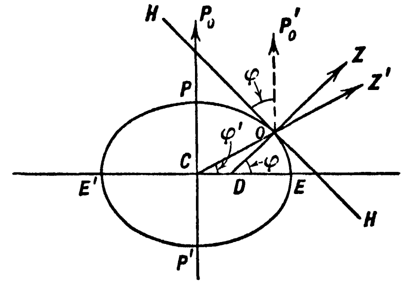

Fig. 1. Astronomic and geocentric latitudes.

The line DOZ represents the direction of **gravity** at the point O and extends to the astronomic zenith of O. The angle EDZ (φ) is the astronomic latitude of the point O. The difference between the astronomic and geocentric latitude of a point, the angle $COD = \varphi - \varphi'$, is defined as the reduction of latitude for the point O.

Because of local influences, such as massive mountains in the vicinity, the direction of the plumb line may not be strictly perpendicular to the surface of the earth. The geographical latitude of a point is the angle, measured in the plane of the local meridian, between the equator and a line drawn perpendicular to the theoretical **geoid** (surface of the earth) through the point in question. The difference between astronomic and geographic latitude is always relatively small, but by no means an inappreciable angle, and is known as station error. Station error is commonly between 4 and 6 seconds of arc, but occasionally amounts to 30 or 40 seconds.

In Fig. 1 CP represents the axis of rotation of the earth, which, if extended, will pierce the celestial sphere in its pole of rotation. The parallel line OP'_0 is the line from the observer at O to the pole of rotation of the celestial sphere and the line HOH represents the plane of the astronomic **horizon** at O. HOP'_0 is the **altitude** of the pole of rotation at O and inspection of the figure will indicate that this is equivalent to the angle EDZ. This gives rise to the common definition that the astronomic latitude of a point is the altitude of the pole of rotation of the celestial sphere at the point.

Astronomic latitude may be determined in a variety of ways by observation of the celestial objects. The most direct method is to observe the altitude of some object on the meridian whose **declination** is known. In Fig. 2 we have a representation of the celestial sphere drawn in the plane of the local **meridian** of the point O. In the figure, HOH' represents the plane of the horizon; $HPZQH'$ represents the local meridian; OP the direction of the pole of rotation; OQ the direction of the equator. $HOP = \varphi$ (the astronomic latitude of O), and $H'OQ = 90 - \varphi$.

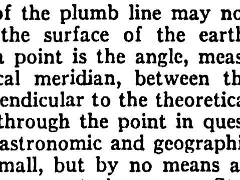

Fig. 2.

Since $H'S$ represents the altitude of a celestial object S which is on the meridian, and QS represents the **declination,** δ, of the object, we have at once the relationship that $\varphi = \delta + 90° -$ altitude. This is the method of determination of latitude most commonly used at sea and presents two fundamental difficulties to the navigator. The instant that the object is on the meridian must be accurately known and also the declination of the object observed. In case both the Greenwich **time** and the **longitude** are known, the instant that the object should reach the meridian may be calculated in advance from the **right ascension** of the object; and the observation of altitude is taken at the predetermined instant. Before chronometers came into

use it was necessary to watch the object very carefully and record the maximum altitude attained by the object. In case the object was the sun, the time that the maximum altitude was obtained was the local apparent noon and was used by the navigating officer for setting the watch time for the ship. If the observed object is a star the declination may be immediately obtained from star catalogues, but in case the sun, whose declination is changing rapidly, is observed, the Greenwich time of observation must be used to obtain the declination from the **ephemeris**.

In case the meridian observation is missed on account of clouds or for any other reason, the **astronomical triangle** may be solved to obtain the latitude if the local time of observation and the declination of the object are both known. In case the object is observed very close to the meridian and the approximate latitude as well as the local time is known, the observation may be "reduced to the meridian" by tables published in a variety of places such as "Bowditch American Practical Navigator."

Modern navigational methods for determining latitude are discussed elsewhere. (See **Celestial Navigation, Dead Reckoning, Fix, Radio Navigation.**)

A meridian altitude of an object is always effected by the correction for **astronomical refraction** which is always subject to error unless the object observed is close to the zenith. For accurate determination of latitude for purposes of geodetic surveying the **zenith telescope** is used and the method will be described under the description of this instrument. (W.E.C.)

LATITUDE AND DEPARTURE. **Bearing.**

LATTICE. **Crystal Structure.**

LATTICE BAR. **Compression Member.**

LAUDANINE. **Alkaloids.**

LAUE PATTERN. **Crystal Structure; X-rays.**

LAUGHING GAS. Nitrous oxide. (See **Nitrogen.**)

LAVA. Molten material which has poured out on the surface of the earth and, due to relief of pressure, may have lost much of its original gas and water content during its relatively rapid consolidation. The term lava is used for both the liquid and the consolidated state of the igneous material. Lava may be erupted either by volcanoes or from fissures. The most extensive lava flows are fissure eruptions, such as the Columbia Plateau **basalts** in Oregon or the plateau basalts of the Deccan, India, which are derived from basic **magma.** Had this magma, either basic or acid, cooled slowly beneath the surface of the earth under great pressure and with all its original gases, the resulting rock would have had a coarser texture and somewhat different mineral content. (R.M.F.)

LAVENDER. **Mint Family.**

LAVENDER OIL. **Volatile Oils.**

LAW OF AVERAGES. The distribution of **sample means** possesses less **variability,** that is, it has a smaller **standard deviation** than the distribution of the variates themselves. This is readily seen since the standard deviation of sample means is $\frac{\sigma_x}{\sqrt{N}}$ (N is the size of the sample), while the standard deviation is σ_x. (See **Law of Large Numbers.**) (L.A.A.)

LAW OF LARGE NUMBERS. There are various laws of large numbers but the essential idea is exactly the same in each case. If the size of a **sample** is increased indefinitely or becomes very large, sample estimates of **population parameters** will ordinarily be very accurate. **Bernoulli's theorem** is the first illustration of a law of large numbers.

In a second law of large numbers we state a corresponding theorem for **sample means** $\bar{X}$ as compared with the population mean m. In the limit as the size, N, of a sample increases, the **probability** of obtaining a discrepancy between a sample mean and a population mean of more than $\epsilon > 0$ in absolute value approaches 0, provided that the **variable** possesses a **standard deviation.**

$$\lim_{n \to \infty} P(|\bar{X} - m| > \epsilon) = 0.$$

There are other "laws of large numbers" somewhat more general. (L.A.A.)

LAW OF SMALL NUMBERS. If a **variable** is distributed in a **Poisson distribution,** then the variable is said to be distributed according to the law of small numbers or rare events, provided m, the mean is small. Bortkiewicz gives as an example the **frequency distribution** of the number of deaths per army corps per year in the Prussian army caused by horse kicks. Another example occurs in **industrial statistics** when the **universe** is essentially infinite, such as the number of defects on an article, since this number might possibly be very large. If the mathematical conditions for a Poisson probability function are not closely observed, the law of small numbers cannot be assumed arbitrarily just because the event is a rare event. (L.A.A.)

LAW OF SUPERPOSITION. **Superposition.**

LAWYER. Pisces, Teleostei. A fresh-water fish (**Pisces**) related to the cods. Also known as the **burbot** and ling. Most common in northern North America. (A.W.L.)

LAZURITE. The mineral lazurite or lapis lazuli has been used since ancient times for jewelry and other ornamental purposes. Ground to powder it forms the pigment ultramarine, now, however, largely superseded by artificial preparations. Lapis lazuli is a mixture of minerals, lazurite being the chief component. This mineral is isometric, and chemically a **sodium, calcium, aluminum sulfo-chloro-silicate.** Lapis lazuli has a hardness of 5–5.5; specific gravity 2.4; color, various shades of blue; luster, vitreous to greasy; translucent to opaque. Localities are Afghanistan, Siberia, Chile, and California. (E.S.C.S.)

LEAD. Symbol: Pb (plumbum). Atomic number: 82. Atomic weight: 207.22. Density: 11.34. Hardness: 1.5. Melting point: 327.5° C. Boiling point: 1620° C. (**Isotopes:** page 290.)

Lead is a white to bluish-gray metal, soft, malleable, and slightly ductile; tarnishes in air, forming a film of oxide, forms oxide scum upon heating the molten metal in air; soluble in dilute **nitric acid; hydrochloric** or **sulfuric acid** attack lead only slightly, the extent depending markedly upon the concentration and the temperature; slowly dissolves in water and consequently the use of lead constitutes a health hazard due to its toxic effect; attacked by solutions of organic **acids** or **sodium** hydroxide. Lead is the end-product of the **uranium-radium** and **thorium** series. Discovery prehistoric. Lead is one of the four most largely produced and utilized metals, and considerable scrap metal is recovered. Used (1) in construction and apparatus where workability is demanded, and definite resistance to corrosion is supplied by the metal, (2) as a constituent of various alloys, especially solder, type metal, pewter, and fusible alloys, (3) for storage battery plates, (4) for shot and bullets, (5) as a protective coating for iron and steel.

Lead occurs principally as sulfide ore (**galenite, galena** PbS) in Missouri, Idaho, and Utah of the United States, Broken Hill of New South Wales, Mexico, and Spain. The sulfide ore is roasted in air, resulting in a variable mixture of sulfide, sulfate, and oxide. The temperature is then raised with the exclusion of air, whereupon the sulfide reacts both with sulfate and with oxide to form **sulfur dioxide** gas and molten lead, which latter is drawn off and cast into blocks. Another method of obtaining lead is by fusion of the sulfide with scrap iron metal, thus yielding molten **ferrous** sulfide **slag** and molten lead separable by difference in densities. The refining of lead is conducted (1) by passing air over the surface of molten lead and removing the oxidized layer or "scum," (2) by **electrolysis** of lead fluosilicate solution in **hydrofluosilicic acid.**

Lead is commercially produced to standards of very high purity. The minimum lead content permitted by the A.S.T.M. Specifications for Pig Lead (7 classifications) is 99.73% and fully refined metal averaging 99.99% lead is obtainable. Large quantities are used for the production of paint pigments and lead tetraethyl for gasoline. Lead is soft and ductile and is readily worked by most of the popular methods, particularly by rolling and extrusion. It is easily formed and readily joined by welding (burning) or by soldering, and can be bonded to steel or be used as a liner for steel, wood, concrete, etc., as required. Lead is widely used because of its excellent resistance to atmospheric corrosion, soil corrosion, and attack by certain of the mineral acids, notably sulfuric and phosphoric. It generally does not resist the action of the organic acids nor the oxidizing mineral acids, such as nitric, and is attacked by alkalis and distilled water.

Acetates: Lead acetate, "sugar of lead" ($Pb(C_2H_3O_2)_2 \cdot 3H_2O$), white crystals, soluble, formed by reaction of lead oxide and **acetic acid,** and then crystallization. Used (1) to furnish a soluble lead salt, (2) as a mordant in dyeing and printing textiles, (3) as a paint and varnish drier; basic lead acetate, white crystals, soluble, formed by reaction of lead acetate solution and lead oxide, and then crystallization. Used (1) as a coagulating, clarifying, and de-acidifying agent for many organic solutions, (2) in weighting silk.

Arsenate: Lead arsenate, arsenate of lead ($Pb_3(AsO_4)_2$), white precipitate, formed by reaction of soluble lead salt solution and **sodium** arsenate solution. Used as an insecticide.

Azide: Lead azide (PbN_6), white precipitate, formed by reaction of soluble lead salt solution and **sodium** azide solution (white solid, formed by reaction of sodamide ($NaNH_2$) upon heating in nitrous oxide N_2O) gas). Used as a detonator.

Borate: Lead borate ($Pb(BO_2)_2$), white crystals, insoluble, by reaction of lead oxide and **boric acid** solution. Used as a paint and varnish drier, and in preparing special types of **glass.**

Bromide: Lead bromide ($PbBr_2$), white precipitate, formed by reaction of soluble lead salt solution and **potassium** bromide solution, melting point 373° C.

Carbonates: Lead carbonate ($PbCO_3$), white precipitate, formed by reaction of soluble lead salt solution and **sodium** carbonate solution in the cold; basic lead carbonate, formed by reaction of (1) soluble lead salt solution and hot **sodium** carbonate solution, (2) lead sheets, **carbon dioxide** and **acetic acid,** for "white lead" paint pigment, the quality depending largely upon the conditions of the reaction.

Chlorides: Lead chloride ($PbCl_2$), white precipitate, formed by reaction of soluble lead salt solution and **hydrochloric acid** or **sodium** chloride solution in the cold, markedly soluble in hot water, melting point of lead chloride 501° C.; lead tetrachloride ($PbCl_4$), yellow liquid, formed by reaction of lead dioxide or chloride and concentrated **hydrochloric acid** in the cold, is explosive on warming.

Chromates: Lead chromate, "chrome yellow" ($PbCrO_4$), yellow precipitate, by reaction of soluble lead salt solution and **sodium** dichromate or chromate solution, melting point of lead chromate 844° C. Used as a pigment; basic lead chromate, red solid, insoluble, formed by heating lead chromate and sodium hydroxide solution.

Fluoride: Lead fluoride (PbF_2), white precipitate, formed by reaction of soluble lead salt solution and **sodium** fluoride solution, melting point of lead fluoride 855° C.

Hydroxide: Lead hydroxide ($Pb(OH)_2$), (probably a basic hydroxide, formed), white precipitate, formed by reaction of soluble lead salt solution and **sodium** or **ammonium** hydroxide solution, soluble in **nitric acid** or excess sodium hydroxide, insoluble in ammonium hydroxide, yields lead oxide and water at 130° C.

Iodide: Lead iodide (PbI_2), yellow precipitate, formed by reaction of soluble lead salt and **potassium** iodide solution, melting point of lead iodide 402° C.

Nitrates: Lead nitrate ($Pb(NO_3)_2$), white crystals, soluble, formed by reaction of lead oxide and **nitric acid,** and then crystallization, decomposes on heating leaving lead oxide residue. Used to furnish a soluble lead salt; basic lead nitrate, formed by reaction of lead nitrate solution and lead oxide.

Oxalate: Lead oxalate (PbC_2O_4), white precipitate, formed by reaction of soluble lead salt solution and **ammonium** oxalate solution, yields lead suboxide on heating at 300° C. out of contact with air.

Oxides: Lead suboxide (Pb_2O), black solid, formed by heating lead oxalate at 300° C. out of contact with the air; lead, oxide, lead monoxide, "litharge," "massicot" (yellowish), "yellow lead oxide" (PbO), yellow solid, insoluble, formed by heating in air any of the following: lead metal, lead dioxide, trilead tetroxide, or lead nitrate. Melting point of lead oxide 888° C., easily reduced to lead metal by heating with dry reducing agents. Used (1) for making many lead compounds, (2) in the manufacture of storage **battery** plates, (3) in compounding **rubber,** (4) in certain **glasses** and enamels for ceramic ware; trilead tetroxide, plumbo-plumbic oxide, "minium," "red lead" (Pb_3O_4), red solid, formed by heating lead oxide at 400° C. for some time, at higher temperatures decomposes to form lead oxide and oxygen, with **hydrochloric acid** yields lead chloride and chlorine gas, with **nitric acid,** lead nitrate and dioxide. Used (1) as a paint pigment especially on iron and steel, (2) in certain glasses and enamels for ceramic ware, (3) in packing metal pipe joints, (4) in compounding rubber; plumbic oxide, lead sesquioxide (Pb_2O_3), reddish-yellow solid, by reaction of **sodium** hypochlorite solution and lead hydroxide; lead dioxide, "brown lead oxide" (PbO_2), brown solid, formed (1) by reaction of trilead tetroxide and **nitric acid,** and then separating the dioxide precipitate from the solution of lead nitrate, (2) by **electrolysis** (at the anode) of lead oxide in the grids of the storage battery (lead metal simultaneously formed at the cathode electrolyte sulfuric acid). Used (1) as an oxidizing agent, e.g., in matches, (2) as one electrode of the lead storage battery.

Phosphate: Lead phosphate ($Pb_3(PO_4)_2$), white precipitate, by reaction of soluble lead salt solution and **sodium** phosphate solution.

Sulfates: Lead sulfate ($PbSO_4$), white precipitate, formed by reaction of soluble lead salt solution and **sulfuric acid** or **sodium** sulfate solution; basic lead sulfate, "sublimed white lead," white solid, formed (1) by reaction of lead sulfate and lead hydroxide in water (slow reaction), (2) by roasting galenite in a current of air. Used as a paint pigment called "sublimed white lead."

Sulfide: Lead sulfide (PbS), brownish-black precipitate, formed by reaction of soluble lead salt solution and **hydrogen sulfide** or **sodium** or **ammonium** sulfide, soluble in dilute nitric acid.

Tetraethyl lead ($(C_2H_5)_4Pb$), colorless liquid, decomposes at 125° C., formed by reaction of ethyl chloride and lead **sodium amalgam.** Used as an "anti-knock" in small concentrations in **gasoline** motor fuel. (See **Worm Gearing.**) (R.K.S., J. S. SMART, JR.)

LEAD AND TIN ALLOYS. Due to its softness, pure lead will very gradually flow or "creep," particularly at elevated temperatures, under low sustained stresses such as the oil pressure in lead-covered power conducting cable, or due to its weight in the case of a deep tank lined with sheet lead. For such purposes lead containing .06% copper ("Chemical" or "Acid" lead) is preferred, due to its superior resistance to "creep."

The addition of antimony in amounts up to 12% greatly improves the casting properties and increases the hardness very materially. These properties make possible the casting of intricately shaped antimonial lead storage-battery grids which, including the weight of the lead oxide paste applied to them, constitute the largest single use for the metal.

Tin and lead in various proportions form a highly useful series of alloys generally known as the soft solders which are used for joining copper, iron, nickel, lead, zinc and even glass. The solders can be applied by means of a soldering tool, by wiping, by hot-dipping or by special machines as in the tin-can industry. Numerous compositions are used, the most popular of which are listed in the accompanying table.

Further additions of bismuth, cadmium, and antimony to the tin-lead alloys result in the low melting or "fusible" alloys widely used as safety devices, the melting points of which can be varied to suit a wide range of requirements. The type metals of the printing industry are lead-tin-antimony alloys having the requisite hardness and good casting properties needed for high-fidelity reproduction.

The **Babbitts,** or white-metal bearing alloys, are generally classified as either tin-base or lead-base. The true tin-base Babbitts contain only tin, antimony and copper, and have been used for many years. The practice of adding up to 25% lead to the tin Babbitts to reduce their cost is to be avoided since the net result is an expensive series of alloys with inferior properties to the inexpensive lead-base Babbitts. The lead-base bearing alloys of the older type usually contain lead, antimony and tin, and while not considered the equal of the tin-base alloys for severe service have been widely employed due to their low cost. In the past few years the lead-base alloy containing arsenic has found very extensive use and has come to the fore of this group since it has successfully met many automotive and other severe service requirements. All of these alloys render their most efficient service when used in the form of a thin lining bonded to a bronze or steel shell. (J. S. SMART, JR.)

REPRESENTATIVE LEAD AND TIN ALLOYS

Name	Pb	Sn	Sb	Cu	Bi	Ag	Cd	Typical Applications
Lead Alloys								
Chemical or acid lead	99.9			.06				Tank linings, coils, etc., power cable sheath.
Cable sheath	98.9		1.0					Telephone cable sheath.
Hard lead	96–92		4–8					Cast shapes, wrought sheet and pipe.
Battery grid metal	92–88	.25	8–12					Cast battery grids.
Solders								
Soft solder	50	50						General purposes, most popular solder.
Wiping solder	60	40						For wiping joints in cables, lead pipes, etc.
	60	37.5	2.5					
"Fine solder"	40	60						For making joints at low temperature.
Solder	95–97.5					5–2.5		High temperature solder.
Fusible Alloys								
Wood's metal	25	12.5			50		12.5	Melts in hot water at 154° F. Wets glass. Wide range of melting points possible with changes in composition for automatic sprinkler systems and other safety devices.
Matrix metal	28.5	14.5	9		48			For anchoring punches, etc., in jigs and fixtures. Expands on freezing.
Bending alloy	26.5	13.5			50		10	Filler for tubes, etc., during bending. Melts out in hot water.
Type Metals								
Electrotype	93	3	4					
Linotype	84	4	12					
Stereotype	80.5	5.75	13.75					
Monotype	76	8	16					Single type.
Tin Base Babbitts								
ASTM #2		89	7.5	3.5				General usage.
ASTM #3		83.3	8.3	8.3				Hard Babbitt.
Lead Base Babbitts								
ASTM #15	82.5	1.0	15	.5	1.0 As			General usage.
ASTM #8	80	5	15					General usage.
ASTM #7	75	10	15					General usage.

LEAD, ENGINE. This is a steam engine term and means the distances the valve has uncovered the inlet port when the piston has reached dead center position. Lead is employed to decrease **wire drawing** of the steam engine cycle. (F.T.M.)

LEAD POISONING. This form of metal poisoning is often seen as an occupational disease. There are

about 150 occupations which may expose the worker to lead poisoning, either from inhaling lead dust or absorbing it through the skin. These occupations include the manufacture of white and red **lead**, rubber, printing materials, storage batteries, pottery, etc. It is much less common now than 20 years ago due to better factory conditions. Poisoning may also occur from the use of hair dyes, cosmetics, and food or water contaminated with lead.

Lead is a cumulative poison, the metal being stored in the solid portion of the body skeleton. For this reason, even after exposure has ceased, its excretion from the body may continue for years.

The symptoms of chronic poisoning are great weakness, constipation, severe abdominal cramps ("lead colic"), marked anemia, palsy, and, at times, psychic manifestations and paralyses.

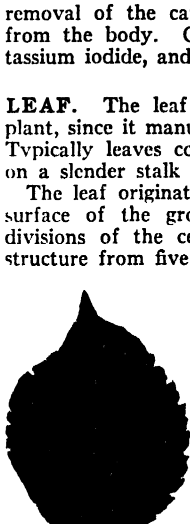
The red **blood** cells of a patient with lead poisoning show a peculiar stippling that is characteristic of this disease. (Figure 2, Plate B, facing page 180.) The deposit of lead sulfide about the blood vessels near the margins of the gums sometimes causes a visible "lead line."

The prognosis is good in most cases of lead poisoning, although symptoms may persist for many years. Paralyses and mental symptoms in advanced cases may be permanent.

Treatment is directed towards relief of symptoms, removal of the cause, and increased excretion of lead from the body. Calcium gluconate intravenously, potassium iodide, and saline cathartics are used. (D.M.H.)

LEAF. The leaf is a most important organ of the plant, since it manufactures food (see **Photosynthesis**). Typically leaves consist of a broad thin lamina borne on a slender stalk and green in color.

The leaf originates as a small protuberance from the surface of the growing tip of the stem. Numerous divisions of the cells of this protuberance produce a structure from five to eight cells thick. Many of these leaf primordia are borne together on the stem tip, and, together with any protecting scales which may cover them, form the **buds** of the stem. At first all the cells of these leaf primordia are alike. Very early in their existence, however, certain cells become distinct by their somewhat elongated shape. These cells are the beginnings of the **vascular** elements. Cell divisions continue in these small bodies until there are present in the bud recognizable but very small leaves which are folded in various ways. In woody plants this development takes place in the year previous to that in which the leaf will unfold. With the advent of the new growing season, growth of the many minute cells of these tiny leaves is very rapid, so that within a few days' time the leaf has unfolded and grown to its mature size. During this enlargement many changes have taken place in the cells of the leaf.



Leaf of apple, illustrating all parts—blade, petiole, and stipules.

The mature leaf is commonly composed of two distinct parts, the broadly expanded, thin green blade, and the petiole or stalk which supports it and connects it with the stem. In many plants there is formed at the base of the petioles a pair of outgrowths called stipules, which in some plants may take the form of a complete sheath. This sheath is well developed in members of the **Carrot Family**. Sometimes the petiole is completely lacking, the blade being attached directly to the stem; leaves of this kind are called sessile leaves. Less frequently the blade of the leaf is lacking, the petiole being expanded into a flattened object looking much like a blade. Certain Australian trees, species of *Acacia* and *Eucalyptus*, exhibit this peculiarity. Leaves of such plants often show progressive changes from those having well-developed blades to those in which the blade is completely lacking, showing clearly that the flattened portion present is a modified petiole. Such flattened petioles are not uncommon, but usually the blade is present, as is the case in the lemon tree. Leaves may be deciduous, falling off at the end of a single growing season, or evergreen and persistent through several seasons. In nearly all cases the leaf fall is brought about by the development of a definite **abscission layer.** In many plants such a layer is formed not only at the base of the petiole but also at the point where the petiole joins the blade.

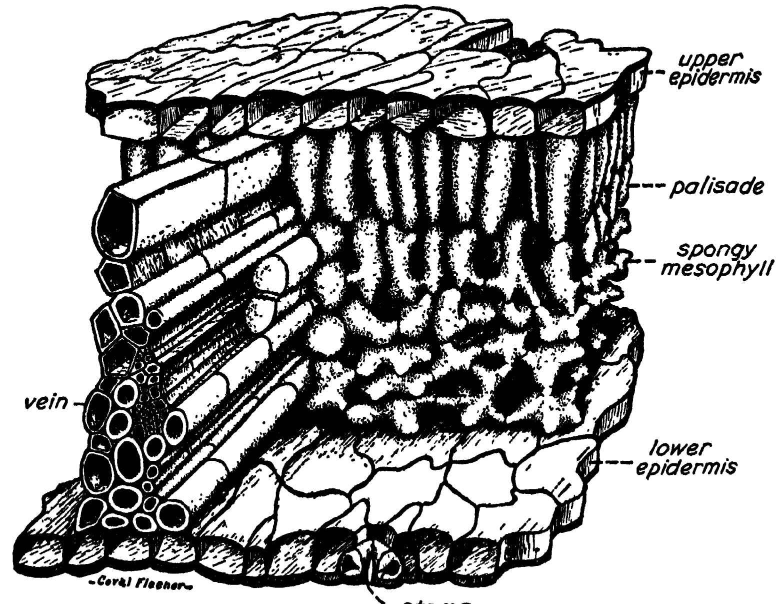
The shape of the blade is extremely varied, ranging from very slender linear leaves to those which are broader than they are long. The margin of the leaf may be entire, that is, without indentations of any sort, or toothed or lobed in various ways, until some are incised nearly to the midrib. If the leaf is completely divided into separate segments it is said to be a compound leaf, in contrast with the undivided leaves, which are simple leaves, no matter how deeply they may be lobed. If the sections of a compound leaf all come from a common point, the leaf is said to be palmately compound; if they are borne along a central axis, the leaf is pinnately compound. While such infinite variations do exist, the leaves of any single species of plant are recognizably constant in shape.

The blade of the leaf is supported by a framework of veins which are also very characteristically arranged. In many leaves, especially in **dicotyledons**, one vein, usually extending through the center of the blade, is more prominent than the others. This is called the main vein or midrib. The others are lateral veins. In most dicotyledons the veins branch abundantly to form an intricately anastomosing network, which reaches all parts of the leaf. In most **monocotyledons** the midrib and lateral veins extend in parallel lines from base to apex of the leaf. Between these many minute veinlets exist, too small to be readily seen, reaching all parts of the leaf.

The cellular structure in leaves is very constant. (see next page for illustrations.) Covering the entire surface of the leaf is the epidermis, a layer of tabular cells. On the upper surface of the leaf the epidermal cells are frequently covered with a layer of cutin, a waxy substance which is impervious to water and so greatly reduces the loss of water by evaporation from the leaf surface. Epidermal cells contain a scant peripheral **cytoplasm,** and a large central **vacuole** full of cell-sap. Usually there are no **chloroplasts** present in the epidermal cells. The cells of the epidermis of the lower surface are similar to those of the upper, but with a less evident cuticle. In the epidermis of the leaf, particularly that of the lower surface, there are many minute openings, called **stomata,** which permit a ready exchange of gases between the interior of the leaf and the external air. Each stoma is surrounded by a pair of guard cells containing chloroplasts. These cells close the stoma by collapsing and open it by expanding. All cells occurring between the upper and lower epidermal layers are called **mesophyll** cells. Beneath the upper epidermis the mesophyll cells form a very distinct layer, called the palisade mesophyll. These are elongated cells with their long axis perpendicular to the surface of the leaf. They contain large numbers of chloroplasts. In them, furthermore, active **photosynthesis** takes place. Occupying all the rest of the leaf is a loose tissue composed of irregularly arranged rounded cells known as the spongy mesophyll. Numerous intercellular spaces separate these cells from one another. Ramifying through the leaf just below the palisade cells are the veins. Each vein is composed of three types of cells. Some of them are thick-walled **xylem** cells which carry water and dissolved mineral

matter to all parts of the leaf. Others are **phloem** cells which carry food away from the green cells of the leaf where they are elaborated. The xylem cells are towards the top of the leaf, the phloem cells towards the bottom. Outside these and often forming a conspicuous tissue are masses of **fibers**, or collenchyma, thick-walled cells which give support to the leaf.

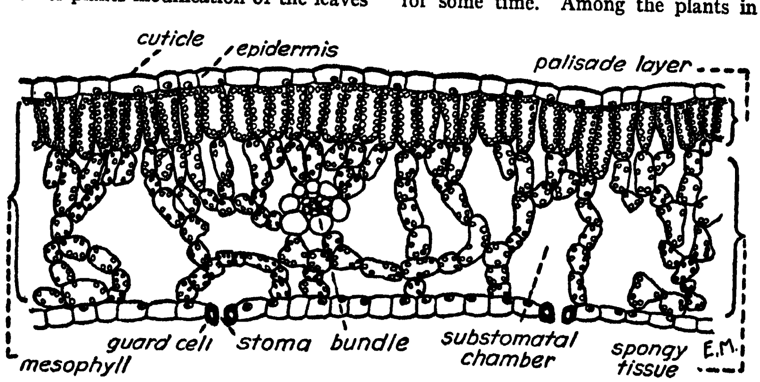
Leaves are often greatly modified. (Various types of leaves are illustrated on the following page.) In many have leaves modified into tendrils, slender thread-like objects which twine tightly around any suitable object with which they may come in contact. Sometimes only the tip of the blade functions in this way, and sometimes only the stipules are thus modified, as in the Carrion flower, *Smilax herbacea*. Many plants of the legume family have pinnately compound leaves, some of the segments of which are changed into tendrils. Weirdest of all are the leaves of species of *Nepenthes*, one of



A portion of the blade of a leaf cut so as to show the internal structure. The cell contents are not represented.

plants they become greatly enlarged and fleshy, and serve as organs of storage of water and food. Many rock garden plants, such as species of *Sedum*, have leaves of this type. Of similar nature are the scale-like leaves which form the greater part of many bulbs, such as those of many lilies. The common onion is composed of the closely enwrapped bases of leaves, swollen with food material. In other plants modification of the leaves the pitcher plants. (See article on **Insectivorous Plants**, where this leaf is described.)

In a few plants the leaf becomes a vegetative reproductive body, having in the notches of its margin, at its tip, or less commonly on its surface, groups of **meristematic** cells which, when the leaf is mature, give rise to tiny plants which remain attached to the parent leaf for some time. Among the plants in which reproduc-



Cross-section of an apple leaf.

becomes extreme as, for example, in the **Pitcher plants** and **bladderworts**.

In other plants, such as the common barberry, the leaf is reduced to sharp-pointed branched spines; in many cases all gradations between these spines and typical leaves may be found on a single branch. In some plants, as the Locust, *Robinia Pseudacacia*, only the stipules are modified to short sharp spines. Many plants tion of this type occurs are species of *Bryophyllum* and *Kalanchoë*.

The principal function of the leaf is to carry on **photosynthesis**. To do this the leaf must receive adequate light. Leaves are not distributed haphazardly on the stem, but in a very definite way which assures them the maximum of light. In many plants the leaves are in pairs on opposite sides of the stem. Each suc-

cessive pair usually grows out at right angles to the pair beneath it, thus preventing overshadowing. Leaves may occur in whorls, in which case there will be three or more leaves growing from each node of the stem.

Types of leaves. 1, 2, elm leaf and oak leaf, both pinnately netted veined; 3, maple leaf, palmately netted veined; 4, black walnut leaf, pinnately compound; 5, buckeye leaf, palmately compound; 6, a pea leaf, with stipules, tendrils, and two unmodified leaflets; 7, portion of a plant of the water mermaid, *Proserpinaca,* with upper leaves modified by immersion in water; 8, grass leaf.

In many plants the leaves are alternate, each node bearing a single leaf. In every case alternate leaves arise from the stem in such a way that a line passing around the stem and through the junction of the petiole with the stem forms a regular spiral. Examination of this spiral shows that the leaves are distributed on it in a very exact mathematical arrangement. In the simplest case the leaves are in two longitudinal rows along the stem, every third leaf being directly above the first; in the next arrangement there are three longitudinal rows, the fourth leaf of the spiral being above the first. In another, and very common, arrangement, there are five rows of leaves, with the sixth leaf above the first. Other more complicated arrangements are found. A common way of indicating the arrangement of leaves on a stem is by means of common fractions. The fraction may be determined by starting at any one leaf and passing by the shortest way around the stem to the next higher leaf and so on until the leaf vertically above the first is reached; the number of turns about the stem from the first to the last leaf gives the numerator of the fraction, and the number of leaves passed gives the denominator. The fractions obtained form a very exact mathematical series; they are $\frac{1}{2}$, $\frac{1}{3}$, $\frac{2}{5}$, $\frac{3}{8}$, $\frac{5}{13}$, $\frac{8}{21}$, $\frac{13}{34}$, etc. The arrangement of leaves on a stem is called phyllotaxy.

Sometimes the exact arrangement is more or less obscured by twisting of the stem during growth. The leaves themselves turn considerably during their growth, petioles twisting to one side or the other, or elongating unequally, in such a way as to bring the blade into a position to receive the most favorable light. (R.M.W.)

LEAF HOPPER. Insecta, Homoptera. Any **insect** of the large family Cicadellidae or Jassidae. They are small to moderate jumping insects which often come freely to light.

Many species are of economic importance and, since they have sucking mouths, they must be attacked with contact poisons such as nicotine sulfate or kerosene emulsion. These sprays are effective against the tender immature insects but the adults cannot readily be killed. (A.W.L.)

LEAF INSECT. Insecta, Orthoptera. Large **insects** of the Old World tropics related to the walking-stick insects. They have leaf-like wings and in some species the body and legs are extended in flat processes which also resemble leaves. (A.W.L.)

LEAF MINER. Larval **insects** which work in the soft tissue of leaves between the upper and lower epidermis. They are necessarily small and are sometimes able to complete their development on a very small part of the food available in a single leaf. The burrow **or** mine shows as a brownish or transparent patch in the leaf and its form is characteristic of the insect making it. The larvae of many of the smallest moths and of some sawflies are leaf miners. (A.W.L.)

LEAF SPRING. **Springs.**

LEAKAGE CURRENT. This is the current which flows or "leaks" along the surface or through the body of an insulator. Except under abnormal conditions such as dirty or moist surfaces or in electronic circuits having very minute currents the leakage is usually negligible. (L.R.Q.)

LEAKAGE REACTANCE. This is the inductive reactance caused by the flux which links only one coil of a **transformer.** The useful flux, of course, links both windings and is the medium of transfer of energy between them. Leakage reactance is one of the major internal impedance components of the transformer. (L.R.Q.)

LEAST COMMON MULTIPLE. The least (or lowest) common multiple of several **polynomials** is the polynomial of lowest degree which contains each of them as a factor. It is usually found by factoring the polynomials separately, and then finding the least common multiple by inspection. (L.L.S.)

LEAST SQUARES. **Principle of Least Squares.**

LEAST SQUARES, METHOD OF. The method of least squares is a statistical method for obtaining the most probable value of a quantity from a set of **physical measurements,** and for obtaining a quantity which is an indication of the precision of the most probable value.

In the development of the theory of the method of least squares two lines of attack have been employed: the observational and the mathematical. In each of these certain fundamental assumptions are necessary. In the observational method the assumption is made that the arithmetic mean of a series of equally reliable observed values of a given quantity, each observation being freed from all systematic **errors of measurement,** is the most probable value of the quantity. To approach the theory from the purely mathematical point of view it is assumed that the accidental errors of observation follow the **Gaussian distribution.** These two assumptions are.

in fact, interdependent. If they are justifiable for the given set of observations, then it may be proved that the sum of the squares of the residuals will be a minimum. If from an individual observation we subtract the most probable value of the quantity, a residual is obtained. It is the purpose of the method of least squares to determine a quantity from a series of observations, whether directly observed, indirectly observed, or computed from observational material, such that the sum of the squares of the residuals shall be a minimum.

In the discussion of the Gaussian distribution it is found that the probability of occurrence of a residual of magnitude x may be expressed by

$$P = \frac{h}{\sqrt{\pi}} e^{-h^2x^2}.$$

In this expression h is a measure of the precision (or relative agreement) of the individual observations of the measured quantity. In practice it is customary to express the precision of a measured quantity, as obtained from a number of independent observations from which all systematic errors have been removed, by certain functions of h rather than by h itself. In practically every case the function is inverse in character, i.e., the smaller the value of the precision indicator the greater is the value of h. The standard method for indicating precision adopted by most American and English workers in the physical sciences is the so-called probable error, which is symbolically expressed by the double sign $\pm$. If the probable error of a most probable quantity A is $\pm R$, then the chance that the true value of the quantity is between $A + R$ and $A - R$ is equal to the chance that the quantity has any value whatsoever outside of these limits. For example, if the length of a certain rod is published as 356.25 cm. $\pm$ 0.15 cm., then the chance that the true length of the rod is between 356.40 cm. and 356 10 cm. is equal to the chance that the length is anything outside of these two limits. Other methods for expressing the precision of a set of observations are in use, such as, for example, mean error, standard deviation, radical mean square error, etc. The meanings of these and other terms for expressing precision will be found in treatises on statistical analysis. The symbol $\pm$ should be reserved for probable error as defined above and should not be used for other terms for expressing precision, unless adequate notice is given to the reader. The methods for actually computing the precision measures of directly observed quantities, indirectly observed quantities, and quantities obtained by computation from observed values, involve too much detail to be included in a work of this character.

It should be carefully noted that the expression of the precision of a set of observational data is based upon certain fundamental assumptions and that if these assumptions are not valid for the particular set of observations, then the expression of precision is meaningless. It has been found that in most cases the accidental observational errors in the fields of astronomy, geodesy, and physics satisfy the Gaussian distribution law and hence least-square adjustments of the results are justifiable. This is not the case in the fields of biology and psychology, where one-sided variations in the observational material may occur to produce unsymmetrical distribution of the observational errors. In such problems great care must be exercised in expressing the precision of the results. A least-square discussion can never improve the quality of the observations, neither can it remove the effects of systematic errors, although a careful discussion of the residuals may indicate the presence of systematic errors. It must never be assumed that the method of least squares is some magical process which can be indiscriminately applied to all types of observational or statistical data. (W.K.G.)

LEAST TIME PRINCIPLE. **Fermat's Principle.**

LEAST WORK. The three equations of static **equilibrium** (see **Statics**) are insufficient to determine the analysis of certain types of structures which, in consequence, are called statically indeterminate structures. The analysis of such structures belongs to the general subject of mathematical theory of elasticity. Several methods of attack have been devised, but none has had so wide an application as the principle of least work. When a structure, either simple or complex, is loaded, there is a certain amount of energy stored in it by virtue of the deformation of its several elastic components. The theory of least work is based on the fact that the natural phenomena attending the deflection of a stressed structure is that the individual parts will be so deflected that the load will be carried with a minimum storage of energy in the elastic members. In the least-work theory, there are two basic propositions. The first is that the linear displacement of the point of application of a load of an indeterminate structure, in the direction of the load, equals the first **derivative** of the energy stored in the elastic structure, taken with respect to the load. The second theorem is that the magnitudes of statically indeterminate reaction forces are such as to make the elastic energy of the system the best possible. (See **Least-Energy Principle.**) (F.T.M.)

LEAST-ACTION PRINCIPLE. **Action.**

LEAST-ENERGY PRINCIPLE. A principle relating to stable equilibrium, and having very wide application. If a system is in stable equilibrium, any slight change in its condition or configuration requiring the performance of work will put it out of equilibrium, so that, if the system is now left to itself, it will return to its former state and in so doing will give up the energy imparted when it was disturbed. Consider, for example, a block of wood floating in a pail of water. If the block is lifted slightly, work is done and the center of mass of the wood-water system as a whole is raised, so that it now has more potential energy. The same would be true if the block were pushed a little farther into the water. In either case, when the block is released, it resumes its former level and the potential energy of the system diminishes to its former minimum value. This illustrates the general principle, which is that a system is in stable equilibrium only under those conditions for which its potential energy is at a minimum.

The principle of least energy is one aspect of the principle of virtual work (see **Equilibrium of Forces.**) (L.D.W.)

LEATHER. **Tannins.**

LEATHER-JACKET. Insecta, Diptera. The tough-skinned **larvae** of some species of **crane flies.** They live in the ground in pastures, hay fields, and grain fields and are sometimes serious pests. Since they come to the surface at night they can be destroyed by the use of poison baits. (A.W.L.)

LE CHÂTELIER LAW. **Equilibrium.**

LECHER OSCILLATOR. **Electric Oscillations; Electric Waves.**

LECHER WIRES. This is a special type of transmission **line** used primarily for the measurement of frequencies in the high radio-frequency range (see **Frequency Meter**). Basically they consist of two parallel wires a few wavelengths (in terms of the frequency to be measured) long which are adjustable in length. While usually adjusted by sliding a shorting bar along the wires they are sometimes fixed in physical length, either open or short-circuited at the remote end, and varied electrically by tuning a series condenser. In any event, if the system is coupled to a source of high frequency the induced waves will be **reflected**

from the end and if the line is electrically an integral number of half-wavelengths long standing waves will result. The nodes or anti-nodes of these may be detected with a suitable detector and the spacing of corresponding points will be a half-wavelength apart, thus allowing the frequency to be calculated. (L.R.Q.)

LEDEBURITE. The eutectic alloy of the iron-iron carbide alloy system. It contains 95.7% iron, 4.3% carbon and forms at 2066° F. from liquid metal on cooling. (R.H.H.)

LEDLOY. Steels containing very small additions of lead to improve machineability. (R.H.H.)

LEECH. **Hirudinea.**

LEEK. **Allium.**

LEEWAY. The difference between the actual direction in which a ship is moving relative to the surface of the water and the direction in which the keel of the ship is pointing is known as leeway. Leeway is usually produced by the pressure of the wind against the side of the vessel and is much more pronounced in the case of sailing vessels than in internally powered ships. The amount of leeway can best be determined by observing the angle between the wake of the vessel and the line of the keel.

In determining the true **course** of the vessel the leeway is treated in the same manner as a **compass correction.** In case the wind is blowing against the left side of the vessel the vessel is said to be on the port tack and the true course will be to the right of the course indicated by the keel. Hence for a ship on the port tack leeway has the same effect as an east or positive compass correction, on the starboard tack leeway is applied as a west or negative correction. (W.K.G.)

LEG. A jointed appendage, used for locomotion on a solid supporting surface by walking, running, or jumping. The jointed appendages of **arthropods** and of **vertebrates** are termed legs. The term is applied to similar structures used for other purposes, such as swimming or burrowing, but those which have undergone great modification have also received special names. The anterior appendages of birds and primates are distinguished as **wings** and **arms**, respectively, but in quadrupedal vertebrates they are still called legs. In human anatomy, the term leg is restricted to the region between the knee and the ankle. (A.W.L.)

LEGENDRE FUNCTIONS. The **differential equation**

$$(1 - x^2)\frac{d^2y}{dx^2} - 2x\frac{dy}{dx} + n(n+1)y = 0$$

is called Legendre's equation. It cannot be solved in terms of elementary functions. It defines a new class of functions, called the Legendre functions; they are also sometimes called surface zonal harmonics. Let n be a positive integer.

Legendre functions of the first kind (also called Legendre polynomials or Legendre coefficients) may be defined by

$$P_n(x) = \frac{(2n-1)(2n-3)\cdots 3.1}{n!}\left[x^n - \frac{n(n-1)}{2(2n-1)}x^{n-2} + \frac{n(n-1)(n-2)(n-3)}{2.4(2n-1)(2n-3)}x^{n-4} - \frac{n(n-1)(n-2)(n-3)(n-4)(n-5)}{2.4.6(2n-1)(2n-3)(2n-5)}x^{n-6} + \cdots\right].$$

$P_n(x)$ is a particular solution of Legendre's equation.

Legendre functions of the **second** kind may be defined by the **series**

$$Q_n(x) = \frac{n!}{(2n+1)(2n-1)\cdots 3.1}\left[\frac{1}{x^{n+1}} + \frac{(n+1)(n+2)}{2(2n+3)}\cdot\frac{1}{x^{n+3}} + \frac{(n+1)(n+2)(n+3)(n+4)}{2.4(2n+3)(2n+5)}\cdot\frac{1}{x^{n+5}} + \cdots\right],$$

when the series is convergent. $Q_n(x)$ is another particular solution of Legendre's equation. Then the general solution of Legendre's equation is $y = c_1P_n(x) + c_2Q_n(x)$, where c_1 and c_2 are arbitrary constants. (L.L.S.)

LEGUME. **Fruit.**

LEIBNITZ' RULE FOR SUCCESSIVE DERIVATIVES OF A PRODUCT. This is a formula for the n^{th} **derivative** of the product of two **functions** in terms of the **successive derivatives** of the factors. It is:

$$\frac{d^n}{dx^n}(uv) = \frac{d^nu}{dx^n}\cdot v + \binom{n}{1}\frac{d^{n-1}u}{dx^{n-1}}\cdot\frac{dv}{dx} + \binom{n}{2}\frac{d^{n-2}u}{dx^{n-2}}\cdot\frac{d^2v}{dx^2} + \cdots + \binom{n}{r}\frac{d^{n-r+1}u}{dx^{n-r+1}}\cdot\frac{d^rv}{dx^r} + \cdots + \binom{n}{1}\frac{du}{dx}\cdot\frac{d^{n-1}v}{dx^{n-1}} + u\cdot\frac{d^nv}{dx^n}.$$

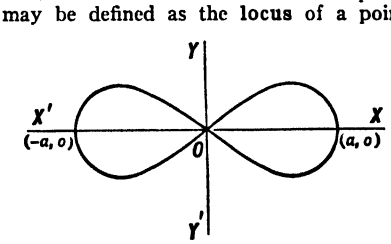
The coefficients are **binomial coefficients.** (L.L.S.)

LEMBERG'S SOLUTION. A solution of logwood (see **Tannins**) digested in aqueous **aluminum** chloride which is used as a stain and reagent for distinguishing between **calcite** or **aragonite** and **dolomite.** Both calcite and aragonite are stained violet by the reaction while dolomite remains unchanged. (R.M.F.)

LEMMA. The lower one of the two **bracts** which immediately subtend the **floret in the spikelet** of grasses. (R.M.W.)

LEMMING. Mammalia, Rodentia. Small animals of northern latitudes. The European lemmings resemble the woodchuck in form but are much smaller, and the American species, *Synaptomys*, are like short-tailed mice. The common lemming, *Lemmus lemmus*, of northern Europe is noted for its occasional migrations. Many thousands of the animals take part in these migrations, crossing mountains, fording streams, and always pushing straight on until they enter the sea and are drowned. (A.W.L.)

LEMNISCATE. The lemniscate is a plane curve which may be defined as the **locus** of a point which



Lemniscate.

moves so that the product of its distances from the points $(-a, 0)$ and $(a, 0)$ is equal to a^2.

Its equation in **rectangular coordinates** is

$$(x^2 + y^2)^2 = 2a^2(x^2 - y^2),$$

and in **polar coordinates** is

$$r^2 = 2a^2\cos 2\theta.$$

(L.L.S.)

LEMON. Citrus Fruits.

LEMON GRASS OIL. Volatile Oils.

LEMUR. Mammalia, Primates. The most primitive animals of the order containing man and the apes and monkeys. Lemurs have a well-developed thumb and great toe, like the other **primates**, but the second toe bears a sharp claw instead of a nail. The body is generally more like that of a squirrel than like the apes and monkeys and the face in many species is peculiarly expressionless, with large staring eyes.

Lemurs constitute a family Lemuridae, containing, in addition to the species named as lemurs, the indri, the sifakas or propitheques, the galagos, the awantibo, the pottos, the lorises or slow lemurs, and the avahi. They center in Madagascar but a few species occur in eastern Africa, southern India, and islands of the Oriental region. The tarsiers and the aye-aye are closely related to the true lemurs. (A.W.L.)

LEMUROIDS. Paleocene.

LENARD RAYS. Cathode Rays.

LENGTH OF PLANE CURVE ARC. The length of a curve arc is defined as the limit of the length of a broken line inscribed in the arc, as the number of pieces increases indefinitely and each piece approaches zero.

Let s represent arc length from a fixed point on a plane curve whose **equation** in **rectangular coordinates** is $y = f(x)$. Then

$$ds^2 = dx^2 + dy^2,$$

and

$$\frac{ds}{dx} = \sqrt{1 + \left(\frac{dy}{dx}\right)^2}, \quad \frac{ds}{dy} = \sqrt{1 + \left(\frac{dx}{dy}\right)^2},$$

and the arc length is

$$s = \int_a^b \sqrt{1 + \left(\frac{dy}{dx}\right)^2} \cdot dx = \int_c^d \sqrt{1 + \left(\frac{dx}{dy}\right)^2} \cdot dy.$$

If the equation of the curve in **polar coordinates** is $r = f(\theta)$, then

$$ds^2 = dr^2 + r^2 d\theta^2,$$

and

$$\frac{ds}{d\theta} = \sqrt{r^2 + \left(\frac{dr}{d\theta}\right)^2},$$

and arc length is given by

$$s = \int_\alpha^\beta \sqrt{r^2 + \left(\frac{dr}{d\theta}\right)^2} \cdot d\theta.$$

If the curve is given by **parametric equations**: $x = f(t)$, $y = g(t)$, then

$$\left(\frac{ds}{dt}\right)^2 = \left(\frac{dx}{dt}\right)^2 + \left(\frac{dy}{dt}\right)^2.$$

(L.L.S)

LENS COATING. Low-Reflection Films on Glass.

LENSES. Mirrors and Lenses.

LENSES, PHOTOGRAPHIC. A photographic lens must form a sharp image on a flat surface extending over an angle of from 15 to 45° from the axis (depending upon the type of lens) at as large an aperture as possible. The problem facing the lens designer is a difficult one; to obtain good definition a high degree of correction is required but in a photographic lens, unlike most optical instruments, the same high degree of correction must be made to include the oblique pencils, and the image must be corrected for a flat field of greater area in proportion to focal length and effective aperture. Progress in the fulfillment of these somewhat contradictory requirements has been hampered to some extent by the materials available. For nearly half a century, until the introduction of the so-called Jena glass in 1886, the glasses necessary for the correction simultaneously of astigmatism and spherical aberration were unavailable. It was only after the introduction of the newer glasses by Schott of Jena that the lens designer was able to produce a large-aperture lens which would at the same time provide good definition over a large field. Attempts in recent years to increase the effective aperture of the photographic lens still further without sacrificing the definition or the area have resulted in objectives of complex construction. The very recent introduction of newer types of glass by the Eastman Kodak Company should have an important bearing on future development in the field of photographic optics.

In the account which follows no attempt will be made to discuss the photographic lens from the historical point of view, nor can every make and type of lens be included. The principal types of lenses will be discussed and the purposes for which generally used.

1. Single lenses. Single meniscus lenses of the type shown in (1) of the accompanying group are used on

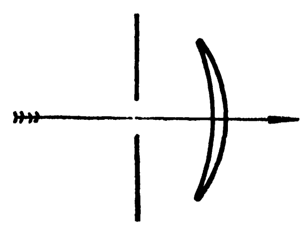


Fig. 1.

only the very cheapest of box cameras. The *single achromatic* lens shown in (2) is much more common even on inexpensive box cameras. Lenses of this type

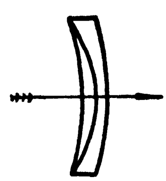

Fig. 2.

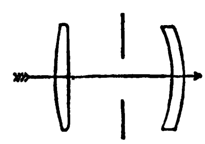

Fig. 3.

are generally made to work at from f/12.5 to f/16 but the definition is not sufficiently good to stand a high degree of enlargement. In some fixed-focus cameras a single lens is placed in front, as shown at (3). If this front lens is positive, it is moved to one side when making pictures of *distant* objects; if a negative lens is used then the front lens is removed for nearby objects.

2. The rapid rectilinear or aplanat. This lens (4), consisting essentially of two single achromatic lenses

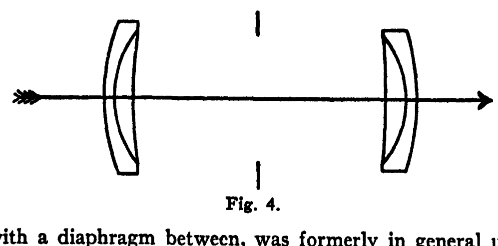

Fig. 4.

with a diaphragm between, was formerly in general use by both amateur and professional photographers. It is now obsolete having been replaced by other designs which are no more difficult to manufacture and provide

superior definition at as large, or larger, aperture. The older lens with a relative aperture of about f/8 will be found on many hand cameras made 10 or 15 years ago.

3. The portrait lens. Many kinds of lenses are used for portrait work but the term portrait lens is applied almost exclusively to a type of lens designed by Josef Petzval in 1841 and shown in (5). This lens was the

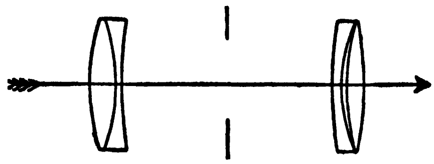

Fig. 5.

first large-aperture lens having a maximum aperture of f/6 when first introduced which was increased by various manufacturers over the next 20 years to f/2.2 in the shorter focal lengths. The definition on and close to the axis is exceptionally good for a lens of such large aperture but falls off rapidly. The field is sharply curved and the illumination diminishes rapidly from the center outwards. These defects are not so noticeable when a lens of long focal length is used for portraits of the head and shoulders and lenses of this type are still favored by many portrait photographers However, even for portraiture, lenses of the Petzval type are being displaced more and more by other types.

4. Convertible lenses. The term convertible is applied to double lenses, the front or rear components of which may be used separately to obtain a different focal length. Lenses of this type are popular with commercial photographers, particularly for outdoor photography. In use, the single component should always be placed to the rear so that the diaphragm is in front. The single component usually requires about twice the exposure of the complete lens, the increase depending upon the largest aperture at which satisfactory definition is obtained. In most cases, the diaphragm plate attached to the shutter is marked separately for the lens as a whole and for each of the two components, if these differ in focal length.

While the rapid rectilinear, or aplanat, should be considered as a convertible lens since the front and rear halves may be used alone, the modern photographer is concerned chiefly with the convertible anastigmatic lenses. The *Dagor* of Goerz (6), the *Protar* of Zeiss (7), and the Turner-Reich (8) are probably the best known in this country. The maximum aperture of these lenses varies from f/6.8 to f/7.7 and the single components at from f/11 to f/16. Lenses of this type cover a large field in proportion to their focal length and, particularly at

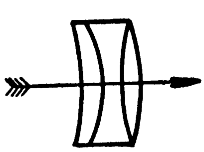

Fig. 6.

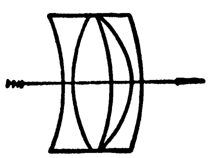

Fig, 7.

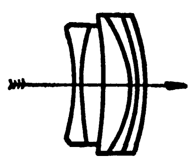

Fig. 8.

the smaller apertures, may be used as medium wide-angle lenses covering an angle of from 30–40° from the axis. This type of lens has received little attention from lens designers in recent years probably because of its relatively small aperture.

5. Triplet lenses. The first really successful anastigmat lens with a large relative aperture was patented by H. D. Taylor in 1895 and placed on the market by Taylor, Taylor and Hobson of Leicester, England, as the *Cooke lens* (9). This lens is still popular, being used on hand cameras where a simple and relatively inexpensive lens is required and also as a portrait

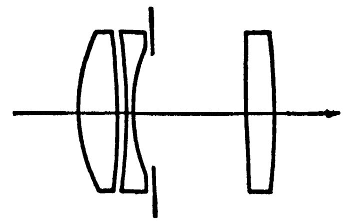

Fig. 9.

lens. It gives good definition at apertures up to f/4.5 and f/3.5 over a field of from 25–30 degrees. The *Heliar* of Voightlander (10) is a modification of the

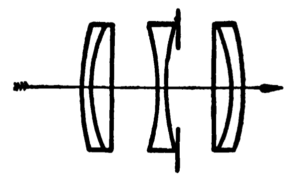

Fig. 10.

simple triplet, the outer elements being composed of two cemented lenses. This results in improved definition over a larger field. A lens of similar design by Dallmeyer of London, known as the *Pentac,* has a relative aperture of f/2 9. The Biotessar of Zeiss (Jena) (11)

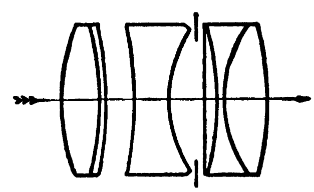

Fig. 11.

with a relative aperture of f/2.7 is similar except that the rear element consists of three cemented lenses.

One of the most popular lenses ever developed is the *Tessar* of Zeiss (12) which may be regarded as a triplet in which the rear lens is composed of two cemented lenses. This lens was designed by Paul Rudolph in 1903 and, since the patents have expired, has been widely copied by other lens manufacturers. The *Velostigmat,* Series of Wollensak, the *Paragon* of Ilex, the *Ektars* (f/3.5, f/4.5 and f/6.3) of Eastman Kodak Co., the *Serrac* of Dallmeyer, the *Skopar* of Voightlander and the *Xenar* (f/2.8, f/3.5, f/4.5) of Schneider are of this type.

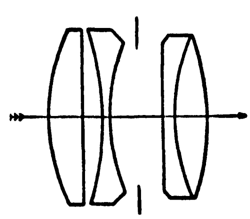

Fig. 12.

The *Aviar* of Taylor, Taylor and Hobson (Leicester, England) with a relative aperture of f/4.5 is a development of the original triplet lens with the central lens divided into two separate lenses of lower power (13). This permits the use of shallower curves and results in improved definition over a larger field than is obtained with the triplet.

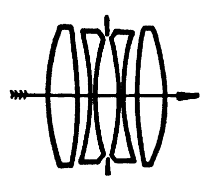

Fig. 13.

Lenses of this type are used by the press photographer on reflex cameras and in the longer focal lengths by commercial and portrait photographers except where an aperture larger than f/3.5 or an angular field exceeding 40° is required.

6. Lenses for miniature cameras. Lenses for the precision miniature camera require a higher degree of correction than lenses to be used on larger cameras because of the small image size and the necessity for subsequent enlargement. For lenses the maximum aperture of which does not exceed f/4.5 or, at the most, f/3.5 satisfactory results may be obtained with lenses of the triplet type, or better yet with one of the modified forms, and in particular the Tessar type.

The *Sonnar* (14) of Zeiss, with a relative aperture of f/1.5, is apparently a development of the earlier Tessar. Although the curves are deeper and the design more

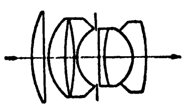

Fig. 14.

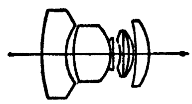

Fig. 15.

complex it is remarkably free from flare and internal reflections. Despite the large aperture the definition is excellent, but the angular field covered is smaller than with the Tessar. The Biogon f/2.5 of Zeiss (15) covers a larger field. Both of these lenses are designed for the *Contax.*

The *Ektar* f/2 of the Eastman Kodak Company, the *Biotar* f/1.4 of Zeiss and the *Xenon* f/2 of Schneider are based upon the so-called Gaussian design (16).

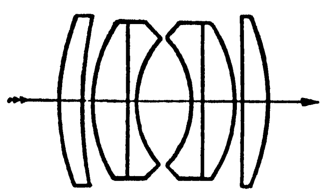

Fig. 16.

This design is notable for the excellent correction obtainable over an exceptionally large flat field at a large aperture.

7. Wide-angle lenses. In general, any lens which includes a wider angle than that normally used is termed a wide-angle lens. For the purposes of this discussion, however, any lens which is designed for use on a plate or film whose diagonal is greater than the focal length will be regarded as a wide-angle lens. While both the press photographer and the user of the miniature camera may employ lenses which include a wider angle than normal and, therefore, may be regarded as wide-angle lenses, the real wide-angle lens (which includes an angle of from 85 to 90°, or higher) is used chiefly by the commercial photographer in making pictures of interiors and exteriors when working in close quarters.

Wide-angle lenses of the type in (17) include an angle of from 85 to 95° at apertures varying from

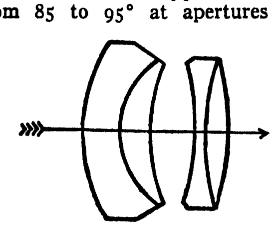

Fig. 17.

f/16 to f/18, depending upon the angle. This is, perhaps, the most popular type of lens among commercial photographers for an extremely wide angle, owing to its excellent definition over a wide angle and to its freedom from flare when windows, lighted lamps, etc., are included in the picture.

The construction shown in (18) does not, in general, include quite as wide an angle but has the advantage that it may be made to work at a larger aperture. Lenses of this design may have a maximum relative aperture of from f/6.8 to f/8. Usually a smaller diaphragm must be used if the widest possible angle is to be included.

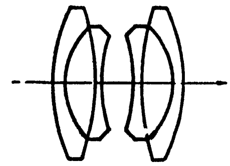

Fig. 18.

The design shown in (19) is more popular in Europe and the British Isles than in this country. Representative lenses of this construction cover an angle of about 90° at a relative aperture of from f/9 to f/11. A special lens of this general type (20) made for aerial mapping includes an angle of approximately 100° and has a relative aperture of f/6.3.

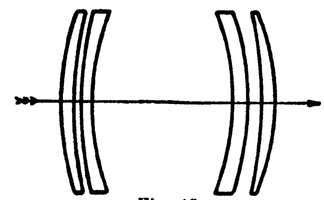

Fig. 19.

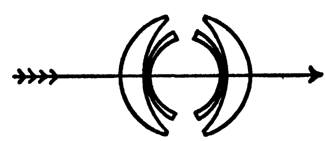

Fig. 20.

8. Telephoto lenses. The term *telephoto* is applied to lenses in which the front element is positive and the rear a negative—or diverging—lens which increases the size of the image formed by the positive element. This type of lens produces a larger image for the same lens-to-image distance (bellows extension) than a lens of the usual type. In other words, the focal length of the lens is greater than the lens to image distance. (Fig. 21.)

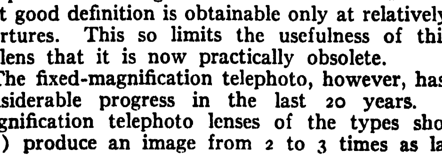

Fig. 21.

The older *compound telephoto* lens in which the focal length can be varied by altering the distance between the positive and negative elements has the disadvantage that good definition is obtainable only at relatively small apertures. This so limits the usefulness of this type of lens that it is now practically obsolete.

The fixed-magnification telephoto, however, has made considerable progress in the last 20 years. Fixed-magnification telephoto lenses of the types shown in (22) produce an image from 2 to 3 times as large as

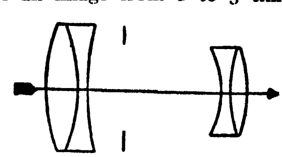

Fig. 22.

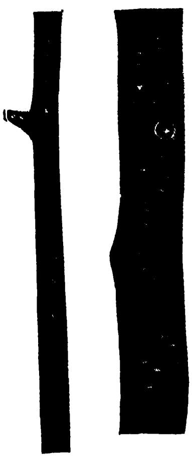
the lenses usually fitted to the cameras for which they are designed and provide good definition at apertures ranging from f/4.5 to f/6.3. The definition, generally speaking, is not equal to that of the best anastigmat lenses and there is usually some distortion, neither of

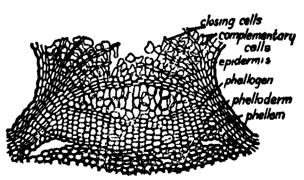
which is sufficient to be of any concern to the average photographer. Telephoto lenses with an equivalent focal length of 40", for example, have been widely used in aerial photography for reconnaissance photographs.

It should be noted that some lenses for miniature cameras and amateur cinematography, which are described as telephoto lenses or as "producing telephoto results" are, in reality, simply lenses of longer focal length mounted in long metal tubes which provide the increased extension necessary. (C.B.N.)

LENTICELS. The young stems of plants are covered with a single layer of cells known as the epidermis. As the stem grows older, this epidermis is lost and replaced by a thicker protective tissue known as cork. The cork cells have walls which are suberized and impervious to gases. The living cells within the stem require an exchange of gases with the outside atmosphere. This exchange occurs through lenticels. A lenticel is a mass of thin-walled **parenchyma** cells loosely arranged so that air spaces are numerous. Through the lenticel gases pass readily. Lenticels appear on the surface of the stem as rough masses, usually protruding somewhat, and either circular or somewhat elongate in shape. They are very irregularly distributed. (R.M.W.)



Stems of apple tree showing external view of lenticels.

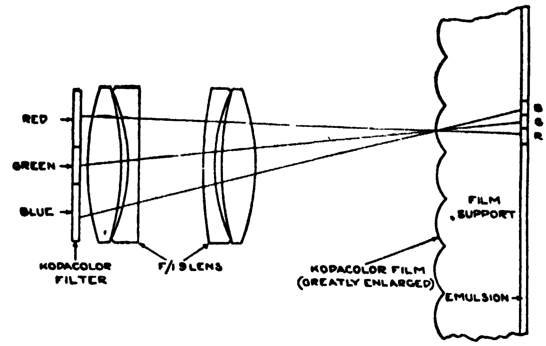


Section through lenticel of cherry. (*Eames and MacDaniels' Introduction to Plant Anatomy*)

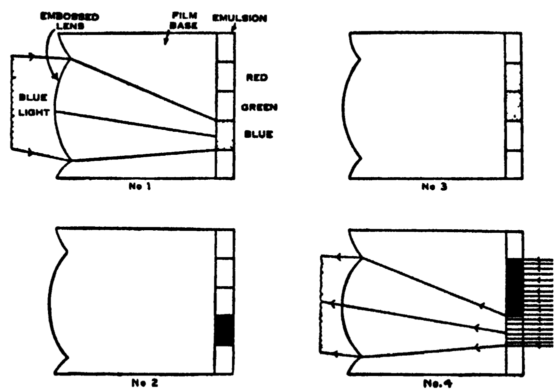
LENTICULAR CLOUDS. Clouds.

LENTICULAR PROCESS. A process of color photography in which minute semi-cylindrical lenses (lenticules) on the film base, in conjunction with a banded color filter on camera and projector lenses, act as an optical color-separation system for both analysis and synthesis. The lenticular process is thus essentially a screen method in which the screen is formed optically on the film during exposure. The lenticules generally take the form of small ridges embossed on the base side of the film, several hundred per in. Such a film is loaded in the camera with the emulsion away from the lens so that the light must pass through the lenticules and film base before exposing the film. The shape of the lenticules is such that they act as minute lenses and the camera lens aperture is thus imaged onto the emulsion. If the camera lens is covered with a banded color filter, the light transmitted by any area of the aperture will depend on the color of the light reflected from the subject and the filter-band color covering that portion of the aperture. The density of the silver image developed in the film will thus be determined.

If a lenticular film is exposed and processed by reversal development and then put into a projector with a similar optical system, the proper quantity of light will be projected through each band of the color filter and the original scene will be reproduced in color by means of an additive synthesis on the screen. Lenticular processes appear at first sight to be a relatively simple solution to the problems of color analysis and synthesis but physical and optical problems as well as projection difficulties have limited any widespread commercial usage. The lenticular system is applicable to two color processes and may also be used as an analysis system for a process in which the color synthesis may be carried out by other than additive projection. (H.C.C.)



General optical system of Kodacolor lenticular process.



Enlarged sections of films show image formation in four stages: (1) exposure, (2) development, (3) bleaching and re-exposure, (4) reversal development and final projection. (*Neblette's Photography.*)

LENZ'S LAW. A general law of **electromagnetic induction,** stated by H. F. E. Lenz in 1833. It points out that the electromotive force induced by the variation of magnetic flux, with reference to a conductor, in the manner discovered by Faraday, is always in such direction that, if it produces a current, the magnetic effect of that current opposes the flux variation responsible for both electromotive force and current. An outstanding illustration is the drag on a generator armature; if the armature circuit is closed, the rotation is opposed by a torque arising from the reaction between the field and the current in the armature conductors. Power must therefore be applied to drive the machine; and the greater the armature current, the more power is required. The effect known as magnetic damping depends upon this principle. A copper disk, when spun between the poles of a strong magnet, quickly comes to rest because of the opposing torque. This arrangement serves as a speed regulator in watt-hour meters. The oscillations of **galvanometer** coils are often damped in a similar manner. (L.D.W.)

LEO (The lion) (Map page 380). The **constellation** of Leo is one of the most easily distinguished of all of the **zodiacal** constellations. The "sickle" of this, the fifth sign of the zodiac, is known to all watchers of the spring and early summer skies. The brightest star in the group, Regulus, is a **double** star but cannot be re-

solved with telescopes smaller than 3-in. aperture because of the fact that in small instruments the bright star masks the fainter one. Gamma Leonis is one of the finest of the doubles with its two components of approximately the same magnitude, one yellow and the other orange in color.

The constellation is also noted for the location of the **radiant point** of the **Leonids**, one of the best known **meteor** showers. (W.K.G.)

LEONIDS. The name Leonids is applied to that **meteor shower** which has probably attracted more attention than any other. Each year, about the 12th of November, a number of meteors are observed coming from a **radiant point** in the **constellation** of **Leo.** Records of the appearance of this shower are found back as far as 585 A.D. The Leonid shower is one in which meteors are distributed all along the orbit, so that a radiant point may be determined practically every year, and also there is a very strong condensation of the meteors into a swarm through which the earth used to pass every 33 years. Probably the greatest display was in November, 1833. Quoting from Silliman's Journal of that year we find: "To form some idea of the phenomenon, the reader may imagine a constant succession of fireballs, resembling rockets, radiating in all directions from a point in the heavens." One observer counted 650 during 15 minutes. During the interval between 1833 and 1866 a great deal of computing was done on the Leonid shower and November 13 was predicted as the date of passage of the earth through the main swarm. The prediction was fulfilled, and at Greenwich, England, eight observers actually counted 8000 meteors, 4860 of them being counted between one and two o'clock in the morning. However, brilliant as the shower was at that time, it apparently was not as striking as the display in 1833. In 1899 there was a moderately good display of the Leonids, but nothing comparable to the showers of 1866 and 1833. The newspapers had promised so much to the general public that the failure of the shower to come up to the expectations proved a rather serious blow to astronomy. The explanation for the failure of the shower to live up to its prediction is to be found in the fact that Jupiter passed very close to the swarm during 1899 and deflected it from the earth's orbit. Further **perturbations** have so deflected the orbit that in 1932, 1933, and 1934 no real shower was observed, although enough meteors were seen during each November to permit of a determination of the radiant point.

It is not possible to make any definite predictions for the future. It should be pointed out, however, that in the centuries preceding 1833 there are several instances where we find no record of striking displays on the basis of the 33-year period. It is very possible that perturbations may again bring the main swarm into such a position that the earth will again pass through it, giving rise to showers comparable with that of 1833. (W.K.G.)

LEOPARD. Mammalia, Carnivora. A large **cat** of the Oriental region and Africa. Its fur is tawny, marked with black rings and spots, although a black variety occurs in which the spots are faintly traceable. A species known as the snow leopard, ***Felis uncia,*** lives at high altitudes in central Asia, and in southeastern Asia a short-legged species called the clouded leopard, ***F. nebulosa,*** is found. The former is spotted and the latter blotched and striped. The cheetah, *Cynaelurus jubatus,* of India and Africa, is a slim long-legged animal marked with small black spots on a tawny to reddish ground. It has been **trained** for use in hunting and is also called the hunting leopard. (A.W.L.)

LEPIDODENDRON. **Paleobotany.**

LEPIDOLITE. This member of the **mica** group of minerals is a **silicate** of **potassium, lithium** and **aluminum,** sometimes with **sodium, florine,** or rarely **rubidium.** Crystals of lepidolite are **monoclinic** but often pseudo-**hexagonal; cleavage,** basal and perfect, being susceptible of splitting into thin laminae; hardness, 2.5–4; specific gravity, 2.8–3.3; luster, pearly; color, reddish to violet, grayish-blue, gray to white. A variety carrying rubidium is yellowish-gray; translucent. It usually is found as granular to scaly masses, in short stocky prisms or less often in eaily cleavable sheets. Lepidolite is characteristic of **pegmatite** veins, frequently being associated with other lithium-bearing minerals such as **tourmaline, spodumene, amblygonite,** and others. It occurs in the Ural Mountains, Czechoslovakia, the Island of Elba, and Madagascar, where it is often found in large sheets. It is found in the pegmatites of New England, California, South Dakota, and New Mexico. The name lepidolite is derived from the Greek meaning scale. (E.S.C.S.)

LEPIDOPTERA. The **butterflies, skippers,** and **moths.** An order of insects characterized by sucking mouths in the adult stage, complete metamorphosis, a **larva** with biting mouth parts, and two pairs of wings covered at least in part with a vestiture of flattened scales. The second order of insects in size, with about 90,000 known species.

Butterflies and moths are widely distributed and because of their bright colors are among the animals known to everyone. The butterflies are diurnal and so are readily observed, but most moths are nocturnal, hence many beautiful species are rarely seen unless they are sought. Skippers are an intermediate group more nearly like the butterflies. The most magnificent species of all three forms are tropical but representatives are found even in the Arctic regions.

The adults visit flowers for nectar or take no food. In the larval stage most species are plant feeders but a few carnivorous forms are known and some are scavengers. The order includes many economic species, among them the clothes moths, the bee moth, and the cut worms. (A.W.L.)

LEPROSY. A chronic infectious disease caused by *Mycobacterium leprae.* The disease presents a great variety of signs and symptoms, depending on what tissue or organ of the body is involved.

Leprosy is a disease of antiquity, and there is evidence that it has existed at least since 2000 B.C. References to the disease are found in the Old Testament. While it has been common in the Orient for several thousands of years, it appeared as a scourge in Europe in the 11th and 12th centuries, and did not subside until the 16th century when segregation of the victims was carried out on a large scale. At present the disease occurs endemically and sporadically, chiefly in the Orient, Australia, Asia, on the Mediterranean, and in Central and South America. There are various other foci of sporadic cases such as some parts of northern and central Europe, the West Indies, Louisiana, Minnesota, and South Carolina in the United States, and several in Canada. Occasional cases are encountered in the larger seaports, both Atlantic and Pacific.

The mode of infection is not definitely known. The nasal mucosa, the gastrointestinal tract, and the skin have been considered as possible portals of entry. The disease is definitely contagious, but years of exposure and contact seem to be necessary for its transmission.

The organism causing leprosy is similar to the tubercle bacillus in appearance and staining characteristics. It is found in great numbers in the nodules occurring under the skin, in discharges from the nose and throat, and in discharges from ulcers. It was first discovered in 1873 by Hansen.

The period of incubation is variable. It may be from a few months to 20 or 30 years. The symptoms of the disease depend largely on the tissue attacked. There are two general types of the disease: (1) nodular leprosy in which the skin is primarily involved; and (2) maculo-anaesthetic leprosy, in which there is an involvement of nervous tissue. A mixed form also occurs showing symptoms of both forms.

In the first stages of nodular leprosy, brownish-red spots appear on the skin, usually on the limbs and face, covering large and small areas of the skin. Later nodular thickenings appear at these sites. The face may show the so-called leonine appearance, due to the thickening of the skin in the region of the forehead, eyes, lobes of ears and around the nose and mouth. The entire skin assumes an unhealthy, dusky appearance. Some of the thickened areas ulcerate and fingers and toes may rot off. Ulceration also appears in the nose and throat and the voice becomes hoarse. The eyes are affected similarly, and blindness may result. This form of the disease may last 10, 20 years, or longer without treatment. Many of the patients die of complicating disorders such as pneumonia, nephritis, tuberculosis and malnutrition.

Maculo-anaesthetic leprosy is characterized by flat, red to brown lesions on the skin, distributed symmetrically. These lesions gradually become insensitive to pain (anaesthetic); trauma, even burns, may occur without the patients feeling pain. Ulceration of the area and contractions will produce deformities.

The outlook for recovery in leprosy has been somewhat improved by modern treatment with chaulmoogra oil, or preparations derived from this oil, used either by subcutaneous or intravenous injections. This has actually arrested cases of leprosy, when the disease was not too far advanced. (R.S.M., D.M.H.)

LEPTITE. **Granulite.**

LEPTOCARDIA. **Cephalochordata.**

LEPTOSTRACA. **Crustacea.**

LESBIANISM. Perverted sexual practices between women. Homosexuality. (R.S.M.)

LESION. Any wound, injury, diseased area or area of local degeneration. (R.S.M.)

LETTER SIZE DRILL. **Drilling.**

LETTUCE. *Lactuca sativa.* **Composite Family.**

LEUCINE. **Aminoacids, Polypeptides, and Proteins.**

LEUCITE. The mineral leucite is a **metasilicate** of **potassium** and **aluminum** corresponding to the formula $KAl(SiO_3)_2$. It is **isometric** at a temperature of about 600° C. and psuedo-isometric at lower temperatures, at which the mineral may possibly be **monoclinic** or even **triclinic**. The external forms remain isometric. It has a conchoidal fracture; is brittle; hardness, 5.5–6; specific gravity, 2.45–2.50; luster, vitreous; color, white or some shade of gray; translucent to opaque. It is commonly found in the more recent lavas of high alkali content. Leucite is seldom reported from **plutonic** rock types. It is a relatively rare mineral. It is found plentifully at Vesuvius and Monte Somma and elsewhere in Italy, and in Germany in the Tertiary volcanic district of the Eifel. In the United States leucite has been found in the Leucite Hills of Wyoming, the Highwood Mts. of Montana and as pseudomorphs in New Jersey and Arkansas. Its name is derived from the Greek word, referring to its white color. (E.S.C.S.)

LEUCO BASE. **Dyes.**

LEUCOCYTE. **Blood.**

LEUCON. Synonymous with rhagon. **Porifera.** (A.W.L.)

LEUKEMIA. A disease of the blood-forming organs in which abnormal numbers of mature and immature **leucocytes** or white blood cells appear in the blood stream. When the bone marrow, from which granular leucocytes originate, is hyperplastic or overgrown, the leukemia is of the myeloid type, and the peripheral blood contains great numbers of immature granulocytes. (See Fig. 6, Plate B, facing page 180). When there is overgrowth of the lymph nodes, the leukemia is of the lymphoid type (lymphatic leukemia), and immature lymphocytes crowd the circulation. Monocytic leukemia is the third type and is believed to be a disease of the reticulo-endothelial system, which consists of specialized monocytic cells found in the liver, spleen, and lymph nodes.

The cause of leukemia is unknown. In some respects the disease resembles an infection, and in other ways it simulates a malignant **tumor.** The various types may be observed in either sex at any age, although most cases occur between 35 and 55 years. The acute form is commonest in early childhood. The disease occurs in various animals as well as in human subjects.

The onset of chronic leukemia is gradual. **Anemia** occurs as a constant feature and its characteristic symptoms, weakness, pallor, shortness of breath, may be the first to appear. The spleen becomes greatly enlarged and its weight alone may cause a dragging sensation in the left abdomen. Basal **metabolism** is increased and fever of some degree is usually present. In the lymphatic form there is general enlargement of the lymph nodes. The circulating blood may contain several hundred thousand white blood cells. Because of the reduction of platelets (see **Blood**) there is a marked bleeding tendency.

Death occurs in chronic leukemia from exhaustion due to progressive anemia, from intercurrent infection, or from **hemorrhage.** With x-ray therapy, remissions lasting for varying periods of time may occur. Patients may carry on a normal life for several years, but death is the eventual outcome in all cases.

Acute leukemia differs from the chronic form in that its onset is abrupt; and its course is rapid and fatal, usually after not more than 8 weeks. The circulating blood is crowded with great numbers of young cells, frequently so immature that an accurate diagnosis as to cell type is impossible. A severe anemia always develops. Moderate enlargement of lymph nodes and spleen, hemorrhage into the skin and mucous membranes, and **stomatitis** with infection and swelling of the gums occurs. There is no effective treatment; x-ray irradiation usually makes the acute disease worse. (D.M.H.)

LEUKOPENIA. A decrease in the normal number of leucocytes in the **blood** stream. This is a usual accompaniment of certain stages of some infectious diseases, while in other infections it is of grave prognostic significance, and indicates a failure of one of the lines of defence of the body. In **agranulocytosis** leukopenia is the chief manifestation of the disease. (R.S.M.)

LEUKORRHEA. A whitish mucoid discharge from the vagina. This may occur normally in slight degree at the end of a menstrual period, but where marked or persistent, is a sign of infection or disease in the **uterus, cervix,** or **vagina.** (R.S.M.)

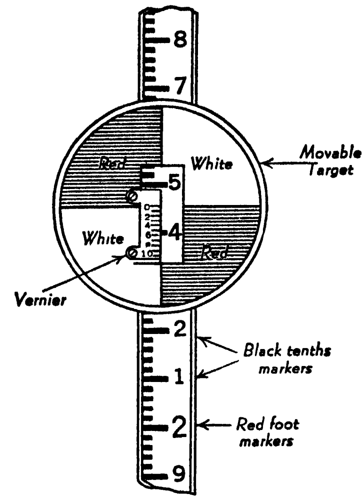
LEVEL. The term level, as an adjective, applies to any direction perpendicular to the force of gravity, and is synonymous with horizontal. The familiar device commonly known as the spirit level finds place not only

in the tool kits of bricklayers and carpenters, but is an essential feature of many delicate physical, astronomical, and engineering instruments. It depends upon the simple principle that an air bubble seeks the highest point of the container holding the liquid in which it is formed. The glass tube of a level is either slightly curved, like a sausage, with convex side upward, or is ground with a curved inner surface. If such a tube is supported on a rigid base, the bubble contained therein always comes to equilibrium at the same point whenever the base has the same given inclination to the horizontal. If the instrument, with its base, be now reversed end to end, the bubble will move to a new position unless the base is exactly horizontal in both positions. By not moving, the bubble indicates that the surface is horizontal along that direction. If the bubble does move, horizontality can be obtained by adjusting until the bubble occupies a point midway between the two positions; then a second reversal should produce no change. If the tube is provided with a scale, the level may be made a very sensitive instrument for measuring angular changes of inclination. The larger the radius of curvature of the tube, the more sensitive is the level.

Bubble tube of spirit level, with curvature somewhat exaggerated.

A surveyor's level is an instrument for determining differences of elevation directly. It is of use in obtaining comparative levels of two points, or in defining the profile of a certain path, such as a roadway, drainage ditch, etc. A level of this type has an accurately made bubble level which is attached to and made exactly parallel with a telescope. In the wye level this telescope rests in Y-shaped supports. These supports are held in turn by the instrument base, which may be adjusted by hand, and which is attached, usually by screwing, to the top of a tripod, upon which the instrument rests when in use. The bubble tube being parallel to the center of the telescope, the latter will automatically be leveled, ready for a horizontal sight, when the bubble tube is level. The dumpy level has the telescope and supports cast in one piece or rigidly connected. Since there are fewer movable parts than in the wye level it can be adjusted more easily and remains in adjustment for a longer period of time. In use, a level is set up and the base is leveled up by means of leveling screws, until the bubble stays in the center of the bubble tube however the telescope is rotated. The telescope barrel contains a ring having cross-hairs, so that when an object is viewed through the eyepiece, the cross-hairs will center on the center of the object being sighted. The imaginary line which joins the optical center of the objective and the cross-hairs in the tube is known as the line of sight. This line should coincide with the line of collimation. The latter is usually the geometric axis of the telescope. The telescope is slightly different from the ordinary field glass, which has no cross-hairs to be focused on the eyepiece. Some levels are erecting, that is, provide an upright image, while others of a more precise or simplified type, produce an inverted view of the object and are known as inverting levels. The dumpy level is of the latter type. (See **Level Rod.**) (L.D.W., F.T.M.)

LEVEL ROD. The length of sight which may be taken with a surveying instrument may be increased—also the facility and accuracy with which the reading is taken—by the employment of a special rod upon which to take a sight. A level rod, then, is a measuring stick graduated and plainly marked in feet, tenths of feet, and hundredths of a foot with the subdivisions and numerals receiving a special treatment to render them easily distinguishable. Size and coloring of the graduations are of great aid to this end. The rod is usually of wood, metal bound, having metal fittings. Telescopic features permit a 12-ft. rod, for example, to be compressed to 6′ in length for ease in carrying. A large movable circle with cross lines, known as a target, aids in centering the cross-hairs of the instrument upon the rod. (Sometimes this target is equipped with a **vernier** making it possible to read elevations to thousandths of a foot. The levelman sets the center of the target which is read by the rodman.) (F.T.M.)



Level Rod. (Vernier target unnecessary except for levelling requiring highest degree of precision.)

LEVER. Machines.

LEVULOSE. Carbohydrates.

LEWIS EQUATION. Spur Gearing.

LEXIS DISTRIBUTION. Coefficient of Dispersion.

LEXIS RATIO. Coefficient of Dispersion.

LEYDEN JAR. The earliest form of electrical **condenser;** attributed to two or three investigators, but generally credited to Muschenbroeck of the University of Leyden (1745). It is said that the discovery arose from an attempt to fix or imprison electricity by making a solution of it in water. A glass bottle contained the water, into which dipped a nail driven through the cork. The bottle was held in the hand while the water inside was charged from a **static machine** by means of the nail. When the operator, with his hand still around the bottle, touched the connecting wire, he received a severe shock. In the usual form of Leyden jar, the hand and the water are replaced by outer and inner coatings of tin or aluminum foil, the inner coating being provided with a rod and chain for convenience in charging. These condensers have low capacitance, but are rugged enough to withstand considerable voltages and are useful for many electrostatic experiments. In one interesting form the coatings are removable, leaving the glass jar itself charged. A highly charged Leyden jar may, incidentally, be somewhat dangerous to the operator, unless carefully handled. (L.D.W.)

LIANAS. In the tropics climbing plants often have woody stems of considerable size, which are called lianas. Many families of plants contain lianas. Some lianas are of economic importance; species of *Landolphia,* native

in the forests of Africa, yield **rubber**. The means by which lianas hold themselves in place are many. Some have tendrils which twine tightly around any available support. Others have **adventitious roots** which attach them to the stems of sturdier plants; still others are provided with hooks of different kinds, which prevent them from sliding from their support. The stems of many lianas twine tightly around each other, and other plants. Lianas are often a very conspicuous feature of tropical forests, hanging in long festoons and trailing irregularly in tangled masses over the ground. (R.M.W.)

LIBIDO. The normal sexual desire. (R.S.M.)

LIBRA. (The scales or the balances) (Map, page 380.) Libra is a small constellation best known because it is the seventh sign of the **zodiac** and its symbol is taken for the autumnal **equinox** (i.e., the point where the sun apparently crosses the celestial **equator** from north to south). The brightest star in the constellation is a wide **double** which can easily be resolved by a field glass. This star carries the Arabic name Zuben el Genubi, the southern scale. (W.K.G.)

LIBRATIONS. The term libration is applied in astronomy to many periodic oscillations. In particular it is applied to slight apparent oscillations of the **moon**, whereby observers on the earth are enabled to observe somewhat more than 50% of the moon's surface. There are three principal librations of the moon: a libration in lunar **latitude**, a libration in lunar **longitude**, and a diurnal (or daily) libration.

The libration in lunar latitude arises from the fact that the **orbit** plane of the moon is inclined at about 6.5° to the plane of the moon's equator. This produces an effect relative to the earth similar to the terrestrial effects relative to the sun which produce the **seasons**. During one half of the **month** the north lunar pole is directed slightly toward the earth, while during the remainder of the month south lunar pole is toward the earth.

The libration in lunar longitude is due to the fact that while the rotation of the moon is quite uniform with a period equal to the period of revolution about the earth, nevertheless the orbital motion is not uniform but is in accordance with the **Keplerian law of areas**. Consider that a certain point on the surface of the moon is directly toward the earth on a date when the moon is in **perigee**. Since the moon is moving more rapidly in its ellipse at perigee than at any other part of its orbit, by the time that the **elongation** has increased to 90° the selected point has not completed one quarter of a rotation and is not directly toward the earth. The result is that the observer will see a slightly different hemisphere of the moon than he did at perigee. By the time the moon has reached apogee the selected point will again be toward the observer and he will have the same view of the moon as at perigee. At this point the moon's orbital motion is a minimum and the selected point will complete a quarter rotation before a quarter revolution is completed and another slightly different hemisphere of the moon will be visible.

The diurnal libration is due to the fact that when the moon is rising the observer sees slightly "over the top" of the moon and at setting slightly under the bottom. This is really a libration of the observer rather than a libration of the moon but is classed with the latter.

The combined result of the librations is that about 41% of the moon is always visible from the earth, or would be if the sun were shining upon it, 41% is never visible, and the remaining 18% is either visible or invisible, depending upon the particular position of the moon relative to the earth.

The term libration is also applied to certain periodic **perturbations** in the orbits of members of the **solar system**. (W.K.G.)

LICHENS. Lichens are perennial plants which are of very great interest because of their unique nature. For while lichens are treated as plants, and separated into genera and species just as other plants are, in reality they are rather a combination of two plants growing together in an association so intimate that they appear as one. Indeed, either of the component plants alone possesses none of the characteristics shown by the two in combination. Such an association of two organisms, living together and apparently of mutual benefit to each other, is called **symbiosis**; lichens are often cited as outstanding examples.

The components of a lichen are always an alga and a **fungus**. The algal constituent is usually one of the simple green **algae**, or, more rarely, a blue green one. The alga can live perfectly well by itself, and is often found growing free on rocks or tree trunks in regions where the lichen would exist. The fungal component is usually a member of the **ascomycetes**. In lichens growing in cooler regions it is always one of this group. There are certain lichens found in the tropics, however, in which the fungal component is a **basidiomycete**. In the lichen, the fungus alone is capable of fruiting, although the algal cells do divide and so increase in number. Lichens having an ascomycete fungus are usually called ascolichens, while those with a basidiomycete are called basidiolichens or hymenolichens. It is very difficult to see how such an association came about, and to determine whether it is really a case of symbiosis or whether it is not parasitism, one of the plants living on the other. Unquestionably the fungus benefits from the presence of the alga, since the latter carries on **photosynthesis**, making food materials which are used by the fungus. The latter, lacking **chlorophyll**, cannot manufacture its own food. It is possible that the alga benefits by the added moisture gathered by the fungus, that the latter protects the alga against desiccation. Certainly the association is well established, and seemingly has been so for a long period of time. Lichens have been "made" artificially, that is, the two components have been grown separately in pure cultures, and when brought together have produced a lichen. So lichens can be formed anew, always with a very constant appearance characterizing the particular form considered.

Lichens are found nearly everywhere where **civilization** has not killed them. They are found on the surface of rocks and soil: they occur on the bark of trees: in the tropics they may be found on the surface of thick evergreen leaves of trees: a few species even grow on rocks submerged by the tides. They are found on mountain tops which are not perpetually covered by snow. They occur from the tropic regions to the polar regions which are not permanently ice-covered. But, being slow-growing organisms and affected adversely by various gases, they are not usually found in the vicinity of large cities.

The shape of the lichen body or thallus is very diverse. Some species are flat crusts growing on or even in the surface of the substratum, whether the latter be trunk of tree or barren rock. Lichens of this type are called crustose. In others the thallus is split up into many radiating divisions, and is called a foliose lichen. Many others have an erect, often much-branched thallus and are called fruticose lichens. The color of the thallus may be yellow, orange, brown, gray or black.

The greater part of the lichen thallus is composed of **fungus** hyphae, which form a compactly tangled mass. The algal cells, usually called gonidia because of the early conception that they were the reproductive cells of the plant, occur in an irregular loosely arranged layer near the outer surface of the thallus. Short irregular branches from the fungus hyphae grow tightly around each algal cell, sending into it short absorbing structures called haustoria. The surface of the lichen is composed of enlarged thick-walled fungus cells which form a compact layer over the more loosely arranged central portions. In

many of the crustose and foliose lichens there are many **rhizoids** which anchor the plant firmly.

One of the ways in which a lichen reproduces is by means of soredia. These are minute bits of lichen, formed on the surface, and composed of one or more of the gonidia together with a small mass of closely associated hyphae. Often these soredia are so numerous as to give to the lichen a powdery appearance. Either through disintegration of the lichen body, or because the continuity of the hyphae breaks down, soredia become free from the thallus. They are then easily spread by wind or by water. They may even be carried about unintentionally by the many small insects and other animals which feed on lichens. Lichens also reproduce by means of **spores**; that is, the fungus component forms special reproductive structures very similar to those formed by similar fungi not forming lichen thalli. In the ascolichens these reproductive structures are open cups or mounds, called apothecia. Commonly these apothecia are of a different color from that of the thallus. Inside each apothecium is a layer of asci, containing ascospores which are freed onto the surface of the ascus-containing layer and disseminated by wind or other agencies. An ascospore from a lichen apothecium can become a lichen only when it chances to reach an algal cell and can form an association with it. Since this will happen only rarely, reproduction of lichens is mainly accomplished by asexual or vegetative means. The formation of spores by the fungus would appear to be a persistence of a habit which was necessary when the fungus lived independently, but is of no value in its present condition.

A lichen; reindeer moss, *Cladonia rangiferina.* (*Smith, Lichens, Cambridge University Press.*)

It has been mentioned that lichens are a foodstuff for many of the lower animals. But some of them are also eaten by higher animals. Reindeer moss, *Cladonia rangiferina,* is the principal food of the reindeer, and may also be used as fodder for other animals. Reindeer moss, not a moss at all, is an erect much-branded lichen which grows abundantly over wide stretches of barren soil. The dense grayish-green tufts grow continuously at the tops, becoming 6–10" tall and attaining great age. Another lichen, *Cetraria islandica,* or Iceland moss, may be used as stock food. In habit it resembles reindeer moss but is coarser and less branched. The latter species may also be eaten by man. Like all lichens it contains an abundance of acid which gives a bitter astringent taste and causes violent digestive disturbances if eaten in any quantity. To get rid of this, the "moss" is gathered when moist, it being soft and pliable then, thoroughly washed to remove the bitter substances and dried. In this condition it may be stored, or it may be powdered first. To use this powdered "moss," it is soaked in water to remove the cetraric acid present, and boiled. It forms a tasteless jelly which is used in making soups, bread and porridges. Another lichen, known as rock tripe (*Gyrophora hyperborea*), likewise bitter and nauseating, if boiled and treated like Iceland moss, becomes edible, if not palatable, and has been eaten by **Arctic** travellers in times of need. The manna of the Bible probably refers to another lichen, *Lecanora esculenta,* which occurs in desert lands.

In former times many lichens were used medicinally, as treatment for lung troubles, as purgatives, and as tonics.

Another and more important use of lichens was as a source of dyes. To obtain the dye the soaked lichen was treated with an alkaline substance, which acted on the acid of the lichen. The purple dye, orchil, was obtained from *Rocella tinctoria,* a lichen of the seaside, in this manner. Only animal fibers can be dyed by it. Another blue dye, litmus, is obtained from *Lecanora tartarea.* Litmus is prepared as a dark brown powder which is soluble in water. Litmus paper is paper which has been soaked in litmus solution. Acids cause litmus to turn red; while alkalis, even in small quantities, will make it blue. Holland produces nearly all the litmus used. Many other lichens yield dyes, some of them blue, others red or crimson, brown and yellow. Today, however, they are little used, modern synthetic dyes having supplanted them.

In those days when powdered wigs were in fashion, another and important use was made of lichens. This was as a hair powder, because of the fact that powdered lichens would retain for a considerable time any fragrance that was given them. So the lichens were packed with sweet-smelling flowers, or other fragrant substances, then dried and powdered. Often other. substances, such as musk, were used with the powdered lichen. (R.M.W.)

LICHI. Mammalia, Artiodactyla. An African **antelope.** The species inhabits swamps in the south central part of the continent. (A.W.L.)

LICORICE. *Glycyrrhiza glabra.* Leguminosae. Licorice is obtained from an herb of southern European countries. The plant grows 4 or 5' tall and has many pinnately-compound, pale green leaves and purplish flowers resembling those of the perennial pea. The fruit is a smooth pod containing several seeds. Licorice is a yellowish substance extracted from the rootstock. In water it swells to a jelly-like mass. It is used in medicines to hide the taste of unpleasant-tasting substances and in the treatment of head colds. But by far the greater part of the licorice root imported is used as a flavoring in chewing tobacco. (R.M.W.)

LIFE ZONE. A geographical area characterized by approximate uniformity of temperature conditions. The life zones are conditioned both by latitude and by altitude, hence a given zone need not be continuous but may, for example, appear at intervals along a mountain range. These zones are of limited value in the study of animal distribution.

In North America three principal zones are recognized, the Boreal, the Austral, and the Tropical. The first is subdivided into the Arctic, the Hudsonian, and the Canadian, ranging from the conditions of the far north to those of Canada and some parts of the northern United States and of more southern mountain regions. The second includes a Transition zone and the Upper and Lower Austral, and the last is not subdivided. (A.W.L.)

LIGAMENT. 1. The connection between the two parts of the shell of **bivalve** mollusks. 2. A strong fibrous band spanning the joint between the ends of two bones in the vertebrates. **Connective tissue. Joint.** (A.W.L.)

LIGATURE. A thread-like material or wire used for tying off blood vessels or other structures of the body during surgical operations. The material may be absorbable (catgut) or non-absorbable (silk or linen) or metal wire. Ligatures are made in various grades of thickness and tensile strength. (R.S.M.)

LIGHT. This term properly refers to the range of **electromagnetic radiation** frequencies associated with **vision;** though the physicist is apt to think of more objective manifestations, such as **photovoltaic effects,** and sometimes even oversteps the limits of the visible range by calling **infra-red** or **ultra-violet** radiation, and even **x-rays,** "light." The wavelengths of visible light extend approximately from 4000 angstroms (extreme violet) to 7700 angstroms (extreme red). Compared with radiation as a whole, this is an extremely limited range. It appears to be an inevitable limitation, however, on account of the strong absorption of most substances for radiation on both sides of it. The **quantum theory** of radiation applies of course to light, the energy quanta of which are called photons. Some of the optical phenomena so readily interpreted on the wave theory, such as **reflection, refraction, interference, diffraction,** and polarization of light, offer difficulties when studied in terms of quanta; the laws of **photoelectric phenomena, photoconductivity,** the **spectrum,** etc., become, on the other hand, much more intelligible. **Geometrical optics** is easily expressed in terms of either. The well known **Huygens principle** and **Fermat principle** apply to any radiation, including light, as does the **electromagnetic constant** representing the speed of radiation in a vacuum. Discussions of **photometry** and of **color** are, however, usually in terms of visual sensation and hence are confined to light proper, though the physical ideas involved are not subject to such limitation. (L.D.W.)

LIGHT, AERONAUTICAL.

Anchor. Light or group of clear lights carried on an aircraft to indicate its position at night while at anchor.

Boundary. Any one of the lights designed to indicate limits of landing area of airport or landing field.

Course. Light projected along course of an airway so as to be visible chiefly from points on or near the airway.

Identification. Group of lights, clear and colored, carried on rear part of an airplane for identification at night.

Landing. Light carried by an aircraft to illuminate the ground while landing.

Obstruction. Red light designed to indicate position and height of an object hazardous to operation of aircraft.

Position. For U. S. commercial aircraft, these consist of a red light on left wing tip, a green light on right wing tip, and a white light at the tail. The wing-tip lights must be visible from dead ahead and from the side. (F.T.M.)

LIGHT ALLOYS. The **aluminum alloys** which have densities approximately ⅓ that of steel and the **magnesium alloys** with densities approximately ¼ that of steel are known as the light alloys. Other possible light alloys are those having lithium or beryllium as the base metal but no commercially important compositions have been developed. (R.H.H.)

LIGHT CURVE. In the study of **variable stars** and in kindred problems in astronomical research, it is desirable to graphically represent the variation of radiation intensity with time. A diagram in which light intensity, on any convenient scale, is plotted as ordinates against time as abscissae is known as a light curve. As the number of observations increases it is frequently possible to detect a periodic variation in the light intensity. After a provisional period has been determined, some convenient epoch is selected and all of the observations are reduced to the cycle of variation embracing the selected epoch by the use of the provisional period. In order that the resulting points may fall on a regular curve, it is frequently necessary to apply a number of corrections to the provisional period. The curve drawn through the plotted points, all reduced to the selected epoch by means of the repeatedly corrected period, is known as the mean light curve. Examples of light curves will be found in the articles on **long period variables** and on **Cepheids.** (W.K.G.)

LIGHT FILTERS. A homogeneous optical medium that is characterized by its absorption in certain regions of the spectrum. A filter is used to change or control the total or relative energy distribution of a beam of light. In photography a filter may be placed over the light source or in some part of the optical path traversed by the light in reaching the photographic emulsion, generally over the camera lens.

A photographic light filter may consist of a glass cell containing a liquid of the proper absorption, a piece of glass or gelatin containing suitable dyes or colorants, or some similar material having the desired absorption as well as satisfactory physical and optical properties.

Photographic filters are generally named in a manner to indicate their use. A color filter, therefore, means a filter showing selective absorption in the visible spectrum, while a neutral density filter is characterized by non-selective absorption in the visible spectrum. Infra-red and ultra-violet filters transmit those spectral regions. The largest group of light filters is the color filters, which may be divided into two main classes, the correction and contrast filters. This division is somewhat arbitrary and there are filters that are not readily so classified.

The correction, or compensating filter, is characterized by a relatively gradual change from absorption to transmission in any given region of the spectrum. Such filters, therefore, afford redistribution of the energy in the light source. Photometric filters, light yellows and many pale green filters, fall into this group. They are used in photography to alter the relative brightness with which differently colored objects are reproduced.

Contrast filters are distinguished by their rather abrupt change, over a short wavelength region, from complete absorption to high transmission. Such filters are used to isolate regions of the visible spectrum and to pass the chosen region quite freely while absorbing all other visible light. Typical contrast filters are the highly saturated red, green, blue and deep yellow photographic filters. Light filters of this type are used extensively in commercial contrast photography, color photography and microscopy.

Polar screens are often used as photographic light filters and exhibit non-selective absorption throughout the visible spectrum, but do absorb **polarized light.** Since the light received at the camera is often polarized, such a filter allows the brightness of various parts of the subject to be altered without changing the relative color balance of the light received by the photographic emulsion.

Graduated light filters are occasionally useful in photography and consist of light-absorbing media, the densities of which are not constant over the surface. Such filters are used to equalize the brightness differences between sky and foreground in landscape photography and to equalize the illumination in color cameras. The sky filter to control brightness in landscape photography is a deeper yellow on the upper portion and pale yellow or clear below. When placed over the lens properly the light from the bright sky is filtered more effectively than light reaching the film from the foreground. Graduated filters for the control of illumination in color cameras may be neutral or colored and are placed in front of the film plane inside the camera. (H.C.C.)

LIGHT YEAR. The light year is a popular method of expressing large distances. It is the distance that light will travel in the course of 1 year. The **velocity of light** is approximately 186,000 miles per sec. or 300,000 kilometers per sec. and there are approximately 31,560,000 sec. in a **mean solar year.** Accordingly

a light year represents a distance of approximately 5.88×10^{12} miles (nearly six million-million miles) or 9.461×10^{12} kilometers.

For purpose of comparison with other astronomical units of distance we find that a star at a distance of one **parsec** (parallax 1″) is at a distance of 3.258 light years, and that a star at a distance of 1 light year is over 63,000 **astronomical units** from the earth. Hence, the astronomical unit bears about the same relation to the light year as the inch does to the mile. (W.K.G.)

LIGHT-FILTER FACTOR. Light filters absorb a part of the incident light and, therefore, transmit less than was present before filtration. In photography the quantity of light present determines the exposure given to the emulsion. Every filter, therefore, has a filter factor that applies to conditions of use and is the increase in exposure necessary to compensate for the light absorbed by the filter. The filter factor is generally determined by the exposure increase necessary with the filter when photographing a neutral gray subject, such as a **gray scale.**

The numerical value of the filter factor, or multiplying factor as it is often called, is not constant since it depends not only on the color of the filter itself, but also on the energy distribution or color of the source of light, and on the relative color sensitivity of the photographic emulsion being used. With a given red filter and panchromatic film, for example, the filter factor would be somewhat greater in daylight than in average tungsten illumination which contains a relatively greater proportion of red light compared to other portions of the spectrum. Likewise, the filter factor for a given yellow filter in daylight would be considerably greater with an orthochromatic emulsion (sensitive only to blue and green) than with a panchromatic emulsion that was sensitive to all colors. (H.C.C.)

LIGHTNING. The electrical condition of the earth's surface and of the atmosphere is quite different in stormy weather from its normal, fair-weather state. Over a level stretch of country in fine weather, there is distributed a negative surface charge estimated at about 0.00027 electrostatic unit per sq. cm. or 0.0014 coulomb per sq. mile. Above this, the electric **potential** of the atmosphere increases with elevation at the rate of about 100 volts per meter, the upper atmosphere being, apparently, positively charged. The earth, the atmosphere, and the **ionosphere** thus form a vast **condenser,** through the dielectric of which there is constant leakage because of ionization. What maintains the charges against this leakage is not well understood.

In a rapidly developing rainstorm clouds become charged, positively at the top and negatively below. According to C. T. R. Wilson, this is brought about by the differential falling rate of large and of very small drops, the former becoming for some reason negatively and the latter positively charged. The cloud thus acts as a huge **static machine** with drops as carriers, which operates until the electric stress becomes so great as to cause a discharge of lightning between the charged surfaces of the same cloud, or between two clouds, or between a cloud and the induced charge on the earth under it. These activities of course greatly modify the distribution of charge and potential in the surrounding area, changes which can be detected by electrometers suitably placed.

It has been estimated that over the entire earth the frequency of lightning averages about 100 flashes every second and that this rate of discharge represents something like 4,000,000,000 kilowatts of continuous power. The flashes are often very long, sometimes several miles, and have been estimated to be from 4–6″ in diameter. Often several flashes, each of very short duration, follow in quick succession over nearly but not quite the same path, thus producing the illusion of forking. Because light travels at the rate of 186,000 miles per sec. and sound at about 1100 ft. per sec., lightning flashes are seen and vanish long before the rumble of thunder is audible unless discharge occurs near the observation point. "Sheet lightning," so called, is merely the reflection or scattering of light from distant flashes by clouds. "Ball lightning" is a very rare manifestation not at all understood. Observers describe it as a small incandescent, hissing globe, moving slowly along in the air, sometimes indoors, now and then touching obstacles and scorching them, sometimes exploding. (L.D.W.)

LIGHTNING ARRESTER. Lightning arresters are applied to electric lines which are exposed to direct or induced **lightning** disturbances, in order safely to conduct the high-frequency or high-voltage lightning disturbance to ground. These may be divided into two types, those used on power circuits, and those used on communication circuits. The former presents the more difficult problem, since a power **arc** tends to follow the **ionized** path created by lightning.

A lightning arrester on a power circuit should normally have so high a resistance to current that at the normal line voltage there will be only a negligible leakage of current through the arrester. Upon reception of abnormal voltages, this arrester should provide a direct and positive path to the ground, and should interrupt any power arc that may tend to follow the high-voltage surge. At present several arrangements satisfy these requirements. The simplest form of lightning arrester is a horn gap, in which two horns, one on the line and one connected to the ground, are separated by a small, set gap above which they flare to a wider separation. When excessive voltage causes breakdown of the resistance of this gap, and a discharge to ground, the power arc which follows will usually be extinguished by the electromagnetic and thermal effects of the arc, which cause it to rise higher on the horns until extinguished by their divergence, creating an ever longer arc path. On the high-voltage transmission lines employed today this extinguishing action is not always reliable, and various types of film and valve arresters have been devised. The first of these was the aluminum **cell,** or electrolytic arrester. It was necessary to connect this arrester to the line through a horn gap, and since its continued operation required periodic recharging, it necessitated some attendance, which is unnecessary in the more recently perfected valve-type arresters. Typical of the latter is the oxide film arrester, which consists of a number of cells in series. A cell is made of a **lead** oxide compound held between metal plates. The assembled cell is covered with lacquer insulation, and a certain number of them is built up into a stack which can be connected from line to ground. The cell would be a good conductor but for the lacquer. A discharge of lightning punctures the latter and causes local heating, which changes the nature of the oxide from conductor to insulator. This cuts short the current which the line voltage forces to follow the lightning discharge. These dry type arresters do not need daily attendance.

The protection of communication circuits and antennae is simpler due to the lack of high voltage on these circuits. A common type consists of two carbon blocks held at a definite spacing in porcelain. These are connected from the circuit to ground so that an abnormal voltage will break down the gap and ground itself. Since there is no power voltage behind the arc, the gap clears itself as soon as the disturbance has passed. (F.T.M.)

LIGHTNING BUG. Insecta, Coleoptera. Common **beetles** of the family Lampyridae which have a luminous organ located on the under surface of the last few segments of the abdomen. They are especially active in warm damp places early in the night, flashing at intervals of a few seconds. Occasionally large numbers of these

insects flash synchronously, a phenomenon that has not been satisfactorily explained. The light apparently serves them in finding mates. (A.W.L.)

LIGNIN. Lignin and **cellulose** are the chief constituents of wood. Lignins are complex substances of unknown composition believed to be polysaccharides. In the manufacture of paper from **wood** it is necessary to remove the lignin, and this is often accomplished by treatment of the wood fibers with such agents as **sulfur dioxide—calcium** bisulfite, or sodium sulfate—**sodium sulfide,** or **sodium** hydroxide. For the details of these various methods, see **Paper.** (R.K.S.)

LIGNITE. **Coal.**

LIGNUM VITAE. *Guaiacum officinale* and *G. sanctum.* This is the heartwood of a tree growing native in the West Indies. It is a valuable, tough resinous wood and very heavy, being the heaviest of all commercial woods. A cu. ft. weighs 76 lbs. Its principal use is in the making of bowling balls, pulley sheaves and mallet heads. (R.M.W.)

LIKELIHOOD. The method of maximum likelihood for the estimation of **population parameters** was introduced by R. A. Fisher. It is extremely important since under certain limitations it affords an easy way of finding **consistent, efficient,** and **sufficient statistics.** Let $P(x, \theta)$ be a **probability function** dependent on a single parameter θ. Then the likelihood of obtaining the **sample** $x_1, x_2, \cdots, x_N$ is defined as the product of the N values of $P(x_i, \theta)$.

$$L = P(x_1, \theta) \cdot P(x_2, \theta) \cdots P(x_N, \theta).$$

We maximize L by considering θ the **variable** or, what is the same thing, maximizing the log L, and solve the resulting equation for θ. In the case of the **normal probability function** the maximum likelihood estimate for the population **mean** is the sample mean, and for the population **variance** the maximum likelihood estimate is the sample variance. The method of maximum likelihood is very useful in the fitting of the **Pearson system,** although the resulting equations are rather difficult to solve. It is also very helpful in finding the asymptotic variance of efficient statistics. (L.A.A.)

LILY FAMILY. Liliaceae. The Lily Family has representatives in all parts of the world, and more especially in the drier regions of the temperate zone. Several members of the family are important vegetables, notably asparagus and onions, while a great many more are cultivated for ornament. Among the latter are the true lilies (the genus *Lilium*), tulips, and hyacinths.

Most members of the Lily Family are herbaceous plants with a shallow fibrous root system. A few species of *Aloe* and *Dracaena* are shrubby or even small trees. Characteristic of the family are underground rhizomes or bulbs, storage organs which enable the plant to survive in regions where protracted dry seasons occur. As a rule, these plants have linear undivided leaves which do not show division into **petiole** and **blade.** The **inflorescences** of the family are very diverse. In some genera the flowers are solitary, in others they occur in **racemes,** while **umbels** occur in still others. The **perianth** of the flower has six separate members in two whorls of three, which are very much alike in size, shape, and color. The **stamens** have conspicuous **anthers.** The ovary is superior, 3-celled, and bears a single **style** with a 3-lobed **stigma.** The fruit is a capsule or a berry.

Members of the genus **Allium** are extensively cultivated for food; less widely grown, but forming an important crop in western countries, is **Asparagus.** In the Eastern World, bulbs of certain species of *Lilium* are used as foods. In the Western World members of this genus are used entirely for ornament. White-flowered species are extensively grown indoors to flower at Easter time. (R.M.W.)

LIMA BEAN. *Phaseolus lunatus.* **Bean.**

LIMAÇON. The limaçon is a plane curve which may be defined geometrically as follows: Draw a circle of radius b passing through the origin of a set of rectangular axes and with its center on the X-axis. Draw a secant line OS cutting the circle at B, and extend OB to P so that $BP = 2a$. As the secant rotates about O, the point P describes the limaçon, as shown in Figs. 1–3.

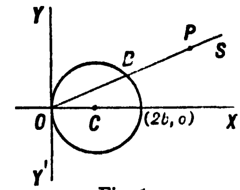


Fig. 1.

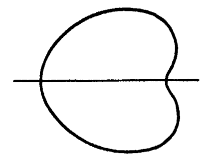
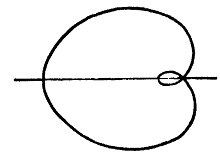




$a > b$ $a < b$

Fig. 2. Limaçon. Fig. 3.

In **polar coordinates,** the equation of the limaçon is

$$r = a - b \cos \theta.$$

If $b = a$, the curve becomes the **cardioid.** (L.L.S.)

LIMB. A jointed appendage, especially of the **vertebrates.** Applied usually to **primates** as a collective term to indicate both arms and legs. (A.W.L.)

LIMBURGITE. An igneous rock with a glassy base, which displays **phenocrysts** of **olivine** and **pyroxene.** (E.S.C.S.)

LIME. For the fruit of this name, see **Citrus Fruits.** In chemistry, lime is a term applied to **calcium** compounds. Limestone, calcium carbonate; caustic lime, calcium oxide; lime water, calcium hydroxide solution; slaked lime, calcium hydroxide solid. Percentage of lime expressed in analyses of chemicals is for calcium oxide (CaO). (R.K.S.)

LIMESTONE. A general term for the great, variable group of **carbonate** rocks whose chief constituent is **calcium** carbonate, usually in the form of the mineral **calcite.** Although limestones are quite common among the **sedimentary rocks,** occurring as true limestones or marbles in all periods from the **Archean** to the present, most of them contain large amounts of impurities, of which the more common are, **magnesia, silica, iron oxide,** iron hydroxide, **clay** and organic matter. Carbonate rocks relatively rich in magnesia are called magnesian limestones. When the magnesia is in the form of the mineral **dolomite** the rock is called either dolomitic limestone or dolomite, according to the abundance of that mineral. Limestones which are composed chiefly of shells and shell fragments are called **coquina.** Limestones which contain **argillaceous** material are called either shaly limestone or calcareous **shales,** according to the proportions of calcite to clay. Limestones which have a high **bituminous** content may be called stink stein because they emit an unpleasant sulfurous odor when struck with a hammer. It has not yet been definitely determined whether fine-grained relatively unfossiliferous limestones are entirely the product of ground-up calcareous shells, or straight chemical precipitates, either of organic or inorganic origin. Probably,

however, the bulk of the limestones, especially those formed during the earliest periods of the earth's history, are composed of **drewite,** which in turn is a bacterial-algal precipitate of fresh or brackish water origin but relatively insoluble in sea water, and therefore preserved when transported and deposited in the sea. At the present time calcareous muds are being precipitated from sea water through the reaction of **ammonium** carbonate on **calcium** sulfate, the ammonium radical resulting from the action of the putrifaction bacteria. Limestones are of considerable economic importance being used: as building and decorative materials, in the manufacture of portland **cement,** lime for plaster, **fertilizers, flux,** chemical lime, etc. In 1934 the production of building limestone in the United States was 539,300 short tons valued at approximately $3,655,000. (R.M.F.)

LIMICOLAE. An old order of birds, partially equivalent to the **Charadriiformes.** (A.W.L.)

LIMIT DIMENSIONING. Interchangeable Manufacturing.

LIMIT GAUGE. Measurement.

LIMITS. We say that the limit of a **function** $f(x)$ when x approaches a is equal to l, when for any arbitrary $\epsilon > 0$ there exists a number $\delta > 0$ such that $|f(x) - l| < \epsilon$ whenever $|x - a| < \delta$. We write $\lim_{x \to a} f(x) = l$, or $\lim_{x \to a} f(x) = l$, or $f(x) \to l$ when $x \to a$.

If a variable continually increases but remains less than some constant c, it approaches a limit; and this limit is either c or some lesser number.

If a variable continually decreases but remains greater than some constant c, it approaches a limit; and this limit is either c, or some greater number.

The limit of the sum of two variables which approach limits is the sum of those limits.

The limit of the product of two variables which approach limits is the product of those limits.

The limit of the quotient of two variables which approach limits is the quotient of those limits, unless the limit of the divisor is o.

A variable which approaches a limit o is called an infinitesimal.

When a variable v increases beyond all bounds, it is said to become infinite, and we write $v \to \infty$.

The symbol ∞ does not denote a number; it merely denotes a mode of variation. (L.L.S.)

LIMNOBENTHOS. Aquatic benthos. **Distribution.** (A.W.L.)

LIMNOLOGY. A division of biology that deals with the living organisms, both plant and animal, in fresh water. It includes the classification and biology of these organisms and their **ecological** relations. (A.W.L.)

LIMNOSCELIS PALUDIS. (Ancestral lizard.) **Fossil Reptiles.**

LIMONITE. The mineral limonite, hydrated oxide of **iron,** corresponds to the formula $Fe_2(OH)_6Fe_2O_3$, but is often very impure due to the admixture of sand and clay. It is not found crystallized but grades from loose porous material to compact masses. Its hardness is variable but pure material is 5–5.5; specific gravity 3.6–4; usual luster, dull to earthy but may be silky to submetallic; color, various shades of yellowish-brown, sometimes nearly black; streak, yellowish-brown; opaque. Limonite is a secondary mineral from the alteration of various other iron-bearing ores or minerals, it is of widespread occurrence and used both as an ore of iron and as a **pigment.** Limonite has been formed in marshy and boggy areas and is frequently called bog iron ore. Limonite is an important ore of iron in Lorraine, Luxemburg, Bavaria and Sweden. It is found in Saxony, Austria, and England. In the United States limonite is found particularly in Connecticut, Massachusetts, Pennsylvania, New York, Virginia, Tennessee, Georgia and Alabama, but these deposits are of little economic importance at the present time. (E.S.C.S.)

LIMPET. Mollusca, Gasteropoda. Marine and freshwater animals related to the snails, with a low conical shell, not spirally twisted. In the common limpets the shell is solid and in the keyhole limpets it is either notched in front or perforated between that point and the apex. Mollusks of the family Capulidae, more closely related to some of the species with coiled shells than to the true limpets, also have shells which are not spiral and are called limpets. One form, *Crucibulum,* is called the cup and saucer limpet and another, *Crepidula,* the boat limpet or slipper shell. (A.W.L.)

LIMPKIN. Aves, Gruiformes. Birds (**Aves**) of two species resembling the rails but larger. One, *Avamus vociferans,* ranges from Florida through the Antilles and Central America and the other, *A. scolopaceus,* lives in tropical South America. Also called courlans. (A.W.L.)

LINE. This term is used in two senses in electrical circuits, the first being as the conducting system for electrical energy between two remote points of the system and the second in terms of the scanning in **facsimile** and **television** systems. For a discussion of the power transmission line see **Electric Power Transmission.** In communications circuits the line takes on added properties, or perhaps we should say that certain properties become much more important. This is due to the much shorter wavelengths used in such circuits so the lines used will frequently be several wavelengths long. Thus at 60 cycles (commercial power **frequency**) a line would have to be a little over 3000 miles long to be a wavelength while in the middle of the audio range (5000 cycles) it would only need to be about 37 miles and at the ultra high radio frequencies only a few inches. If a line has a length of the order of a wavelength or more and is not matched (see **Matching**) reflection and resultant standing waves will result. Often this is a serious drawback to its useful function but for high radio frequencies this property is used to great advantage. A line having standing waves appears at its input terminals to be a resonant circuit (alternately as a series and a parallel type) when adjusted to multiples of a quarter-wave in length. Since at the very high radio frequencies a line a quarter-wavelength long is only a few inches such lines are often used to serve as resonant circuits for **tanks** in **oscillators, amplifiers,** etc. Used in this connection they are superior to ordinary lumped inductance and capacitance circuits as they have a much higher Q and when properly constructed will cause much lower radiation losses. If these lines are adjusted in length to something other than quarter-wave multiples they act as inductance or capacitance, depending upon the exact length. Such lines are used for a variety of functions, e.g., **tanks,** radio-frequency **chokes,** tuning elements, coupling elements, etc. They are widely used at frequencies of a hundred or so megacycles and at still higher frequencies are the only satisfactory means for tuning and coupling circuits. In these applications the **co-axial line** or **wave guide** are ordinarily used since they do not radiate but at the lower frequencies parallel lines are sometimes used for convenience. Various short- and open-circuited lines are useful for impedance **matching** at **radio frequencies.** In power circuits the losses of the line, while important from an efficiency standpoint are not too serious but in telephone circuits these losses may be an appreciable part of the total power and consequently are a serious prob-

lem. Also a line which is long enough to be comparable to a wavelength will produce appreciable phase shift and this may cause trouble in communication circuits. Important constants of lines may be summed up in the following equations:

$$\gamma = \sqrt{zy} \qquad |I| = |I_s|e^{-\alpha l}$$
$$\gamma = \alpha + j\beta$$
$$Z_0 = \sqrt{z/y} \qquad I = I_s e^{-\gamma l}$$

where z is the series **impedance** of the line per unit length, y the shunt **admittance** per unit length, γ the **propagation constant,** α the **attenuation constant,** β the **wavelength** or phase constant, Z_0 the **characteristic impedance,** $|I|$ the magnitude, I the vector current at a distance l from the sending end, I_s the sending end current, e the base of the natural logarithms. The phase shift along the line may be found from

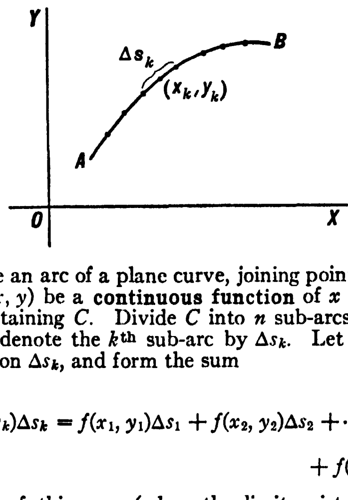
$$\text{Phase} = \beta l.$$

(L.R.Q.)

LINE DIAGRAM. **Skeleton Diagram.**

LINE FINDER. This is one of the automatic switching units used in a machine-switching telephone office and serves to locate the line initiating a call when the receiver is removed from the hook by the calling party. (See **Telephony.**) (L.R.Q.)

LINE INTEGRAL. A line integral is an important mathematical concept which is a natural extension of the idea of the **definite integral** of a function of one variable.



Let C be an arc of a plane curve, joining points A and B and let $f(x, y)$ be a **continuous function** of x and y in a region containing C. Divide C into n sub-arcs by points on C and denote the k^{th} sub-arc by Δs_k. Let (x_k, y_k) be any point on Δs_k, and form the sum

$$\sum_{k=1}^{n} f(x_k, y_k)\Delta s_k = f(x_1, y_1)\Delta s_1 + f(x_2, y_2)\Delta s_2 + \cdots + f(x_n, y_n)\Delta s_n.$$

The **limit** of this sum (when the limit exists), as each $\Delta s_k \to 0$ (and $n \to \infty$) is called a line-integral of $f(x, y)$ along the path C, and is denoted by

$$\int_C f(x, y)ds.$$

Now let $P(x, y)$ and $Q(x, y)$ be continuous functions of x and y in a region, and let C be a given path (arc of a plane curve). As before, divide C into n sub-arcs and let Δs_k denote the k^{th} sub-arc, and let Δx_k and Δy_k be the **projections** of Δs_k on the X-axis and Y-axis respectively. Form the sums

$$\sum_{k=1}^{n} P(x_k, y_k)\Delta x_k \quad \text{and} \quad \sum_{k=1}^{n} Q(x_k, y_k)\Delta y_k;$$

if these sums approach limits as each $\Delta s_k \to 0$ (and $n \to \infty$), these limits are defined as line-integrals of P and Q, respectively, along the path C, and are denoted by

$$\int_C P(x, y)dx \quad \text{and} \quad \int_C Q(x, y)dy.$$

The combination

$$\int_C P(x, y)dx + \int_C Q(x, y)dy,$$

which is generally written

$$\int_C (Pdx + Qdy)$$

is the usual way in which line integrals occur.

The line integral $\int_C f(x, y)ds$, defined first, can be expressed in the form $\int_C Pdx + Qdy$.

Line integrals are sometimes called curvilinear integrals.

If the path C is given by an equation of the form $y = \phi(x)$, we may replace y by $\phi(x)$ and dy by $\phi'(x)dx$ in the integral $\int_C Pdx + Qdy$, and obtain an ordinary **definite integral** in one variable of the form $\int_{x_1}^{x_2} F(x)dx$. Similarly, if path C is given by an equation of the form $x = \psi(y)$.

If the path C is given by **parametric equations** $x = \phi(t)$, $y = \psi(t)$, we may express P and Q in terms of t and dx and dy by $\phi'(t)dt$ and $\psi'(t)dt$, respectively, and obtain an ordinary integral of the form $\int_{t_1}^{t_2} F(t)dt$.

A line integral

$$\int_C (Pdx + Qdy + Rdz)$$

along a path C in space may be defined in a similar manner to that in a plane; in this case P, Q, R are functions of three variables x, y, z.

By use of **Green's theorem in the plane,** it can be shown that, if P and Q are two functions of x, y which, together with their first **partial derivatives,** are **continuous** within and on the boundary of a certain region, then the necessary and sufficient condition that the line integral in the plane $\int_C (Pdx + Qdy)$ may be independent of the path C in this region is that $\dfrac{\partial P}{\partial y} = \dfrac{\partial Q}{\partial x}$.

If the preceding line integral $\int_C (Pdx + Qdy)$, in which one end point of path C is a variable point (x,y), be denoted by u, then $\dfrac{\partial u}{\partial x} = P$, $\dfrac{\partial u}{\partial y} = Q$.

In order that the line integral $\int_C (Pdx + Qdy + Rdz)$ in space have the same value for all paths C joining the same two points, it is necessary and sufficient that

$$\frac{\partial P}{\partial y} = \frac{\partial Q}{\partial x}, \quad \frac{\partial Q}{\partial z} = \frac{\partial R}{\partial y}, \quad \frac{\partial R}{\partial x} = \frac{\partial P}{\partial z},$$

provided P, Q, R and their partial derivatives are continuous in a region surrounding the paths C.

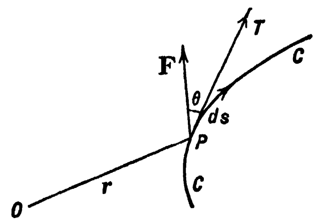
If this line integral be denoted by u, then

$$\frac{\partial u}{\partial x} = P, \quad \frac{\partial u}{\partial y} = Q, \quad \frac{\partial u}{\partial z} = R,$$

provided one end point of C is a variable point (x, y, z).

(I.I.S.)

LINE INTEGRAL OF A VECTOR FUNCTION. A line integral of a vector function is a mathematical notion of importance in mathematical physics.



Let $F(r)$ be a **vector function** of the position vector r. Then the line integral $\int_C F \cos\theta\, ds$ along a path C, where θ is the angle between F and the element of arc ds, is called the line integral of the vector function $F(r)$, and is denoted by $\int_C F\cdot dr$ in vector notation. (L.L.S.)

LINE OF APSIDES. A line which contains the major axis of an **ellipse** is known as the line of apsides of the ellipse. In astronomy the term is used to indicate the line joining **perihelion** and **aphelion** points in an **orbit** and extending to infinity to cut the **celestial sphere.** (W.K.G.)

LINE OF NODES. The line of nodes is the astronomical term applied to line of intersection of any two fundamental planes. The line of nodes for the **moon** is the line of intersection of the plane containing the moon's **orbit** with the plane of the **ecliptic.** The line of nodes for any member of the **solar system,** other than **satellites,** is the line of intersection of the plane of the orbit of the object with the plane of the ecliptic. The line of nodes for the earth is the line of intersection of the plane of the earth's **equator** with the plane of the ecliptic. (W.K.G.)

LINE OF POSITION. In **navigation** any line on the surface of the earth upon which a ship is known to be located, is called a line of position. If two or more lines of position are known, the ship must be at their point of intersection. A position determined by the intersection of lines of position is known as a **fix.**

Lines of position are usually circles, either great or small. In most cases, the distance of the center is so great in comparison with the length of the plotted line that the curvature is not apparent in the plot. In some cases, however, we may find both points of intersection of two circles of position appearing on the plot. In these cases a dead-reckoning position will indicate which one is the desired fix. Lines of position are obtained by methods of **pilotage, celestial navigation,** or **radio navigation.** (W.K.G.)

LINE SQUALL. Extremely turbulent roll-type squall cloud usually found at the leading edge of squall lines associated with rapidly moving cold fronts. (P.E.K.)

LINE SPECTRA. Atomic Spectra.

LINE-OF-SIGHT TRANSMISSION. This term is commonly applied to the range of transmission of very high frequency radio stations such as **television** and frequency-modulated stations. At these high frequencies the radio waves are not reflected from the **ionosphere** so no **sky wave** returns to earth, thus limiting the range to that covered by the **ground wave.** This is refracted around the surface of the earth to only a slight extent, so while line-of-sight is not strictly accurate it is fairly descriptive. It is also inaccurate in that radio waves, even at these frequencies, will pass through objects which are opaque to visible light. (L.R.Q.)

LINEAR ALGEBRAIC EQUATIONS. A linear algebraic equation in one unknown is a **polynomial equation** of the first degree, and may be written in the form $ax + b = 0$. It may be solved by transposition and division.

A linear algebraic equation in two variables is represented by the general form $ax + by + c = 0$. It may be satisfied in general by an unlimited number of pairs of values of x and y. The graphic representation of such an equation gives a straight line in the plane.

A linear algebraic equation in three variables is represented by the form $ax + by + cz + d = 0$. It is represented graphically by a plane. (L.L.S.)

LINEAR ALGEBRAIC EQUATIONS, SYSTEMS OF. A system of linear equations in two or more unknowns is a set of linear equations which are considered together with the object of determining whether they are satisfied by one or more sets of values of the unknowns and of finding these values if such exist.

A solution of such a system of equations is any set of corresponding values of the unknowns which satisfy the equations of the system.

The general form of a system of two linear equations in two unknowns may be written

$$\begin{cases} a_1x + b_1y = c_1 \\ a_2x + b_2y = c_2, \end{cases}$$

that of a system of three linear equations in three unknowns may be written

$$\begin{cases} a_1x + b_1y + c_1z = d_1 \\ a_2x + b_2y + c_2z = d_2 \\ a_3x + b_3y + c_3z = d_3, \end{cases}$$

and similar forms for more unknowns.

A system of linear equations in which the number of equations is the same as the number of unknowns may be solved algebraically by the method of elimination by addition and subtraction, or by the method of substitution, or by the method of comparison, or by **determinants.** A system of two equations with two unknowns may also be solved graphically.

If a system of linear equations with the number of equations the same as the number of unknowns has only one solution, the equations are said to be independent and consistent. If the system has no solution, the equations are called inconsistent. If the equations of the system are satisfied by an unlimited number of values of the unknowns, the equations are called dependent.

An inconsistent pair of linear equations in two unknowns is represented graphically by a pair of parallel straight lines. A dependent pair of linear equations in two unknowns is represented graphically by one straight line used twice.

A system of two linear equations in two unknowns may be solved by the method of elimination by addition and subtraction, by multiplying both equations by such multipliers that the coefficients of one of the unknowns are the same in both equations, then adding or subtracting these equations to eliminate the one unknown, obtaining a linear equation in one unknown, which may be immediately solved; substitution of this value of the unknown in one of the original equations again gives one linear equation with one unknown. Or, the second unknown may be found by eliminating the first unknown as in the preceding.

In the method of substitution, one of the given equations is solved for one unknown in terms of the other and this is substituted in the other equation, obtaining one linear equation in one unknown.

In the method of comparison, both of the given equations are solved for the same unknown in terms of the other unknown, these are equated, and the resulting linear equation in one unknown solved.

For a system of three equations in three unknowns, the algebraic procedure for solution would be: Eliminate one of the unknowns from one pair of equations and also from another pair; solve the resulting two equations for the two unknowns in them, as just described; substitute the resulting values in one of the given equations to obtain the value of the third unknown. An exactly similar procedure applies to systems of more equations with more unknowns, the number of equations being the same as the number of unknowns.

A system of two linear equations with two unknowns may be solved graphically by constructing the **graphs** (straight lines) of the two equations (in **rectangular coordinates**) and finding the **coordinates** of the intersection point.

By making use of **determinants**, the solution of systems of linear equations may be expressed in convenient and compact form as follows:

The solution of the system of equations

$$\begin{cases} a_1x + b_1y = c_1 \\ a_2x + b_2y = c_2 \end{cases}$$

is given by

$$x = \frac{\begin{vmatrix} c_1 & b_1 \\ c_2 & b_2 \end{vmatrix}}{\begin{vmatrix} a_1 & b_1 \\ a_2 & b_2 \end{vmatrix}}, \quad y = \frac{\begin{vmatrix} a_1 & c_1 \\ a_2 & c_2 \end{vmatrix}}{\begin{vmatrix} a_1 & b_1 \\ a_2 & b_2 \end{vmatrix}},$$

provided the denominator $\begin{vmatrix} a_1 & b_1 \\ a_2 & b_2 \end{vmatrix} \neq 0$. If this denominator is zero and if the numerators are not both zero, the equations have no solution and are inconsistent; if all three determinants are zero, the equations are dependent.

The solution of the system of equations

$$\begin{cases} a_1x + b_1y + c_1z = d_1 \\ a_2x + b_2y + c_2z = d_2 \\ a_3x + b_3y + c_3z = d_3 \end{cases}$$

is given by

$$x = \frac{\begin{vmatrix} d_1 & b_1 & c_1 \\ d_2 & b_2 & c_2 \\ d_3 & b_3 & c_3 \end{vmatrix}}{D}, \quad y = \frac{\begin{vmatrix} a_1 & d_1 & c_1 \\ a_2 & d_2 & c_2 \\ a_3 & d_3 & c_3 \end{vmatrix}}{D}, \quad z = \frac{\begin{vmatrix} a_1 & b_1 & d_1 \\ a_2 & b_2 & d_2 \\ a_3 & b_3 & d_3 \end{vmatrix}}{D},$$

where $D = \begin{vmatrix} a_1 & b_1 & c_1 \\ a_2 & b_2 & c_2 \\ a_3 & b_3 & c_3 \end{vmatrix}$, provided $D \neq 0$. If $D = 0$, the equations are inconsistent or dependent.

A system of n linear equations in n unknowns has a single solution if the determinant of the coefficients is not zero; the value of any unknown can be expressed as a fraction whose denominator is the determinant of the coefficients and whose numerator is the determinant obtained from the denominator determinant by replacing the column of coefficients of this unknown by the column of constant terms (when these are on the right hand side of the equations). This is known as Cramer's rule, and may be expressed symbolically thus:

The solution of the system of equations

$$\begin{cases} a_{11}x_1 + a_{12}x_2 + \cdots + a_{1n}x_n = c_1 \\ a_{21}x_1 + a_{22}x_2 + \cdots + a_{2n}x_n = c_2 \\ \cdots\cdots\cdots\cdots\cdots\cdots \\ a_{n1}x_1 + a_{n2}x_2 + \cdots + a_{nn}x_n = c_n \end{cases}$$

is given by

$$Dx_1 = C_1, \quad Dx_2 = C_2, \quad \cdots, \quad Dx_n = C_n,$$

where

$$D = \begin{vmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \cdot & \cdot & \cdots & \cdot \\ a_{n1} & a_{n2} & \cdots & a_{nn} \end{vmatrix} \neq 0,$$

and C_k ($k = 1, 2, \cdots, n$) is what D becomes when the elements of its k^{th} column are replaced by $c_1, c_2, \cdots, c_n$ respectively.

The system of equations is inconsistent if the denominator determinant $D = 0$ and if any one or more of the numerator determinants $C_1, C_2, \cdots, C_n$ is $\neq 0$.

If the constant terms $c_1, c_2, \cdots, c_n$ of a system of linear equations are all zero, the equations are called homogeneous. Such a system is therefore of the form

$$\begin{cases} a_{11}x_1 + a_{12}x_2 + \cdots + a_{1n}x_n = 0, \\ a_{21}x_1 + a_{22}x_2 + \cdots + a_{2n}x_n = 0, \\ \cdots\cdots\cdots \\ a_{n1}x_1 + a_{n2}x_2 + \cdots + a_{nn}x_n = 0. \end{cases}$$

If a system of n homogeneous equations in n unknowns has a solution other than the trivial one where each unknown is 0, then the determinant of the coefficients $D = 0$. Conversely, if in such a system the determinant $D = 0$, then the system has infinitely many non-trivial solutions.

In general, a system of n equations with less than n unknowns will have no common solution, except under certain special conditions; a system of n equations with more than n unknowns will have an unlimited number of sets of values of the unknowns satisfying it. (L.L.S.)

LINEAR CORRELATION. If 2 **variables** x and y are connected by a linear relationship $y = a_1x + b_1$ and $x = a_2y + b_2$, then x and y are linearly correlated The two equations connecting x and y are called **regression** lines. These are readily found as $y - \overline{Y} = \frac{r\sigma_y}{\sigma_x}(x - \overline{X})$ and $x - \overline{X} = \frac{r\sigma_x}{\sigma_y}(y - \overline{Y})$ where r is the **coefficient of correlation,** $\overline{X}$, $\overline{Y}$ are the respective **means,** σ_x and σ_y are the respective **standard deviations.** The **standard error of estimate** of y is given by

$$\sigma_e^2 = \frac{\Sigma(y - y')^2}{N}$$

for N observations where y is the actual value, and y' is the value given by the regression line. The values of a_1 and b_1 may also be found by solving the normal equations

$$\Sigma y = a_1 \Sigma x + Nb_1$$

$$\Sigma xy = a_1 \Sigma x^2 + b_1 \Sigma x$$

for a_1 and b_1. This is the method of moments which, in this instance, is the same as the method of **least squares** for evaluating a_1 and b_1. Similarly a_2 and b_2 may be found. We may test a regression line for significance by the **analysis of variance,** and also test whether the regression is linear or curvilinear.

In a **correlation** table, the regression line of y on x, $y = a_1x + b_1$, is the line of best fit in the sense of least squares for the means of the columns, and the regression of x on y, the line of best fit for means of rows. (L.A.A.)

LINEAR DEPENDENCE AND INDEPENDENCE OF FUNCTIONS. If n functions $f_1(x), f_2(x), \cdots, f_n(x)$ are connected by an identical relation of the form

$$c_1f_1(x) + c_2f_2(x) + \cdots + c_nf_n(x) = 0,$$

where the c's are not all 0, the functions are said to be linearly dependent. If no such relation exists, they are called linearly independent.

For example, sin x, cos x and sin $(x + a)$ are linearly dependent; but x, e^x and sin x are linearly independent. (L.L.S.)

LINEAR DIFFERENTIAL EQUATIONS. The ordinary **differential equation**

$$\frac{d^ny}{dx^n} + P_1\frac{d^{n-1}y}{dx^{n-1}} + P_2\frac{d^{n-2}y}{dx^{n-2}} + \cdots + P_{n-1}\frac{dy}{dx} + P_ny = R,$$

in which the coefficients P_1, P_2, $\cdots$, P_n are given **functions** of x which do not depend upon y, and R is a given function of x, is called a linear differential equation of order n.

If $R \equiv 0$ (identically), the equation is called a **homogeneous** linear differential equation, otherwise it is called non-homogeneous.

Fundamental properties of linear differential equations are the following:

If y_1 is a **solution** of a homogeneous differential equation, then cy_1 is also a solution, where c is an arbitrary constant.

If y_1 y_2, $\cdots$, y_n are n **linearly independent** solutions of a homogeneous differential equation of the n^{th} order, then $y = c_1y_1 + c_2y_2 + \cdots + c_ny_n$ is also a solution, and is the **general solution.**

If y_p is a **particular solution** of a non-homogeneous differential equation (without any particular constants of integration), and if y_1, y_2, $\cdots$, y_n are n linearly independent solutions of the corresponding homogeneous equation (of order n), and if c_1, c_2, $\cdots$, c_n are n arbitrary constants, then the general solution of the non-homogeneous equation is $y = y_p + c_1y_1 + c_2y_2 + \cdots + c_ny_n$.

Let us now consider the case of linear differential equations with constant coefficients, i.e., the case where the coefficients P_1, P_2, $\cdots$, P_n are constants.

Denote $\frac{dy}{dx}$ by Dy, $\frac{d^2y}{dx^2}$ by D^2y, etc., so that D denotes the symbolic operator $\frac{d}{dx}$. Then the differential equation can be written in the form

$$(D^n + A_1D^{n-1} + A_2D^{n-2} + \cdots + A_{n-1}D + A_n)y = R,$$

where the A's are constants and R is a function of x. The expression in the parentheses may be considered as a symbolic polynomial in D, and denoted by $f(D)$ where f denotes a polynomial function. The non-homogeneous equation is then $f(D)y = R$, and the corresponding homogeneous equation is $f(D)y = 0$.

According to one of the fundamental theorems stated above, the solution of a non-homogeneous equation depends on the general solution of the corresponding homogeneous equation; so we consider first the homogeneous equation.

For a given homogeneous equation $f(D)y = 0$, the **function** $y = e^{mx}$ will be a solution of the equation if m satisfies the **polynomial equation** $f(m) = 0$, which is called the characteristic equation or auxiliary algebraic equation.

Let m_1, m_2, $\cdots$, m_n be the roots of this equation $f(m) = 0$ (assuming the differential equation to be of the n^{th} order). Then there are three cases to consider.

(1) If the roots m, m_2, $\cdots$, m_n are real and distinct, the general solution of the differential equation is

$$y = c_1e^{m_1x} + c_2e^{m_2x} + \cdots + c_ne^{m_nx}.$$

(2) If two or more of the roots m_1, $\cdots$, m_n are equal, the solution in (1) must be modified: if r of the roots are equal to a, the group of corresponding terms in (1) is to be replaced by

$$e^{ax}(c_0 + c_1x + c_2x^2 + \cdots + c_{r-1}x^{r-1}).$$

(3) If **complex** values occur among the roots m_1, $\cdots$, m_n, the solution in (1) may be put in a more convenient form, by use of **Euler's theorem,** as follows: corresponding to a pair of conjugate complex roots $\alpha + i\beta$ and $\alpha - i\beta$, the solution will contain the terms

$$e^{\alpha x}(A \cos \beta x + B \sin \beta x),$$

where A and B are arbitrary constants; this can also be written

$$A' \cdot e^{\alpha x} \cos (\beta x + B'),$$

where A' and B' are arbitrary constants.

Let us now consider the non-homogeneous linear differential equation with constant coefficients.

The general solution of a homogeneous equation $f(D)y = 0$ is called the complementary function of the corresponding non-homogeneous equation $f(D)y = R$; we shall denote it by y_c. Then if y_p denotes any particular solution of $f(D)y = R$, the general solution of the non-homogeneous equation will be $y = y_c + y_p$.

To find the particular solution y_p, various methods are available; we shall mention only a few.

1. Method of undetermined coefficients: In this method we assume a form which the particular solution will take, using undetermined coefficients, which are then determined by substitution in the differential equation. For the most common cases, we take the following assumed forms:

a. If R is a polynomial in x, say

$$R = a_0x^n + a_1x^{n-1} + \cdots + a_n,$$

assume, in general,

$$y_p = A_0x^n + A_1x^{n-1} + \cdots + A_n,$$

where A_0, A_1, $\cdots$, A_n are undetermined coefficients; but if D^m is a factor (of highest degree) of $f(D)$, then assume

$$y_p = x^m(A_0x^n + A_1x^{n-1} + \cdots + A_n).$$

b. If $R = ce^{ax}$, assume, in general,

$$y_p = Ae^{ax},$$

where A is an undetermined constant; but if $(D - a)^m$ is a factor of $f(D)$, assume

$$y_p = x^m \cdot Ae^{ax}.$$

c. If $R = c_1 \sin ax$ or $c_2 \cos ax$ or $c_1 \sin ax + c_2 \cos ax$, assume, in general,

$$y_p = A \sin ax + B \cos ax,$$

where A and B are undetermined constants; but if $(D^2 + a^2)^m$ is a factor of $f(D)$, assume

$$y_p = x^m(A \cos ax + B \sin ax).$$

d. If $R = e^{ax}\phi(x)$, where $\phi(x)$ is a function of the type in *a* or *c*, put $y = e^{ax} \cdot z$, divide out e^{ax} and we obtain an equation of the type in *a* or *c*.

2. Short-cut rules:

a. If $R = e^{ax}$, then $y_p = \frac{1}{f(a)} e^{ax}$.

b. If $R = \sin ax$ (or $\cos ax$), then

$$\frac{1}{f(D^2)} = \frac{1}{f(-a^2)} \cdot \sin ax \text{ (or } \cos ax).$$

3. Method of successive differentiation of the given differential equation: Differentiate successively the given equation and obtain, either directly or by elimination, a homogeneous linear differential equation (with right-hand member 0). Solve this homogeneous equation for its general solution, which will consist of the complementary function y_c of the original equation plus additional terms involving constants of integration. Substitute these additional terms in the original differential equation, equate coefficients of like terms and determine the coefficients.

4. A factoring method: If $f(D)$ can be factored into linear factors $(D - m_1)$ $(D - m_2)$ $\cdots$ $(D - m_n)$, we may

reduce the given differential equation to a system of n first order linear equations thus: For definiteness, suppose $n = 3$, so that $f(D) = (D - m_1)\ (D - m_2)\ (D - m_3)$. Put

$$(D - m_1)y = u, \quad (D - m_2)u = v, \quad (D - m_3)v = R.$$

We may solve these first order linear equations successively, starting with the last, and finally obtain y as a function of x.

There are also other methods, such as the method of variation of parameters, a method based on a decomposition of $1/f(D)$ into partial fractions, etc., which cannot be described here.

The solutions of a few important special forms of linear differential equations (with constant coefficients) are listed here:

1. The equation $\dfrac{d^2x}{dt^2} - k^2x = 0$ has the solution:

$$x = c_1e^{kt} + c_2e^{-kt}.$$

2. The equation $\dfrac{d^2x}{dt^2} + k^2x = 0$ has the solution:

$$x = c_1 \cos kt + c_2 \sin kt = A \cos (kt + \alpha) = B \sin (kt + \beta).$$

3. The equation $\dfrac{d^2x}{dt^2} + k^2x = a$ has the solution:

$$x = c_1 \cos kt + c_2 \sin kt + \frac{a}{k^2} = A \cos (kt + \alpha) + \frac{a}{k^2}$$
$$= B \sin (kt + \beta) + \frac{a}{k^2}.$$

4. The equation $\dfrac{d^2x}{dt^2} + k^2x = a \cos nt + b \sin nt \ (n \neq k)$ has the solution:

$$x = c_1 \cos kt + c_2 \sin kt + \frac{1}{k^2 - n^2} (a \cos nt + b \sin nt).$$

5. The equation $\dfrac{d^2x}{dt^2} + k^2x = a \cos kt + b \sin kt$ has the solution:

$$x = c_1 \cos kt + c_2 \sin kt + \frac{1}{2k} \cdot t(a \sin kt - b \cos kt).$$

6. The equation $\dfrac{d^2x}{dt^2} + 2l\dfrac{dx}{dt} + k^2x = 0$ has the solution:

(a) if $l^2 = k^2$: $x = e^{-lt}(c_1 + c_2t)$,

(b) if $l^2 > k^2$: $x = e^{-lt}[c_1e^{\sqrt{l^2-k^2}\cdot t} + c_2e^{-\sqrt{l^2-k^2}\cdot t}]$,

(c) if $l^2 > k^2$: $x = e^{-lt}[c_1 \cos \sqrt{k^2 - l^2}\cdot t + c_2 \sin \sqrt{k^2 - l^2}\cdot t]$

or

$$x = Ae^{-lt} \cos (\sqrt{k^2 - l^2}\cdot t + \alpha)$$
$$= Be^{-lt} \sin (\sqrt{k^2 - l^2}\cdot t + \beta).$$

A linear differential equation of the type

$$x^n \frac{d^ny}{dx^n} + A_1x^{n-1} \frac{d^{n-1}y}{dx^{n-1}} + \cdots + A_{n-1}x \frac{dy}{dx} + A_ny = R,$$

where the A's are constants and R is a function of x, may be reduced to a linear differential equation with constant coefficients by the substitution $x = e^z$ or $z = \log x$. Such an equation is sometimes called a homogeneous linear equation, although this conflicts with another use of the term.

Differential equations may occur in systems of linear differential equations in several unknown functions. The general method for solving such equations is to combine the equations so as to give an equation in one unknown function, i.e., eliminate all but one unknown function from the equations, and then use the previous methods. (L.L.S.)

LINEAR DIFFERENTIAL EQUATION OF FIRST ORDER. **Ordinary Differential Equations of First Order and First Degree.**

LINEAR FUNCTION. A linear function is a **polynomial function** of the first degree, and is therefore a **function** of the form $ax + b$, where a and b are **constants** and x is the **variable.**

The **graphic representation** in **rectangular coordinates** of any linear function $y = ax + b$ is a **straight line** with **slope** a and cutting off on the Y-axis an intercept b. (L.L.S.)

LINEAR TRANSFORMATION. A linear (homogeneous) transformation of a set of variables x_1, x_2, $\cdots$, x_n is given by a system of n **linear equations**

$$\begin{cases} a_{11}x_1 + a_{12}x_2 + \cdots + a_{1n}x_n = y_1, \\ a_{21}x_1 + a_{22}x_2 + \cdots + a_{2n}x_n = y_2, \\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot\ \cdot \\ a_{n1}x_1 + a_{n2}x_2 + \cdots + a_{nn}x_n = y_n \end{cases}$$

with given coefficients a_{ij}. (L.L.S.)

LINEAR VECTOR FUNCTION. A linear vector function is a type form of mathematical expression which finds its principal application in certain parts of mathematical physics.

Let **v** be a **vector variable** expressed in terms of a system of non-coplanar vectors $\mathbf{a}_1$, $\mathbf{a}_2$, $\mathbf{a}_3$ by $\mathbf{v} = v_1\mathbf{a}_1 + v_1\mathbf{a}_2 + v_3\mathbf{a}_3$. Then if

$$\mathbf{f} \equiv f(\mathbf{v}) = v_1f(\mathbf{a}_1) + v_2f(\mathbf{a}_2) + v_3f(\mathbf{a}_3),$$

and if $f(\mathbf{v})$ is continuous, then $\mathbf{f} \equiv f(\mathbf{v})$ is called a linear vector function.

If $f(\mathbf{v})$ is a linear vector function, then

$$f(k\mathbf{v}) = kf(\mathbf{v}),\ f(\mathbf{u} + \mathbf{v}) = f(\mathbf{u}) + f(\mathbf{v}).$$

(L.L.S.)

LINEN. **Flax.**

LINES OF FORCE. **Fields of Force.**

LINESHAFT. **Shaft.**

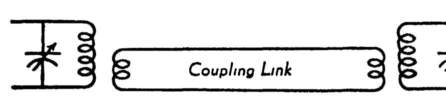
LING. **Burbot.**

LINGUATULIDA. **Pentastomida.**

LINGULA. **Invertebrate Paleontology.**

LININ. **Cell.**

LINK COUPLING. This is a rather common system of inductive coupling used in radio transmitter circuits. The diagram is almost self-explanatory, the primary



Link-coupled tank circuits.

circuit has a coupling winding of a few turns coupled to it, this being connected by a short transmission line to a similar coil inductively coupled to the second circuit. (See also **Coupled Circuits.**) (L.R.Q.)

LINKAGE. **Electromagnetic Induction; Inductance; Coupling; Heredity.**

LINNET. **Finch.**

LINOLEUM. **Flax; Jute.**

LINSANG. Mammalia, Carnivora. *Linsanga.* Slender predacious animals with short legs and very long tails. Related to the civets Several species are Oriental and one African. (A.W.L.)

LINSEED OIL. **Flax; Esters.**

LINTEL. A lintel is a **beam** which carries the wall **load** of a building over an opening such as a window or a doorway. It is supported by the walls on either side of the opening. If these walls extend far enough on both sides of the opening to be able to resist a horizontal thrust, **arch** action can be developed in the wall above the opening. In this case the loading is usually assumed to be triangular with a maximum intensity at the center of the **span.** (C.W.C.)

LION. Mammalia, Carnivora. *Felis leo.* One of the best known species of the **cat** family from its long eminence as the "king of beasts." Like the tiger, the lion reaches a length of 10′ from tip to tip and a weight of 500 lbs. It is uniformly tawny as a rule but varies from much lighter yellowish shades to very dark brown. The male usually has a full mane but this also is a variable character; males with no mane have been found.

Lions are nocturnal in habit and are said to be generally shy, although they will attack man under some conditions. They sometimes hunt in groups, sharing the animals that they kill, and sometimes eat the carcasses of animals that they have not killed, even when badly decomposed.

The lion ranges over all of Africa and into Asia as far as Mesopotamia and northwestern India. Many of the specimens seen in menageries and with circuses were born in captivity. (A.W.L.)

LIP. A fleshy fold at the external orifice of a cavity, especially those which bound the mouth of the vertebrates. (A.W.L.)

LIPARITE. The term liparite is synonymous with **rhyolite,** but used chiefly by European geologists. The word was derived from the Lipari Islands where liparites are quite common. (E.S.C.S.)

LIPOMA. A benign **tumor** made up of fat cells. Lipomas occur commonly in the subcutaneous tissues about the head and neck. They cause no symptoms. (D.M.H.)

LIPPMANN FRINGES. The Lippmann **interference** fringes or laminae constitute an interesting photographic demonstration of stationary waves of **light.** A film of special fine-grained photographic emulsion is backed by mercury, which serves as a reflector. Monochromatic light falling normally upon the film and reflected by the mercury gives rise to interference in stationary waves whose nodes and antinodes are in planes parallel to the reflector. At the antinodes the photographic action is a maximum, while at the nodes there is none. Hence when the film is developed the silver deposits in layers corresponding to the antinodes, ½ wavelength apart. The laminar structure therefore depends upon the color of the light. Neuhauss has succeeded in making photomicrographs of the cross-section of the film, resembling a cut jelly-cake.

The silver layers may be made to act as reflecting planes whose spacing is just right to cause reinforcement by interference when the reflected light is of the same wavelength as that to which the plate was exposed. White light is thus selectively reflected, so that if part of the plate had been exposed to green light, that part would reflect green, etc. Lippmann adapted this principle to the production of photographs in natural colors; but the technique of the process is very difficult and it has not come into practical use. (L.D.W.)

LIQUATION. A process of magnetic differentiation believed to take place as a result of the separation of two immiscible liquids from the parent **magma.** (E.S.C.S.)

LIQUEFACTION OF GASES. Consideration of this subject at once emphasizes a distinction which must be made between gases, in the technical sense of that term, and vapors. Properly speaking, a gas cannot be liquefied at all until it is first reduced to a vapor by lowering its temperature below the critical point. (See **Critical State.**) The problem thus resolves itself into two parts, one of **refrigeration** and one of compression; and further, from a practical standpoint, one of storage.

To liquefy carbon dioxide (as for making carbonated drinks) requires only a compressor and a bath of ice-water to keep the temperature down during compression; and when liquefied, the CO_2 can be stored indefinitely in sealed steel drums capable of withstanding 1200 or 1500 lbs. per sq. in. of pressure. The reason is that the critical temperature of CO_2 is about 31° C. Atmospheric temperature exceeds this amount only in very warm weather. Ammonia (NH_3), with a critical temperature of 132° C., is still easier to liquefy. But nitrogen (and hence **air**) must first be cooled below −147° C. and kept there during the compression, a requirement far beyond the reach of ordinary refrigeration methods.

In 1857 the process of "regenerative cooling," also known as the "cascade" method, was devised by Siemens, to be perfected later by Linde, Hampson, and others. The essential features of this technique are as follows: The gas to be liquefied is first pre-cooled by ordinary means, such as ammonia or "dry ice," or even cold water, then highly compressed while kept cool by removal of the heat of compression. The container is surrounded by a jacket, and the highly compressed gas is released through a small escape valve into this jacket. The escaping gas falls in temperature, both on account of doing external work against the pressure in the jacket and, with most gases, also on account of the **Joule-Thomson** effect. The jacket communicates with the compression pump, and is so designed that the cool gas, to reach the outlet, must circulate around the chamber containing the warmer, high-pressure gas, thus acting as a "heat exchanger." It should be clear that as each unit mass of the gas traverses again and again the cycle composed of compressor, cooling coil, escape valve and jacket, it must become progressively colder; until finally its critical temperature is reached. Further operation now results in the formation of liquid drops, which accumulate in the lower part of the jacketed high-pressure chamber, from which the liquid can be drained off.

Hydrogen and helium are much more difficult to liquefy than other gases, because of their very low critical temperatures (−240° C. and −268° C., respectively), and because in the case of hydrogen the Joule-Thomson effect is a rise instead of a fall of temperature until very low temperatures are reached. Hydrogen must therefore be pre-cooled by evaporating liquid air or otherwise, while helium requires evaporating liquid hydrogen as a pre-cooling agent. Hydrogen was first liquefied by Dewar (1898) and helium by Onnes (1908).

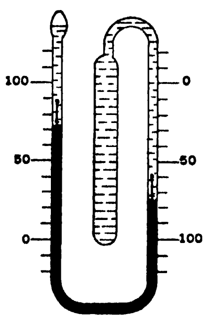
Liquid air, hydrogen, etc., cannot be stored in closed containers, as can ammonia and carbon dioxide, but must be kept at atmospheric pressure in a Dewar flask, or thermos bottle, the low temperature being maintained by the evaporation of the liquid itself, as long as it lasts. (L.D.W.)

LIQUID CRYSTALS. **Cybotaxis.**

LIQUID STRUCTURE. **Cybotaxis.**

LIQUID-EXPANSION THERMOMETER. This familiar instrument for measuring **temperature,** developed by Fahrenheit and others, makes use of the relative expansion of a liquid and its transparent container. The use of mercury as a thermometric substance is recommended by its high boiling point

(+357° C.) and low freezing point (−39° C.), and by the constancy of its expansion coefficient. Alcohol is often substituted, because of its much lower freezing point (−114° C.), and because its expansion coefficient is more than six times that of mercury; it is also lighter and cheaper. Its boiling point, however, is so low (78° C.) that it cannot be used for high temperatures; and it must be stained to be easily visible. In some mercury thermometers an inert gas is introduced above the mercury, the pressure of which, as the mercury expands, raises the boiling point of the mercury and hence increases the range. The Beckmann mercury thermometer has a very large bulb and a very fine bore with a storage reservoir for mercury at the top. It is used only for differential temperature measurements, with a range of only a few degrees, and is graduated to hundredths of a degree.



A maximum-minimum thermometer. (Sixe's form.)

Some thermometers are designed to indicate the maximum or the minimum temperature attained during a given period. The best maximum thermometers employ mercury, with a constriction just above the bulb at which the mercury thread separates when the temperature starts to fall, leaving the top of the column to mark the highest temperature. Minimum thermometers employ alcohol, with a light, solid index or marker just inside the free surface. As the temperature falls, this marker is pushed down by the surface tension, and remains at the lowest point attained. In a thermometer devised by Sixe, both maximum and minimum temperatures are similarly indicated by a small iron marker, which can be adjusted by means of a magnet.

Liquid thermometers are subject to certain inherent errors, among which are those due to the unequal temperature of bulb and stem and to the imperfect recovery of the volume of the bulb after heating. The latter effect may accumulate over a long period, requiring recalibration from time to time, especially if the instrument is used over wide ranges of temperature. (L.D.W.)

LIQUIDS. States of Matter; Hydrostatics; Hydrokinetics.

LIROCONITE. The mineral liroconite is a hydrous **arsenate** of **copper** and **aluminum** of uncertain formula. It is a **monoclinic** mineral usually in very small crystals; hardness 2–2.5; specific gravity 2.9; vitreous luster; color various shades of blue, blue-green and green. It appears to be a secondary mineral associated with other copper compounds as **malachite**. It is found in Czechoslovakia and Cornwall, England. (E.S.C.S.)

LISSAJOUS CURVES. Harmonic Motion.

LISSAJOUS FIGURES. One of the many uses of the cathode ray oscilloscope is its use as a frequency comparison instrument so oscillators may be calibrated or unknown frequencies determined by visual comparison with a known frequency on the tube screen.

When two sine waves, varying about axes at right angles, are combined the resultant figure is no longer a sine wave but varies with the relative time phase of the waves and with their relative frequency. For example, if the waves have the same frequency the resultant is a straight line when they are in time phase (or 180° out of phase) and is an ellipse for all other values of phase position. For equal amplitudes of the original waves and 90° phase the ellipse is the special case of the circle. If the frequencies of the two waves are not the same the resultant becomes more complicated but gives a definite pattern whenever the frequencies are in the ratio of whole numbers to one another. Fig. 1 shows a graphical construction for a frequency ratio of 1:2.

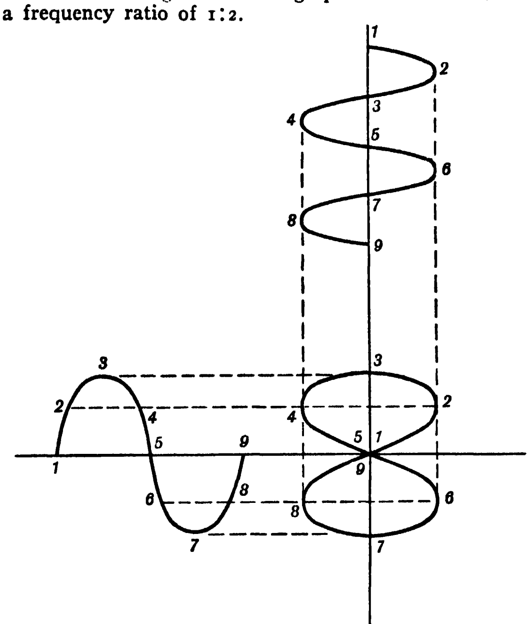


Fig. 1.

If sine waves of voltage are applied to the vertical and horizontal deflecting plates of an oscilloscope tube it does the job of combining them and gives the resultant on the screen. Thus two waves of equal frequency applied to the two sets of plates give an ellipse (the straight line and circle may be considered special cases of the ellipse), two waves with frequencies in the ratio of 1:2 give a figure similar to Fig. 1, and so on. If the frequency ratio of the waves is not a ratio of whole numbers the oscilloscope screen pattern will not be stationary and may even move so rapidly that it appears as a blur. However, whenever two waves whose frequency ratio is that of whole numbers the pattern, which is a Lissajous figure, will appear stationary. The frequency ratio of the applied waves will be equal to the ratio of the number of horizontal to the number of vertical tangencies (if the figure is imagined as inscribed in a rectangle). Thus in Fig. 2, there are two horizontal tangencies and three vertical ones so the frequency ratio of the waves applied to the horizontal and vertical plates is 2:3. The extension of this method to the calibration of an oscillator is obvious, a known frequency is applied to one set of plates and the oscillator output to the other, then as the frequency

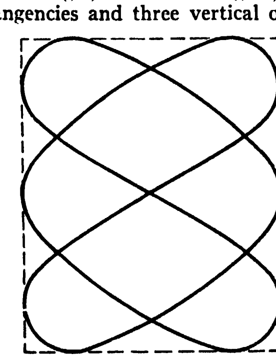

Fig. 2.

of the oscillator is varied a known ratio of frequencies will be obtained each time a stationary figure is obtained. A variation is to use a calibrated variable-frequency oscillator to determine a given unknown frequency by varying the oscillator until its output gives a fixed pattern with the unknown and noting the oscillator frequency from its calibration. (L.R.Q.)

LITCHFIELDITE. A **nephelite syenite** consisting of **albite, nephelite,** and **biotite** with small amounts of **cancrinite** and **sodalite.** It derives its name from the type locality at Litchfield, Maine. (E.S.C.S.)

LITCHI. *Litchi chinensis.* Sapindaceae. The litchi tree is a native of southern China, and has spread extensively in cultivation through many southern Asiatic countries. It has **pinnately** compound leaves, the leaflets of which are **lanceolate** and leathery. The small flowers are borne in **panicles,** and have no petals. The fruit is roughly spherical, 1–1½" in diameter, with a hard brittle rind. Within this rind is a fleshy translucent pulp, the aril, the part which is eaten. When fresh it is most delectable; when dried (the form in which it appears in American markets), it is much shrunken. The fruit contains a single seed. (R.M.W.)

LITER. A metric measure of volume, comparable with the quart. Originally it was identical with the cu. decimeter (1000 cc.). On account of the change in the metric standard of mass and the basis upon which it is fixed, the liter is, however, now defined as the volume of 1 **kilogram** of pure water at its maximum density (4° C.), which is about 1000.028 cc. Volumetric apparatus formerly graduated in cc. is now commonly rated in milliliters. (L.D.W.)

LITHARGE. **Lead.**

LITHIFICATION. **Lithify.** Literally to turn to stone. A term commonly applied to the consolidation and hardening of sediments so as to fôrm a **sedimentary rock.** (R.M.F.)

LITHIUM. Symbol: Li. Atomic number: 3. Atomic weight: 6.940. Density: 0.534 at 20°. Melting point: 186° C. Boiling point > 1200° C. Isotopes 6 (7.9%), 7 (92.1%).

Lithium is a silver-white metal; harder than **sodium** but softer than lead; tough and may be drawn into wire or rolled into sheets; tarnishes rapidly in air, preserved under naphtha; reacts with water forming lithium hydroxide solution and **hydrogen** gas. Discovered by Arfvedson in 1817.

Lithium occurs in **lepidolite** (lithium mica, lithium aluminosilicate, 1%–3% Li) **spodumene** (lithium aluminosilicate, 4% Li), **amblygonite** (lithium aluminum fluorophosphate, 8% Li) in Saxony, France, Manitoba and Quebec, South Dakota, Arizona, New Mexico and California. The lithium-containing mineral is digested with concentrated **hydrochloric acid** and the resulting soluble chloride, after removal of other metals, is converted into slightly soluble **carbonate.** Lithium metal is obtained by **electrolysis** of fused lithium **potassium** chloride mixture out of contact with air. Lithium is used (1) as a deoxidizer and degasifier for nonferrous castings, (2) as vapor for producing a protective atmosphere in furnaces for heat treating of steel.

Chloride: Lithium chloride ($LiCl$), white solid, deliquescent, melting point 614° C., soluble in water and in alcohol.

Hydride: Lithium hydride (LiH), white crystals, by heating lithium metal in hydrogen.

Hydroxide: Lithium hydroxide ($LiOH$), white solid, melting point 450° C., soluble.

Oxide: Lithium oxide (Li_2O), white solid, by heating lithium metal in oxygen or dry air, reactive with water to form soluble lithium hydroxide; lithium peroxide (Li_2O_2), white solid, by reaction of **hydrogen peroxide** and lithium hydroxide solution in alcohol, and later dehydration of the precipitate.

Other soluble salts: Lithium sulfate (Li_2SO_4); lithium nitrate ($LiNO_3$); lithium perchlorate ($LiClO_4$) (soluble in alcohol).

Slightly soluble salts: Lithium carbonate (Li_2CO_3); lithium phosphate (Li_3PO_4); lithium fluoride (LiF).

Lithium carbonate and citrate are used in medicine as "lithia water," a **diuretic** of doubtful value.

Volatile lithium salts, such as the chloride, color the bunsen flame carmine red. (R.K.S.)

LITHOCYST. A small hollow organ containing a solid particle, found at the base of a tentacle on the margin of certain **hydrozoan** medusae. It is also called an otocyst or statocyst. Superficially like the tentaculocysts of jellyfishes but not fundamentally related. (A.W.L.)

LITHOGRAPHIC LIMESTONE. **Jurassic.**

LITHOLOGY. Literally the graphic study of rocks, hence a synonym for **petrography,** but not **petrology.** This term is usually restricted, however, to the purely descriptive macroscopic study of rocks, without the aid of the **petrographic microscope.** (R.M.F.)

LITHOPHYSAE. Lithophysae are concentric shells of crystalline material occurring in **lavas** and are often very fragile. They are usually very small but may reach a diameter of several inches. The term is derived from the Greek words meaning stone, and puff up. (E.S.C.S.)

LITHOPONE. **Pigments, Paints, Varnishes; Barium; Zinc.**

LITHOSPHERE. The term lithosphere, from the Greek meaning a stone, and a sphere, refers to the solid, rocky outer portion of the earth as distinguished from the barysphere, a term also derived from the Greek meaning heavy, and sphere, and designating the unknown interior which is supposed to consist of matter heavier than the surface materials. The true lithosphere, which is formed only of the types of rocks which are now observable to the geologist, is assumed to be only approximately 60 miles thick. A common but inaccurate synonym of lithosphere is "crust."

About 99.5% of the solid outer crust of the earth is made up of eleven elements, combined in various ways, forming mainly **silicates** and **oxides,** and less commonly **carbonates** and **phosphates.** Clarke and Washington (1925) designate as petrogenic or rock-forming elements the following 22 arranged in the table in order of their abundance in the 10-mile crust of igneous and sedimentary rocks. They designate as metallogenic elements **copper, zinc** and all elements of higher atomic weight. (See **Chemical Composition.**)

ELEMENTS IN ORDER OF THEIR ABUNDANCE IN THE 10-MILE CRUST OF IGNEOUS AND SEDIMENTARY ROCKS OF THE EARTH

Element	%	Element	%
1. **Oxygen**	46.71	12. **Carbon**	0.094
2. **Silicon**	27.69	13. **Manganese**	0.090
3. **Aluminum**	8.07	14. **Sulfur**	0.052
4. **Iron**	5.05	15. **Barium**	0.050
5. **Calcium**	3.65	16. **Chlorine**	0.045
6. **Sodium**	2.75	17. **Chromium**	0.035
7. **Potassium**	2.58	18. **Fluorine**	0.029
8. **Magnesium**	2.08	19. **Zirconium**	0.025
9. **Titanium**	0.62	20. **Nickel**	0.019
10. **Hydrogen**	0.14	21. **Strontium**	0.018
11. **Phosphorus**	0.13	22. **Vanadium**	0.016
		Remainder	0.057
	99.47		0.530

Most rocks are, accordingly, silicates or aluminosilicates of five elements, namely, iron, calcium, sodium, potassium, magnesium. Excluding the rare gases, helium, neon, argon, only six of the elements (namely, lithium, beryllium, boron, nitrogen, scandium, cobalt) up to and including nickel (number 28 in the periodic classification) are not contained in the above list. Beyond nickel only three elements (namely, strontium, barium, zirconium) appear.

Among the considerations of particular significance are (1) the high percentage of silicon, (2) the *relatively* high percentage of elements similar to silicon, namely, aluminum (3rd), titanium (9th), zirconium (19th), (3) the unique position of iron (4th) above, but number 26 in the periodic classification, (4) the positions of the alkali metals (sodium 6th, potassium 7th) and alkali earth metals (magnesium 8th, calcium 5th, strontium 22nd, barium 16th), (5) the low percentages of the familiar elements, hydrogen, carbon, nitrogen, sulfur, phosphorus, chlorine, (6) in most cases the even-numbered elements are relatively more abundant than the adjoining odd-numbered elements. Rocks in the 10-mile crust of the Earth:

Igneous rocks, 95% (75% of this is $SiO_2 + Al_2O_3$); shale, 4 (74% of this is $SiO_2 + Al_2O_3$); sandstone, 0.75 (78% of this is SiO_2); limestone, 0.25 (84% of this is $CaCO_3$); total, 100.00 (of the total 60% is SiO_2, and 15% Al_2O_3).

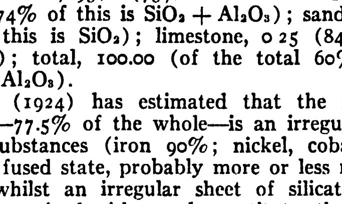
Barnett (1924) has estimated that the interior of the earth—77.5% of the whole—is an irregular core of metallic substances (iron 90%; nickel, cobalt, copper 7%) in a fused state, probably more or less mixed with silicates, whilst an irregular sheet of silicates as slag, more or less mixed with metal, constitutes the remaining 22.5%. (R.K.S., R.M.F.)

LITMUS. Lichens; Indicators.

LIT-PAR-LIT. A term derived from the French, meaning bed by bed, which is used to define banded **gneisses** produced by the injection of igneous material along planes of **foliation**, usually with an accompanying alteration by **contact metamorphism.** (R.M.F.)

LITTORAL. Inhabiting the shore line of the ocean in shallow waters and in the tidal zone which is periodically exposed to the air. (A.W.L.)

LITUUS. The lituus is a spiral curve represented by the equation $r^2\theta = a$ in **polar coordinates.** (L.L.S.)



Lituus.

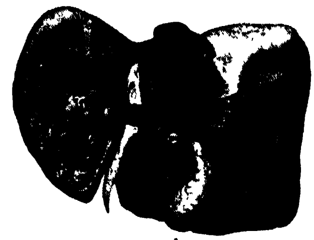
LIVE CENTER. In machine tools, the center which rotates with the work. (See **Dead Center; Lathe.**) (H.C.H.)

LIVE LOAD. Load.

LIVER. A large gland associated with the **digestive system** of vertebrates. It secretes the bile which is discharged into the intestine, absorbs from the blood the products of **carbohydrate** digestion and stores them as glycogen, acts on nitrogenous wastes and returns them to the **blood** in the form of **urea** and related compounds, and destroys worn-out red corpuscles. Other equally important functions are deamination, detoxication, production of fibrinogen and prothrombin and storage of the anti-anemia principle.

The bile discharged through the intestine plays an uncertain role in the digestion of fat and carries with it some of the more complex waste products of the body.

In structure the **vertebrate** liver is very complex. It develops as a hollow outgrowth of the embryonic gut just behind the stomach which forks to produce the gall-bladder and the liver. The connection with the gut persists as the common bile duct. In the adult the liver cells are arranged in cords, separated by blood channels with incomplete lining known as sinusoids. Within the cords minute bile capillaries between the cells converge to larger and larger ducts which ultimately form the main hepatic duct. The gland receives blood from an arterial supply and also from the portal vein. The latter drains blood from the capillaries of the intestine and breaks up into sinusoids in the liver. These small passages are drained by the hepatic vein.



A

Liver. View is from undersurface, showing the gall-bladder (A).

The name liver has also been applied to large digestive glands in the phyla **Mollusca, Arthropoda,** and **Echinodermata.** (A.W.L.)

LIVERWORTS. Bryophytes.

LIZARD. Reptilia, Sauria. Mostly small animals, some species attaining a length of several feet, usually elongate with short legs and a long tail. They are closely related to the snakes but differ in having eyelids and in having the ventral surface of the body as well as the upper covered with small scales.

The classification and nomenclature of these animals is confused. The lizards are sometimes grouped with the snakes but some authorities regard them as a separate order of **Reptilia.** (See also **Fossil Reptiles.**)

There are many species of lizards but with the exception of the poisonous **Gila monster** and the edible **iguanas** they are of no economic importance. A few of the smaller species are eaten to a limited extent.

Among the lizards whose names do not indicate the association with this group are the **geckos, iguanas, swifts, chameleons, chuck-walla, mountain boomer, horned toads, glass snakes, Gila monster, race runner, skinks, agamas, molochs, anolises, basilisks, scheltopusik, blind worms, monitors, teju,** and **amphisbaena.** (A.W.L.)

LLAMA. Mammalia, Artiodactyla. A domestic animal, *Lama huanacus glama,* found in the high altitudes of western South America and on lower ground in the southern part of the continent. It has moderately long legs and a long neck, and is one of the New World representatives of the **camel** family. The animal is a source of wool, hides, meat and milk and is used as a beast of burden.

The name llama is sometimes applied to the entire group including the wild **vicunia** and **guanaco** and the domestic **alpaca** as well as the true llama. Both of the domestic species are supposed to have been derived from the guanaco. The llama is the larger animal but does not produce such fine wool. (A.W.L.)

LLOYD'S MIRROR. Young's Interference Experiment.

L.M.T.D. Log mean temperature difference. An average temperature difference between the hot and cold side of a piece of equipment, e.g., a heat exchanger, for use where the temperature difference may vary along the equipment. Its form is

$$\frac{\Delta T_1 - \Delta T_2}{2.3 \log \dfrac{\Delta T_1}{\Delta T_2}}$$

where ΔT_1 is the temperature difference at one end of the equipment and ΔT_2 is the temperature difference at the other. (D.E.M.)

LOACH. Pisces, Teleostei. Small bottom-feeding fishes (**Pisces**) of Europe and Asia. They have a long slender body and a group of barbels near the mouth. The European species are eaten.

A few fishes of similar form but not closely related are called African loaches. (A.W.L.)

LOAD. Any **force** which is supported by a body is called a load. The forces which in turn support the given body are called reactions. A concentrated load is a theoretical force having a contact area infinitely small compared with the area of the surface of the body upon which the force acts. A distributed load is one whose area of contact covers, wholly or partially, the area of the supporting surface of the body. Distributed loads are uniform if the intensity is the same for each unit of area covered by the load. When this intensity varies, the distributed load is non-uniform.

Loads may be classified as central, torsional or bending, depending upon the effect on the body. A central load is a concentrated load whose line of action passes through the **center of gravity** of the surface under consideration. A distributed load is a central load if the line of action of the **resultant** acts through the center of gravity of the surface. If the central force is at right angles to the surface it is called a direct or axial load. Tensile loads are axial loads which cause an increase in the length of a member. Compressive loads are axial loads which decrease the length of a body. Central forces which act in the plane of the surface under consideration are shearing loads. A torsional load is a force which causes a body such as the **shaft** of a machine to twist about its longitudinal axis. Loads which tend to change the **radius of curvature** of a body are called bending loads. Forces which bend a beam are known as transverse loads. An eccentric load, which is a type of bending load, is a force acting normal to a surface but not passing through the center of gravity of the surface.

A classification of loads which is important to the structural designer, is that which distinguishes between dead and live loads. A permanent load acting on a structure, such as its own weight, is called a dead load. Variable or moving loads are classed as live loads. Snow, wind and merchandise constitute variable loads. Moving loads are made up of the weight of people, vehicular traffic, railroad trains or street cars. The dead weight of traveling **cranes** and their loads must often be considered as live loads when designing the supporting structure.

Structural and machine elements are frequently subjected to moving loads. That part of the total kinetic energy of the moving body which is absorbed by the resisting element itself is known as an energy load. If the moving body and the supports of the resisting element are assumed to be inelastic, all of the kinetic energy is absorbed by the resisting body.

In structural engineering the kinetic energy absorbed by a structural element is usually small because the velocity is relatively low. Consequently it is common practice to use a force which is a certain percentage of the weight of the moving body and assume that its action on the element is equivalent to the dynamic effect. These percentages are obtained from empirical formulae and the equivalent load is called an impact load.

A load which is applied to a machine or structural element many times during the useful life of the element is called a repeated load. The force on a **piston** rod of a steam engine and the live load on bridges are typical examples. (C.W.C., F.T.M.)

LOAD, AIRCRAFT.

Basic Load (Stress Analysis). The load on a structural member or part in any condition of static equilibrium of an airplane. When a specific basic load is meant, the particular condition of equilibrium must be indicated in the context.

Designed Load (Stress Analysis). A specified load below which a structural member or part should not fail. It is the probable maximum applied load multiplied by the factor of safety. Also, in many cases, an appropriate basic load multiplied by a design load factor.

Full Load. Weight empty plus useful load; also called gross weight.

Normal Load (Stress Analysis). The load on that part of a wing assumed to be unaffected by tip losses or similar corrections. In any given case, it may be a basic, design, gross, net, or ultimate load, depending on the context.

Pay Load. That part of the useful load from which revenue is derived, viz., passengers and freight.

Ultimate Load (Stress Analysis). The load that causes destructive failure in a member during a strength test, or the load that, according to computations, should cause destructive failure in the member.

Useful Load. The crew and passengers, oil and fuel, ballast other than emergency, ordnance, and portable equipment. (F.T.M.)

LOAD FACTOR, AERODYNAMIC. The ratio of dynamic to static load on a structure is sometimes referred to as the load factor. Thus load factor becomes an allowance for acceleration and impact. This term is in common use in the field of aeronautics to specify design loads and to report flight-maneuvering loads. The following discussion will relate to this field.

Load factor in aviation is the ratio of the external load, applied or expected to be applied to an airplane, to the design weight. The limit factor describes the load which it is assumed or known may be safely experienced but will not be exceeded in operation. Flight load factors in excess of 1 result from maneuvering, encountering gusts, and experiencing various kinds of ground reactions when landing. Obviously assumptions or predictions of limit load factors are an essential part of airplane stress analysis procedure. Whenever a pilot causes an airplane to travel in a curved flight path, as in a loop, a turn, a zoom, he imposes a load factor in excess of 1 on the airplane. Fighter aircraft must have inbuilt strength to resist exceptionally high acceleration loadings resulting from combat maneuvers. But to build equivalent safety into a commercial airplane in order to safeguard the few pilots who might wish to engage in violent acrobatic maneuvers is a penalty on the speed, economy and pay load which is not warranted by the general conditions of usage. Consequently, government specifications for **airworthiness** require only strength to meet all emergencies of normal reasonable use of the airplane. A placarded maximum diving speed is displayed in the pilot's compartment and the designer has based his structural strength on load factors predicted to arise from encountering gusts, or maneuvering, at speeds not to exceed the placard speed. Thus it would be entirely possible for a foolhardy pilot to damage structurally, or even crash an airplane certified by the government as

being airworthy if he were to dive it to a speed considerably in excess of the placarded, and then do an abrupt pull-up. The **CAA** states that at any speed much greater than about twice the stalling speed, the pilot has it in his power to pull the wings off almost any (civilian) airplane.

Some typical maneuvering load factors are:

60° banked turn	2.0
80° banked turn	5.7
Loop	3.0
Pull-ups	4.0
Spin	2.5
Landing (normal)	2.5

Gust load factors vary between 3 and 4.5 for most commercial designs. (F.T.M.)

LOAD FACTOR, ELECTRIC. The ideal electric load, from the standpoint of equipment needed and operating routine, would be one of constant magnitude and steady duration. Such an ideal load is shown in Fig. 1(a). The cost to produce an elementary area of this load curve (i.e., one kilowatt-hour) could be from ½ to ¾ of that to produce the same unit under the more frequently realized condition illustrated in Fig. 1(b). Hence the problem of variable load is a

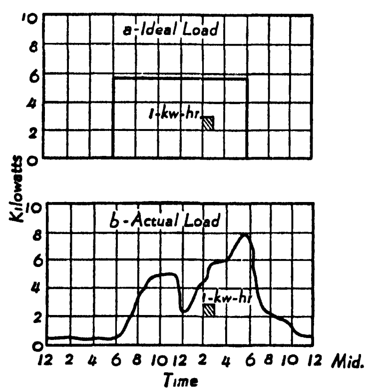


Fig. 1.

vital one, for, from the industrial viewpoint, the cost of manufactured articles includes an energy charge as an element of no inconsiderable proportion, while from the utility viewpoint, the chief concern is to put each kilowatt-hour on the transmission line at as low a production cost as possible.

The general conclusion is that industrial processes and domestic uses impose highly variable demands upon the capacity of a plant. The exceptions do not disprove this as a basic operating condition of most generating equipment. Even though the characteristics of the demand made by any one user will hardly be understood until his conditions of use are fully investigated, one might suppose, for purposes of illustration, that this has been accomplished. Then Fig. 2 might represent the domestic demands of two adjacent residences. There is, apparently, no great similarity between them, nor would one expect a similarity unless he knew the family life of the two sets of occupants to be similar. Furthermore, the next residence might have a still different form of load curve, and so on for still other residences. This is all the result of the natural fact of the individual differences of persons. However, as the number of customers increases, the effect of individual differences is submerged to the general use conditions of the community, and the resulting load curve is typical.

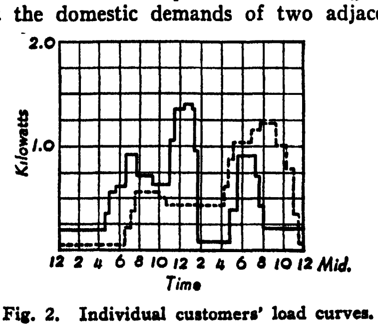

Fig. 2. Individual customers' load curves.

The variable load problem has injected into the language a number of terms. The basic information is the operating data of demanded load plotted against time sequence. This is commonly referred to as a load curve and usually appears with kilowatts as the power unit and hours as the time unit, the sequence being the 24 hours beginning with midnight. The most important variations of this are the monthly and annual load curves, each of which is the average of the daily load curves over the period named.

Some information other than the kilowatt-hour magnitude of energy produced is needed to describe an operating condition. Evidently the relation of the peak load to the average in some measure satisfies this requirement. This relationship is expressed in the load factor. The daily, monthly, or annual load factor is the average load over the time specified divided by the maximum peak. The latter is seldom taken as the maximum instantaneous peak but rather as the maximum 15-minute, half-hour, or even hour-long peak. In general, the length of time over which the peak load shall be measured is increased as the period of time in which it might occur is increased from the daily to the monthly or the annual period. Load factor should not be confused with power factor, with which it has nothing in common. (F.T.M.)

LOAD LINE. This is the graph of current against voltage of the load in the plate circuit of a **vacuum tube** and is superposed on the plate characteristic of the vacuum tube. Fig. 1 shows a typical family of plate characteristic curves with a load line plotted on them.

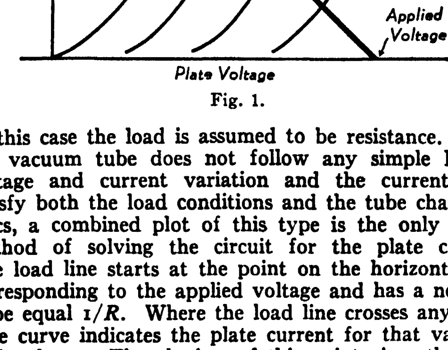

Fig. 1.

In this case the load is assumed to be resistance. Since the vacuum tube does not follow any simple law of voltage and current variation and the current must satisfy both the load conditions and the tube characteristics, a combined plot of this type is the only simple method of solving the circuit for the plate current. The load line starts at the point on the horizontal axis corresponding to the applied voltage and has a negative slope equal $1/R$. Where the load line crosses any given tube curve indicates the plate current for that value of grid voltage. The abscissa of this point gives the drop across the tube and the applied voltage minus this value gives the load voltage. By assuming various values of grid voltage a complete picture of the plate current for any assumed variation of grid voltage may be obtained. Other types of loads may be handled in a similar man-

ner, the load line representing the current-voltage characteristic of the load. (L.R.Q.)

LOADING. **Telephony.**

LOADING COILS. **Telephony.**

LOADING POTS. These are the metal tanks in which loading coils are placed for protection from the elements. They are usually mounted on pole-supported racks and have the cables entering through weatherproof seals. (See **Telephony.**) (L.R.Q.)

LOADING, WING. **Performance Parameter; Airplane.**

LOAM. **Soil.**

LOBATA. **Ctenophora.**

LOBECTOMY. Surgical removal of a lobe of a **gland** or **organ**, such as the lung. (R.S.M.)

LOBSTER. Crustacea, Decapoda. A large marine animal (**Decapoda**) resembling the crayfishes in form. The American lobster, *Homarus americanus*, found on the Atlantic Coast from Labrador to North Carolina, attains a length of over 20″ and a weight of almost 30 lbs., but as a result of large numbers being caught for food they are now rarely taken above 1′ long. The Norway lobster, *Nephrops norvegicus*, a smaller species with more slender pinchers, is among the marine species known as crayfishes, as also are the spiny lobsters of the warmer latitudes in both Atlantic and Pacific oceans. The spiny lobsters, *Palinurus vulgaris*, differ conspicuously from the true lobsters in the absence of the large pinchers. Both are important as food.

The American lobster is taken in traps (lobster pots) baited with dead animal matter. The catch has declined from a peak of 100,000,000 lobsters annually to a small fraction of that figure but measures of protection and propagation are expected to aid in restoring partly their former abundance. The similar European lobster has followed the same course. (A.W.L.)

LOCAL ATTRACTION. In surveying, the deviation of a magnetic **compass** needle from the magnetic **meridian** as the result of a local magnetic field is referred to as local attraction. Local attraction may be detected at a station by taking **forward** and **back bearings** of one or both of the adjacent **transit lines.** If these bearings agree there is no local attraction at the station or at the terminal point of the other transit line or lines. (C.W.C.)

LOCATION SURVEY. **Surveying.**

LOCK NUT. **Screw Fastenings.**

LOCKJAW. **Tetanus.**

LOCOMOTION. The process of moving from place to place, a characteristic power of most animals and a lesser distinction between them and the majority of plants.

Locomotion is necessary to animals because their food is organic and in most environments does not reach the animal through external forces. Even the **sessile** animals, which may or may not be capable of some locomotion, often accomplish the same end by bringing food within reach through their own activities.

In the water the weight of the surrounding medium is so great that the animal may float, and the resistance offered to its body is sufficient to be utilized for propulsion. The body is so shaped that resistance is little in the direction of locomotion but great where propulsive effort is expended. Projections from the surface which beat against the water like oars or push or pull by undulating are common organs of locomotion here. They include **cilia** and **flagella** in one-celled and small multicellular forms, specialized jointed appendages of **arthropods**, and fins and flippers of **vertebrates.** Undulation of the body itself is a sufficient means of propulsion in some animals.

Some aquatic forms rest on the bottom and the terrestrial animals are forced to rest on some solid support at least intermittently because the air is too light to float them. In many of these forms the friction of contact with a solid is utilized by the development of movable supporting appendages which are shifted alternately to change the animal's position. This means of locomotion is known as walking. Other animals, notably the worms, creep through the action of muscles in the body wall. The body is progressively elongated and shortened, parts being thrust ahead and then drawn up to the maximum point of advance. In this type of locomotion they are aided by suckers or setae in some cases to grip the supporting surface.

Running may involve no other difference from walking than more rapid movement or it may also involve a change in the order of movement of the appendages and in their position when used, as in the various gaits of a horse. Jumping always differs in that the appendages set farthest back must be powerful enough to project the entire animal through the air. It is highly developed in such insects as the flea beetles and the grasshoppers and in the frogs and kangaroos among the vertebrates. In this class a gallop is no more than a series of leaps.

Locomotion in the terrestrial vertebrates also shows progressive change in the manner of using the appendages. The entire sole of the foot rests on the ground in man and the apes, and they are said to be plantigrade. This posture is well adapted to walking but not to running. Animals that need speed are digitigrade, resting on the tips of the toes. This position adds the length of the feet to that of the legs and permits a longer stride. It also adds the springiness incidental to the greater freedom of the ankle joint. The final expression of this position of the leg appears in the unguligrade (**Ungulata**) hoofed animals where only the hoof comes into contact with the ground. Man is plantigrade in walking and at rest but rises to his toes when he runs.

The locomotion of snakes is a highly specialized creeping process in which the ribs serve as the movable appendages and the grip of the body on the ground is provided by the broad scales of the ventral surface which project backward.

Climbing animals may merely run along branches, aided by sharp claws to provide a secure grip. The sloths, however, have the claws developed as great hooks which suspend them in an inverted position. They walk as well as hang upside down. The primates show the most extreme specialization for a form of locomotion in the trees called brachiation. Their pectoral appendages are arms, adapted for grasping and suspension, and the pelvic appendages are supporting legs. They move by swinging from branch to branch or by shifting from one hold to another, as human beings climb.

Locomotion in the air is a highly specialized process of **flight.** (A.W.L.)

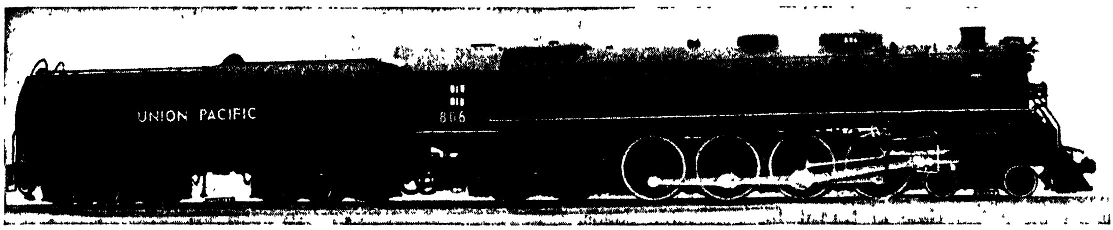
LOCOMOTIVE. The locomotive is a self-propelled vehicle having an excess of power over its own propulsive needs, so that it is enabled to draw a useful load, generally a train of railway cars. While formerly all railway locomotives were steam propelled, one now sees other propulsive media employed in this service, some of which have made large inroads into fields formerly the province of the steam locomotive. Briefly, the types of locomotives encountered at present are: first, steam

driven; second, **electric motor** driven (this reference is principally to the electric locomotive obtaining its power from third rail or elevated trolley. While the storage battery locomotive has a definite place in industrial haulage and switching, it is not suited to line service. Many of the light-weight streamlined passenger trains powered by Diesel engines have electric drive); third, **Diesel,** and other **internal combustion engine** driven locomotives. Due to the high **load factor** and uniform operating conditions of rail locomotives, the Diesel engine is particularly well suited for use where internal combustion drive is employed. There is at present a growing tendency on the part of the railroads, stimulated by public interest, to employ specially built Diesel powered train units for high-speed passenger runs. Other locomotive types are the **steam turbine** and the **compressed air** locomotives; the former, having enjoyed some measure of success in Sweden, is now being tried in the United States. The latter is a common mine type. There is some experimentation with gas turbine propelled locomotives.

The main function of a locomotive is to exert a draw bar pull at the coupler. This it accomplishes by applying a rotative effort to driving wheels which rest on the track. Since the draw bar pull cannot possibly exceed the weight on the drivers multiplied by coefficient of friction between driver and track, it is seen that there is not the same urge for light-weight construction in a locomotive as in the power plant, for example, of the transport airplane. The elements of the locomotive consist, in part, of a frame and running gear, the latter consisting, in part, of a number of wheels called drivers, to which the propulsion is transmitted in the form of a rotation. The reactions developed at the wheel bearing are transmitted through the frame to the coupler. Another element is the source of power. In the common steam locomotive this is an expansion steam engine receiving steam from a **boiler,** and exhausting against atmospheric pressure. By means of a throttle **valve** located on the steam line leading to the engine, and by **valve gear** adjustments, the power developed in the engine cylinder is varied to suit the needs. In the electric locomotive, two or more motors with special windings are so arranged with controllers that their power output may be varied in several steps. They draw their power from a third rail, or overhead trolley. In a Diesel locomotive the engine is built in multicylindered form for smoothness of operation, and in order to obtain a high speed design. The engine is **governor** controlled, and operates at constant speed, driving an **electric generator.** This generator is connected through the control arrangement with the driving motors, which are mounted on the locomotive trucks.

Typical of the Diesel drive are the specifications of a recent twelve-car streamlined train. The total locomotive **horsepower** is 3600, this being divided between four 900-horsepower Diesel engines. These engines are 12 cylinder V-type, two-cycle full Diesels, of 8-in. bore and 10-in. stroke, operating at 750 rpm. The engines are water-cooled, and connected directly to d-c generators.

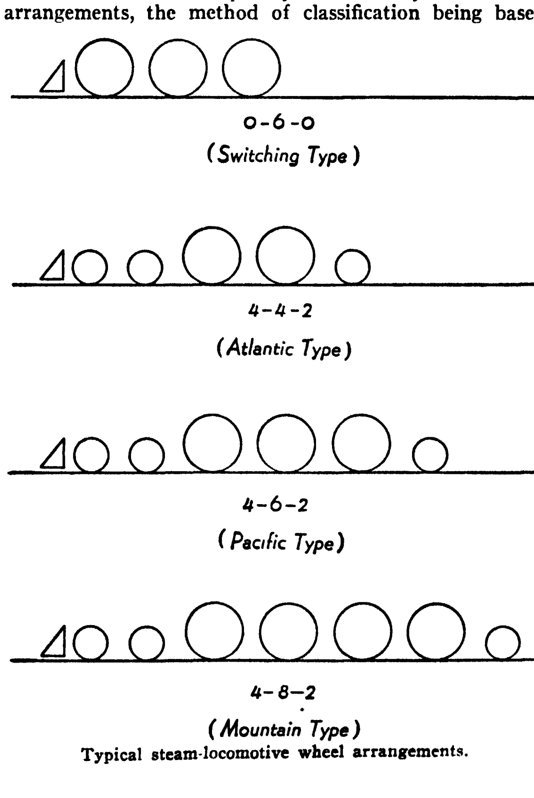
In the steam locomotive, another essential element is the **boiler** in which the steam is raised. Through many years of evolution, the boiler has become standardized on a horizontal fire tube type, with completely water-cooled **furnace.** The furnace end is placed at the rear of the locomotive, and the products of **combustion** pass forward through the tubes to the smoke box, from whence they are discharged upwards to the atmosphere through a short stack. This type of boiler, in large sizes, has tubes of sufficient size so that **superheater** elements may be installed in them, and the use of superheated steam has greatly improved the performance of the steam locomotive. Due to the use of stay-bolt construction to hold the inner and outer shells of the water leg around the furnace, the boiler pressures carried are limited to approximately 250 lbs. per sq. in. The combustion system includes oil firing, hand firing of lump coal on grates, and **stoker** firing of coal. **Draft** is obtained by aspirator action of the exhaust discharging into the stack. As the locomotive is non-condensing in operation, sufficient supply of water for a run must be carried in the tender tank. From the tender tank it is pumped and heated by an **injector,** which is the most common means used to supply feed water to a locomotive boiler.



Locomotive.

The principal structural material of the steam locomotive is steel. There is a great deal of fabrication of plate steel and steel shapes, which are assembled both by welding and riveting. In recent years, the heavier portions, including the frames and cylinders, have been made of steel castings. Wheels are cast iron, cast steel, or wrought steel, and revolve in plain wick-lubricated **bearings,** or, as is the case on many recent locomotives, in roller bearings.

Locomotives are frequently classified by their wheel arrangements, the method of classification being based



Typical steam-locomotive wheel arrangements.

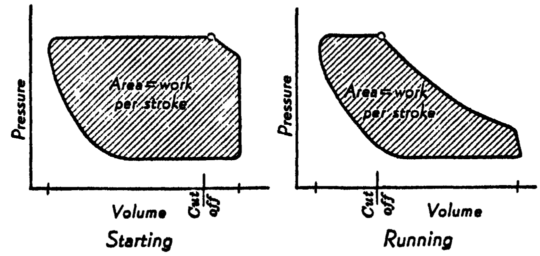
upon the position and number of wheels of the leading truck, the drivers, and the trailing truck. Some typical wheel arrangements, with corresponding classifications, are shown in the accompanying figure. The **cylinders** are mounted with axis longitudinal, and in line with the center line of the drivers. Steam locomotives are two-, three-, or four-cylindered, the most common arrangement being two cylinders. Where three cylinders are used, the third cylinder is mounted under the boiler, and between the other two. Although compound-expansion locomotives have been built, the common locomotive is a single-expansion type. The **connecting rod** which extends from **crosshead** to one of the drivers is enabled to transmit propulsion equally to all drivers by use of the **side rod**, to which the **crank pins** of all drivers are connected. The trailing truck under the cab is frequently fitted with a booster engine, which is used solely to help get a train started, after which it is disconnected. On some locomotives, the booster drives on the leading tender truck.

Typical dimensions of a modern steam freight locomotive are: boiler pressure, 245 lbs. per sq. in.; cylinders, 25-in. bore by 34-in. stroke; total weight, 400,000 lbs.; weight on drivers, 260,000 lbs.; diameter of drivers, 69 in.; draw bar pull, 64,000 lbs.

In both freight and passenger service, train schedules have been stepped up in speed. In freight service, higher speeds mean less time in transit for perishable goods, and savings such as reducing amount of care needed for livestock in transit, reducing amount of ice needed to refrigerate, etc. In passenger service, high-speed trains with modern coaches redirected public attention to the railroads, and have succeeded in reestablishing the latter as a personal transportation medium competing with other modern high-speed systems. As an outgrowth of this trend, several special streamlined locomotives have been built and placed in service. While the first of these were Diesel engine powered, several streamlined steam locomotives have now been built. The beneficial effects of streamlining do not begin until speeds in excess of 50 m.p.h. are made. However, the streamlined trains are given schedules calling for high speeds, speeds which may, on occasion, exceed 100 m.p.h.

The horsepower capacity in the steam locomotive varies from 1200 to 3000 horsepower, and occasionally is somewhat higher. Diesel and steam locomotives must have an equivalent power capacity in order to haul the same trains; however, superior performance has been obtained with Diesel passenger locomotives of lower power when hauling specially built light-weight trains. The **boiler efficiency** of a steam locomotive averages from 40% to 50% under load. While this may seem rather low compared to the performance of stationary steam generating boilers, the conditions of operation of locomotive boilers require a compromise between efficiency and practicability for motive service. The overall efficiency of the steam locomotive is about 4%. The power developed by a steam locomotive varies with the speed, and in this respect the Diesel-electric locomotive enjoys an advantage, since it may be built and operated as a constant power locomotive. The Diesel engine may be run at full rated power at various train speeds. Thus, with a lower maximum power, it may have superior accelerating properties at low speeds. For starting purposes, the **valve gear** of the steam locomotive is set so that the steam is cut off from the cylinders relatively late in the stroke. This gives considerable more **work** available per revolution than when the cut-off is advanced to a more normal and economical point. This is illustrated with the pressure-volume diagram showing conditions in the cylinders at starting and running. The **mean effective pressure** may be made nearly equal to full boiler pressure with very late cut-off; however, this operation is so wasteful of steam that it is employed only for **starting** heavy loads.

The complete locomotive includes, in addition to the elements mentioned above, an enclosed cab containing the principal train and locomotive controls conveniently



Cylinder pressure-volume diagrams for two load conditions.

arranged for operation by the engineman. Shelter and good vision, important qualities which the cab should offer, are apparently more easily obtained in the Diesel and electric designs than in the steam locomotive having a cab at the rear of the boiler. The locomotive must have air brake equipment and control, as well as lighting and various safety devices.

The steam locomotive has been evolved and perfected through approximately a century of mechanical progress. The design has become standardized, with the result that in spite of size, weight, and power, the steam locomotive is relatively cheap at present. With the exception of water-borne carriers, there is no way of transporting goods which costs so little per ton mile carried as the locomotive drawn railway freight. (F.T.M.)

LOCUS OF AN EQUATION. The locus of a point subject to one or more conditions is the set (or totality) of all points satisfying the given condition or conditions.

The locus of an **equation** in two **variables** is the set of all points in a plane whose **coordinates** satisfy the given equation and only such points. Such a locus is in general a **plane curve.**

To simplify the plotting of the graph (or locus) of a given equation:

1. The intercepts on the axes should be found.
2. The symmetry of the locus should be investigated.
3. The extent of the locus should be investigated.
4. The existence of horizontal and vertical **asymptotes** should be investigated.

Suppose a plane locus is given by its equation in **rectangular coordinates.**

To find the X- and Y-intercepts of the locus, put $y = 0$ in the equation and solve for x, and put $x = 0$ and solve for y, respectively.

Two points are said to be symmetrical with respect to an axis if this axis is the perpendicular bisector of the segment joining the given points.

Two points are said to be symmetrical with respect to a center if this center is the mid-point of the segment joining the given points.

A figure or curve is said to be symmetrical with respect to an axis or center if every point on the figure or curve has a symmetrical point (with respect to the axis or center) which also lies on the figure or curve.

To test the equation for symmetry:

If an equation is unaffected by replacing y by $-y$, the locus is symmetric with respect to the X-axis.

If an equation is unaffected by replacing x by $-x$, the locus is symmetric with respect to the Y-axis.

If an equation is unaffected by changing both x and y into $-x$ and $-y$, respectively, the locus is symmetric with respect to the origin.

For an algebraic curve (whose equation is an **algebraic equation** in x and y): the locus is symmetric with respect to the X-axis if no odd powers of y occur in the equation; it is symmetric with respect to the Y-axis if no odd powers of x occur in the equa-

tion; it is symmetric with respect to the origin if every term in the equation is of even degree or is of odd degree.

The extent of a locus is determined by finding the values of one variable for which the corresponding value or values of the other variable are imaginary or complex. Complex coordinates cannot be plotted.

An asymptote of a curve is a straight line which the curve approaches closer and closer so that the distance between the curve and the line may be made as small as we please by going out sufficiently far along the curve.

To find the horizontal and vertical asymptotes of an algebraic curve, solve the equation of the locus for each variable in terms of the other, let the one variable increase beyond all bounds numerically and find the corresponding limiting value of the other.

The locus of an equation in three variables is the set of all points in space whose coordinates satisfy the given equation and only such points. Such a locus is in general a surface.

The locus of two equations in three variables is in general a curve in space. It may be regarded as the intersection curve of the two surfaces represented by the two given equations taken separately.

In the discussion of the equation of a **surface,** we should examine the following items:

The intercepts of the surface on the coordinate axes should be found by putting the coordinates equal to zero in pairs in the equation of the surface and solving for the remaining coordinate.

The traces of the surface on the coordinate planes (intersection curves of the surface with these planes) are found by putting in turn each coordinate equal to zero in the equation; this gives the equations of the curves.

Then the curves of intersection of the surface by planes parallel to the coordinate planes are found by putting each coordinate in turn equal to various constant values.

The symmetry of the surface may be investigated by methods analogous to the case of plane curves. (L.L.S.)

LOCUST. **Grasshopper. Cicada.** The term is more properly applied to the short-horned **grasshoppers.** These include the migratory locusts which sometimes appear in Africa, Asia, and the plains of North America as serious crop pests. (A.W.L.)

LOESS. Loess is a buff-colored, wind-blown deposit of fine silt or marl, usually unstratified, which is often exposed in bluffs with steep to vertical faces. Loess is found in the United States in the Mississippi valley from Louisiana to Iowa, and along the course of the Missouri. The average thickness of the loess here is about 20′, but may range to 50–100′. Loess also occurs in central Europe, Mongolia and China where it is said to attain a thickness as great as 300′. The loess of the United States and Europe is believed to be the finer materials first transported and deposited by the waters of the melting ice sheets of the glacial period, and later blown to considerable distances and sometimes deposited in lakes. The Asiatic loess seems to be wholly wind transported, the source of the dust being, perhaps, the great deserts of central Asia. In the latter case the accumulation of such thick deposits is attributed to the binding power of successive generations of grasses whose former existence is suggested by a network of narrow tubes. (R.M.F.)

LODE. **Ore Body.**

LODESTONE. **Magnetite; Magnetism.**

LOG. In **navigation** the term log is used with two different meanings: a speed-measuring device, and a record book. Prior to the middle of the 19th century the speed of a ship relative to the surface of the water was measured by the log chip and line. "Heaving the log" was a duty that was performed every time the ship's bell was struck, i.e., every half-hour, and the speeds determined were entered in a book, which came to be known as the log book. Since this log book was always available to the watch officer, it became customary to enter all important incidents relating to the operations of the ship, behavior of members of the crew, conditions of the weather and sea, and, in fact, anything that the watch officer might think worthy of recording. This "deck log" was turned over to the Captain and he abstracted all important material and made up the ship's log. At present, practically every department of the ship, deck, engine room, ordnance, steward, etc., keeps its individual rough log and from these the ship's log is made up under the supervision of the Captain.

The oldest and perhaps even now the most accurate and reliable method for determining the speed of a ship relative to the water is by use of the log chip and line. The log chip is a wooden quadrant, loaded along its circular edge so that it will float upright in the water. It is attached to the log line by a 3-legged bridle, the upper leg of which is attached to the apex of the log chip in such a manner that a sharp jerk will free it. Then the log chip may be easily hauled back to the ship. When the log chip is thrown overboard it floats nearly submerged, with the flat surface perpendicular to the motion of the ship, and the line runs out over the stern with the speed at which the ship is moving through the water. For measuring the speed at which the line runs out, a sand glass was originally used. For speeds under 4 **knots** a 28-second glass was employed, and for higher speeds a 14-second glass was available. The line was divided into lengths by threading pieces of fish line through it at specified distances. In the pieces of fish line, 1, 2, 3, etc., knots were tied to indicate the number of lengths that had run out in the given time. The distance between markers was determined by the ratio between 28 seconds to the number of seconds in an hour:

$$\frac{\text{distance}}{6080 \text{ ft.}} = \frac{28 \text{ sec.}}{3600 \text{ sec.}} \quad \text{hence distance} = 47'\ 3.5''.$$

In order that the log chip may be well clear of the turbulence in the wake, a certain amount of stray line is provided, with a red marker indicating the beginning of measurement.

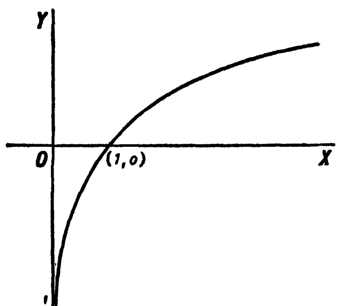
To "heave the log" two men are necessary, one to tend line and the other to operate the sand glass. The first operator throws the chip overboard and gives the word "Tip" when the red marker passes through his fingers. When the last grain of sand runs through the glass the timekeeper calls "check" and the line tender grabs the line. This gives the sudden jerk necessary to free the bridle. He then notes the number of "knots" and approximate fractions thereof that have passed through his fingers and reports that number to the officer of the deck, the number of **knots** being equal to the speed of the ship in **nautical miles** per hour.

The use of the log chip and line gives the instantaneous speed of the ship, and the values obtained over a day must be averaged to obtain the total distance run. Many different types of **patent logs** have been devised to give both speed and distance run. They are all subject to unexpected errors and should be checked frequently by comparison with the log chip and line. On the high-speed ships of the modern navy, the old-fashioned line is impracticable. To check patent logs the number of seconds required for a given length of line to run out is determined by means of a stop watch and the speed calculated. (See **Patent Log** and **Air-speed Meter.**) (W.K.G.)

LOGARITHMIC CHART. A method of representing change by means of a curve drawn on chart paper hav-

ing right-angled, logarithmically spaced coordinates. Semi-logarithmic charts have one rectilinear and one logarithmic scale. Logarithmic scales are often used because many functions and formulae will take a straight-line form on this type of chart, in contrast to a curved form on rectilinear paper. (H.C.H.)

LOGARITHMIC CURVE. Many of the properties of **logarithms** are exhibited graphically by the logarithmic curve. The logarithmic curve, whose equation is $y = \log_e x$, is shown in the accompanying figure. It is



$y = \log_e x.$

the same as the **exponential curve,** whose equation is $y = e^x$, except in different position. It crosses the X-axis at the point (1, 0), is **asymptotic** to the Y-axis as $x \to 0$, and to the right of the point (1, 0) it rises more and more slowly.

The graph of $y = \log_a x$ (for example, $y = \log_{10} x$) is of the same form as the preceding, except of different **slope.** (L.L.S.)

LOGARITHMIC DIFFERENTIATION. Sometimes a **derivative** is found most easily by taking **logarithms** on both sides of the defining functional equation and then differentiating. This is called logarithmic differentiation. (L.L.S.)

LOGARITHMIC EQUATIONS. A logarithmic equation is an **equation** in which the unknown occurs in a **logarithm.** Such an equation may often be solved by using the definition of logarithms to reduce the equation to an **exponential** form. (L.L.S.)

LOGARITHMIC FUNCTION. If x and y are two **variables** related by the **exponential functional** relation $x = B^y$, where $B > 0, \neq 1$, then y is called a logarithmic function of x, and we write $y = \log_B x$. The logarithmic function is a **transcendental function.** It is the **inverse function** to the exponential function. (L.L.S.)

LOGARITHMIC MEAN TEMPERATURE DIFFERENCE. Mean Temperature Difference.

LOGARITHMIC PAPER. Logarithmic paper is paper ruled from scales on the two perpendicular axes, in which at least one of the scales is logarithmic. In semi-logarithmic paper, the one scale is a uniform scale while the other scale is a **logarithmic scale.** In log-log paper, both scales are logarithmic scales. (L.L.S.)

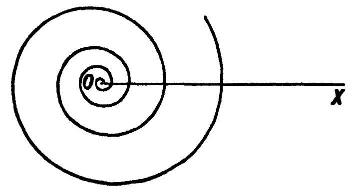
LOGARITHMIC SCALE. A logarithmic scale is one in which the distance from the origin to any scale mark is proportional to the **logarithm** of the number attached to that mark.

Thus, the accompanying figure shows a (common) logarithmic scale with the numbers 1, 2, 3, $\cdots$, 10, $\cdots$ attached to the division marks; if we take OI as the unit of length, then the distances OA, OB, OC, etc., are represented by log 2, log 3, log 4, etc., so that $OI = \log 10 = 1$. In going from left to right, the scale marks will become closer and closer together.

Logarithmic scale.

The logarithmic scale is applied in the **slide-rule** and in **logarithmic paper.** (L.L.S.)

LOGARITHMIC SPIRAL. This is the spiral curve represented by the equation in **polar coordinates:** $r = e^{a\theta}$ or $\log r = a\theta$. It is also sometimes called the



Logarithmic spiral.

equiangular spiral, since it cuts all radii from the origin at a constant angle. (L.L.S.)

LOGARITHMS. Logarithms are **exponents,** relative to a given base. Calculations involving **multiplication, division,** raising to **powers** and extraction of **roots** can usually be carried out more quickly and with less labor by the use of logarithms than by direct arithmetic calculation. Certain **equations** require the use of logarithms for their solution.

The logarithm of a number to a given base is the **exponent** of the **power** of the base which equals the given number; if $N = B^L$, then $L = \log_B N$. The logarithm of a number N to a base B is denoted by $\log_B N$.

For any positive base $B \neq 1$, we have:

$$\log_B 1 = 0, \quad \log_B B = 1.$$

The fundamental laws of logarithms are:

1. The logarithm of a product of two or more positive factors is equal to the sum of the logarithms of the factors:

$$\log (MN) = \log M + \log N.$$

2. The logarithm of the quotient of two positive numbers is equal to the logarithm of the dividend minus the logarithm of the divisor:

$$\log (M/N) = \log M - \log N.$$

3. The logarithm of a power of a positive number is equal to the logarithm of the number multiplied by the exponent of the power:

$$\log M^n = n \log M.$$

4. The logarithm of a real positive root of a positive number is equal to the logarithm of the number divided by the index of the root:

$$\log \sqrt[n]{M} = \frac{1}{n} \log M.$$

Any positive number not equal to 1 can be used as a base of a system of logarithms. However, only two particular numbers are in general use as bases, namely 10 and a number denoted by e.

The system of logarithms which uses 10 as a base is called the common system (or Briggs' system) and logarithms to the base 10 are called common logarithms. This system is especially adapted to the application to numerical calculation and is used principally for such work.

The number e is an **irrational** and **transcendental number** defined by the **infinite series**

$$1 + \frac{1}{1!} + \frac{1}{2!} + \frac{1}{3!} + \cdots,$$

or by the limit

$$\lim_{n \to \infty} \left(1 + \frac{1}{n}\right)^n,$$

and its approximate value is 2.71828.

Logarithms to the base e are called natural logarithms (or sometimes Napierian logarithms, or hyperbolic logarithms). They are particularly adapted to analytical work, but are not of much direct service as a mere aid to computation.

The symbol $\ln N$ is frequently used for natural logarithms instead of $\log_e N$.

General properties of common logarithms are:

A common logarithm in general consists of two parts, an integral part called the characteristic, and a non-integral part, less than 1, usually expressed as a decimal, called the mantissa.

The mantissa of the common logarithm of a number is independent of the position of the decimal point in the number, and depends only on the succession of digits that make up the number.

The characteristic of the common logarithm of a number is independent of the digits that make up the number but depends entirely on the position of the decimal point in the number.

The characteristic of the common logarithm of a given positive number may be found by the following rules:

The characteristic of the common logarithm of any positive number greater than 1 is positive and is 1 less than the number of digits in the integral part of the number. The characteristic of the common logarithm of a positive number less than 1 is negative and is numerically 1 more than the number of ciphers between the decimal point and the first significant figure in the given number.

So-called tables of logarithms contain the mantissas of logarithms of numbers, to a specified number of decimal places. Four-place, five-place, six-place, seven-place, eight-place and even fourteen- or more place tables are published and in use. A graphic table has also been published which has many features to recommend it.

In the use of a table of logarithms, **interpolation** based on a principle of proportional parts is generally required. This principle is: a small change in the number produces a change in its logarithm which is very nearly proportional to the change in the number.

The anti-logarithm of a given logarithm is the number whose logarithm is the given value.

The co-logarithm of a number is the logarithm of the reciprocal of the given number and is equal to minus the logarithm:

$$\text{colog}\, N = \log (1/N) = -\log N.$$

The co-logarithm is frequently used to simplify logarithmic calculation when quotients are involved.

Formulae for change of base of logarithms are the following:

$$\log_b N = \log_a N \cdot \log_b a,$$
$$\log_b a \cdot \log_a b = 1,$$
$$\log_e N = \log_{10} N \cdot \log_e 10,$$
$$\log_{10} N = \log_e N \cdot \log_{10} e,$$
$$\log_e 10 \cdot \log_{10} e = 1,$$
$$\log_{10} e \approx 0.434294, \ \log_e 10 \approx 2.302585,$$
$$\log_e N \approx 2.302585 \log_{10} N,$$
$$\log_{10} N \approx 0.434294 \log_e N.$$

The number $\log_{10} e \approx 0.434294$ is called the modulus of the common system of logarithms with respect to the natural system; and the number $\log_e 10 \approx 2.302585$ is called the modulus of the natural system with respect to the common system.

The calculation of logarithmic tables is usually based on the use of logarithmic series. The basic series is:

$$\log_e (1 + x) = x - \frac{x^2}{2} + \frac{x^3}{3} - \frac{x^4}{4} + \cdots,$$

which is **convergent** when $|x| < 1$, but it is too slowly convergent for practical computational purposes. It can be transformed into the **series**

$$\log_e (N + 1) = \log_e N + 2\left[\frac{1}{2N+1} + \frac{1}{3}\frac{1}{(2N+1)^3} + \frac{1}{5}\frac{1}{(2N+1)^5} + \cdots\right],$$

which is convergent for all values of N. By taking $N = 1, 2, 3, \cdots$ successively, the logarithms of integers can be calculated from this series. It is only necessary to calculate the logarithms of prime numbers in this way, as logarithms of composite numbers can be found by combination of these.

A graphical representation of many of the properties of logarithms is furnished by the **logarithmic curve.** (L.L.S.)

LOGISTIC CURVE. The logistic curve is a growth curve used to describe functions which continually increase, gradually at first, more rapidly in the middle growth period, and slowly again, reaching a maximum at the end of the growth. We write its equation

$$y = \frac{k'}{1 + e^{a+bx}}, \quad b < 0,$$

the symmetrical logistic. A more general form is

$$y = k_1 + \frac{k_2}{1 + e^{a+bx+cx^2}}, \quad c < 0,$$

the asymmetrical or skew logistic. The values of k', k_1, k_2, a, b, and c are found by the method of averaging, the method of **least squares,** the method of selected points, or by a transformation $1/y$ using moments. The logistic curve was discovered by Verhulst and has been applied extensively by Pearl and Reed to the growth of the population of various regions and countries. (L.A.A.)

LOGWOOD. Haematoxylin. *Haematoxylon campechranun.* Leguminosae.

LOIN. The lower or posterior part of the back, near the hips. Usually in the plural. (A.W.L.)

LONGERON. A principal longitudinal member of the framing of an airplane fuselage or nacelle, usually continuous across a number of points of support. (F.T.M.)

LONGITUDE. The longitude of a point on the surface of the earth is the angular distance measured along the earth's **equator** from the **meridian** through Greenwich, England, to the point where the local meridian of the point cuts the equator. Longitude may be expressed either in units of time (hours, minutes and seconds) or angle (degrees, minutes and seconds). It is measured east or west from Greenwich through 12 hours or 180°. For convenience in **navigation,** west longitude is marked plus (+) and east longitude minus (−).

Since **time** is defined as **hour angle,** the difference between Greenwich time and local time must be equal to the local longitude. In case Greenwich time is greater than local time the longitude will be west, if smaller the longitude is east. Both the Greenwich and local time

must be expressed in the same system, i.e., the hour angle of the same object must be considered.

The longitude of a celestial object is the coordinate in the ecliptic system of **spherical coordinates** measured along the ecliptic from the **vernal equinox** in the direction of the sun's annual motion to the great circle through the pole of the ecliptic and the object.

Determination of Terrestrial Longitude. The problem of determination of terrestrial longitude resolves itself into two parts: the determination of local time and the determination of the Greenwich time at the same instant.

The most accurate method for determination of local time is to observe the instant of passage of a star of known right ascension across the local meridian. The **meridian circle** is used for this purpose and is essentially an **altazimuth** instrument accurately fixed in the azimuth of the local meridian. By using a large number of stars with accurately known right ascension it is possible to obtain local time with an accuracy of about one thousandth of a second.

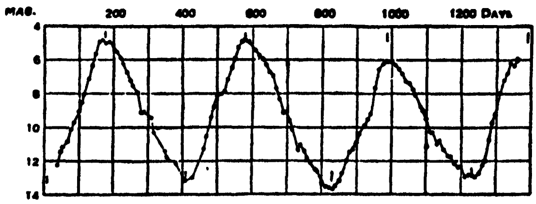
The meridian circle is a fixed instrument and not available for ordinary field work or for navigational purposes. For such purposes several different methods for determining local time are available. The method most commonly employed is to observe the **altitude** of some celestial object of known **declination** either with an **altazimuth** instrument or with a **sextant.** If the **latitude** of the observer is known the **astronomical triangle** is then solved to obtain the hour angle of the observed object. If the object observed is a star the **right ascension** of the star added to the computed hour angle will be the sidereal time at the instant of observation. In case the altitude of the sun has been measured, the computed hour angle will be the local apparent time.

In spite of the fact that methods for measuring the altitude of celestial objects have been known for 2000 years and the solution of the astronomical triangle understood for nearly half that period, it was not until the 18th century that any method for determining Greenwich time at sea was available for the solution of the longitude problem. The first practical method was the employment of the **moon's** motion through the stars as a clock hand. The angular distance of the moon from certain bright stars was tabulated in **Ephemerides** for Greenwich time throughout the year. The measurement of **lunar distance** to find Greenwich time was far from accurate and it was not until late in the 18th century that the perfection of the **chronometer** made it possible for navigators to carry Greenwich time with them. Formerly, the chronometer rate had to be determined while the ship was in port and then the chronometer was treated with great care in order that this rate should remain constant. At present time signals are sent out by radio by observatories of the various nations so that navigators may determine the Greenwich time and hence their chronometer corrections with great accuracy. In fact the errors introduced by measurement of altitude and determination of dead-reckoning latitude, which must be used in the solution of the astronomical triangle, are larger than the errors in the Greenwich time.

Modern navigational methods for determining longitude are discussed elsewhere. (See **Celestial Navigation, Dead Reckoning, Fix, Radio Navigation.**) (W.K.G.)

LONG-JAW. Pisces, Teleostei. One of the freshwater **herrings,** *found in* deep water *in* the Great Lakes. (A.W.L.)

LONG-PERIOD VARIABLES. Examination of the curve appearing in the article on **variable stars,** indicates that there is a considerable group of variables with periods greater than 100 days. This group of objects is known as the long-period variables. More than half of the long-period variables have periods between 250 and 400 days. The accompanying figure (Light curve of the long period variable χ Cygni)



Light curve of the long period variable χ Cygni. *(From observations, during the years 1922 to 1925, by the American Association of Variable Star Observers.)*

shows the **light curve** of a long period variable. Examination of the diagram indicates at once that the characteristics of variation do not repeat themselves exactly from cycle to cycle. This irregularity in the shape of the light curve from cycle to cycle is characteristic of all long-period variables. All of the long-period variables are red stars, most of them being M **spectral class,** with a few in the N, R, and S classes.

There is no adequate explanation for the variability of the long-period variables. The pulsation theory, as discussed for the **Cepheid** variables has many attractive features, but on the basis of this theory we should expect the stars to be hottest when they are of smallest diameter and this is exactly contrary to the observed diameters of **Mira.** The similarity between the forms of the light curves of certain long-period variables and the **sun-spot** curve has frequently been commented upon, and the statement is sometimes made that our sun is a long-period variable with period of about 11 years. However, the period is much longer than any known long-period variable and, furthermore, the sun is a G-type star, so it seems that variability in the sun and in long-period variables must be totally different phenomena. (W.K.G.)

LONG-RANGE FORECASTING. Weather Forecasting.

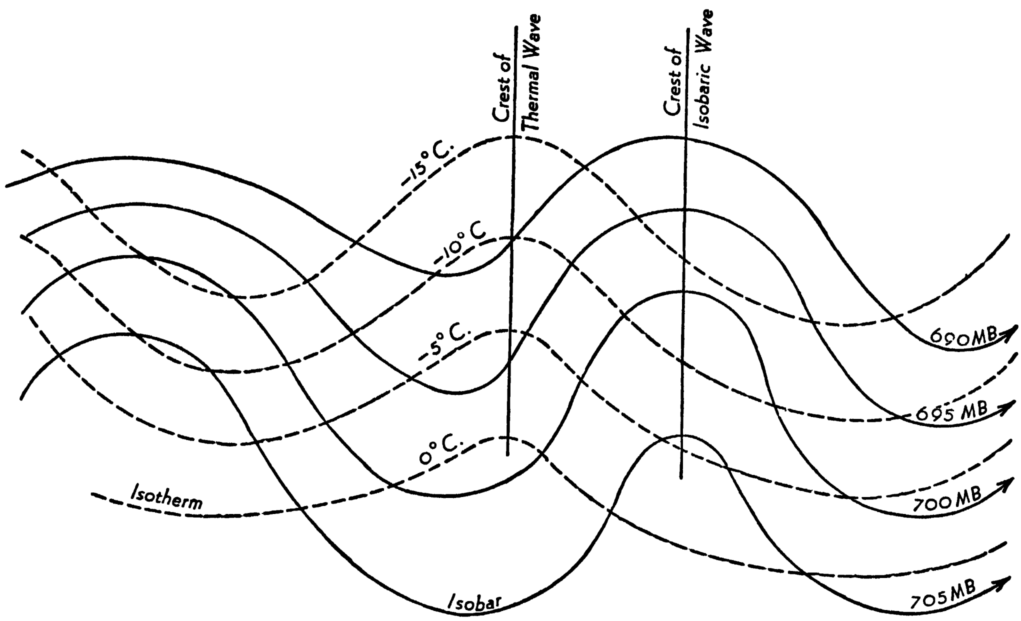
LONG WAVES IN THE PREVAILING WESTERLIES. There develop in the westerlies, particularly during the cold months of the year, certain perturbations which cause the westerlies to blow alternately northward and southward in a sinusoidal wave pattern but always with a component of velocity directed from west to east. Wave crests are associated with anticyclones at ground and near ground levels, whereas troughs are associated with cyclones. There is, therefore, a definite relation between the sinusoidal perturbations of the westerlies and large-scale surface weather phenomena. Progression eastward, or retrogression westward, of the crests and troughs is usually about the same as surface anticyclones and cyclones. Sinusoidal perturbations can, therefore, be used for prognostic purposes computing their velocities. These velocities are given by the formula:

$$C = U - \frac{bL^2}{4\pi^2}$$

in which C = The velocity of the wave.
U = The west to east component of air motion.
L = The wave length of the waves.
b = The rate of change in the coriolis parameter northward.

Wave velocities may be positive, zero, or negative; positive indicating easterly movement, negative, westerly movement.

Isotherms aloft also assume partial or complete sinusoidal form under some conditions. The following rela



Long waves in westerlies.

tions between amplitudes of the thermal and the streamline wave apply:

$$C = U\left(1 - \frac{A_s}{A_t}\right)$$

in which A_s = Streamline amplitude.
A_t = Thermal amplitude.

From this the following conclusions are possible:

1. If the amplitude of the thermal wave is greater than the streamline wave and the two are in phase, cyclones and anticyclones will have a slow eastward component of movement.

2. If the thermal wave is 180° out of phase with the streamline wave, cyclones and anticyclones move eastward rather rapidly. The smaller the amplitude of the thermal wave in relation to the streamline wave, the more rapid will be the movement of surface systems.

3. If the amplitude of the thermal wave is less than the streamline wave and the two are in phase, cyclones and anticyclones will move with a slow westward component (retrograde motion).

4. If the amplitudes of the thermal and streamline waves are the same and the waves are in phase, the surface systems will have no east-west component of movement.

The first two of these conditions are common: the latter two occur but are not usual. (P.E.K.)

LOOMING. **Mirage.**

LOON. Aves, Gaviiformes. *Gavia*. Large birds (**Aves**) with short legs, webbed feet, and strong sharp beak. They are powerful swimmers and divers and are called divers as well as loons. (A.W.L.)

LOOP ANTENNA. A loop antenna, when used with radio transmitters or receivers, possesses valuable directional properties. (See **Directional Antenna.**)

On ships and airplanes, a loop antenna equipped with a **compass card,** whose 000°–180° line is parallel to the longitudinal axis of the ship, may be used to obtain relative **bearings** of radio stations. In using the loop, the position of minimum intensity is sought for. In other words, the indicating needle on the compass card is in a direction perpendicular to the plane of the loop, and the observer rotates the antenna until the position of minimum signal intensity is found. The reading of the dial will then give a **line of position** through the ship and the radio station. With the simple loop there is no method for telling on which side of the instrument the station is located. To overcome this difficulty, the loop antenna is combined with a non-directional antenna as described under **radio compass.** (See **Radio Bearing, Radio Beam, Radio Navigation.**) (W.K.G.)

LOPHOPHORE. A ridge surrounding the mouth or closely related to it in the phyla **Bryozoa, Brachiopoda,** and **Phoronidea.** It bears the tentacles. (A.W.L.)

LOPOLITH. The term proposed by Grout in 1918 for large concordant **lenticular, igneous** intrusives which differ from **laccoliths** in that the center is depressed so that its upper surface, together with the overlying strata, form a basin instead of a dome (R.M.F.)

LORAN. The word loran is derived from the phrase long range navigation and is used to indicate the system of **hyperbolic navigation** which has the longest range of all systems thus far developed. In common with GEE navigation, loran signals are of the pulse type and, in the progress of the developmental research, many different combinations of **radio frequencies** and pulse rates were used. One of the systems developed is known as Standard Loran and has been recommended by the U. S. Coast Guard for use in commercial air and sea **navigation.** Standard loran has a range over water of about 750 nautical miles in daylight and 1400 during the night. The range over land is very much less than this. Since loran is a hyperbolic system, the stations must operate in pairs as "master and slave." The slave station is essentially a relay station. The plans of the Coast Guard provide for a system of about 70 stations which will effectively cover the sea lanes along both coasts of the United States, the **great circle tracks** from this continent to the British Isles and, by using some of the conquered islands in the Pacific, the various important trade routes over that ocean.

Standard loran operates on radio frequencies of 1950, 1850, and 1750 kc. Fourteen recurrence rates, i.e., intervals between signals, are in use on each of the fre-

quencies. The frequency and recurrence rate assigned to each loran pair provide positive identification for the station.

The time systems of the master and slave stations are such that the signal from the master always reaches a ship during the first half of the recurrence cycle, and that from the slave during the second half. This is accomplished by including a delay circuit in the slave timing system that delays the retransmission of the signal received from the master until half the recurrence period has elapsed. See Fig. 1(a) and (b).

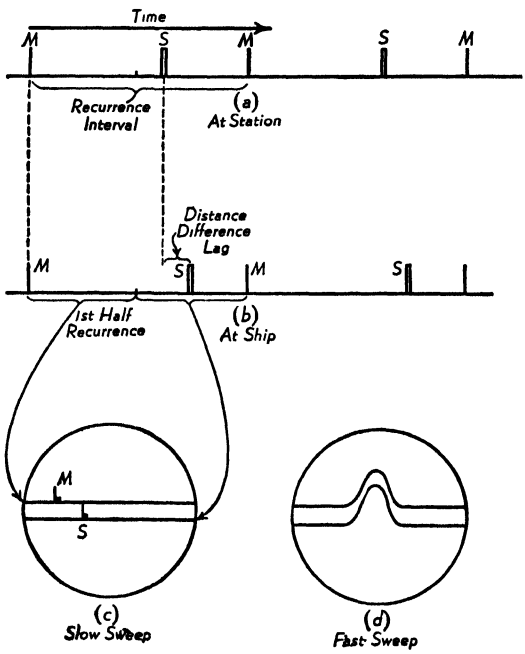


Fig. 1.

Standard receiving equipment has been designed for ships and planes in which both the receiving and timing units are present, with selector switches permitting the operator to set on the frequency and recurrence rate assigned to any loran pair he wishes to use. Differential amplifiers, synchronized by the timing circuit to the recurrence rate of the station, act on both the master and slave signals to deliver them at equal strength to the indicator unit.

The slow sweep of the oscilloscope ("viewing scope") appears as two parallel lines, one covering the first half of the recurrence cycle and the other the second half. Hence the signals received from the master appear on one line and from the slave on the adjacent parallel line. See Fig. 1(c). An adjustment is provided to allow for correction of slight variations in the crystal control of the timing unit and, when this is properly set, the desired signals remain stationary on the scope. The signals from other stations, which may be within range and operating on the same frequency, will drift along the line since their recurrence interval will be different from that of the pair being used.

When the signals are properly "set up" on the scope, a set of time markers is thrown on the screen and a determination is made of the time interval between reception of signals from the master and slave. This will include the delay interval at the slave station, but, since this is standard for each recurrence rate, it may be allowed for. A delay circuit is now introduced and the signals brought into approximate coincidence. With this adjustment made, a fast sweep spreads out the signals so that close coincidence may be established [see Fig. 1(d)] and the time interval measured to within one microsecond.

Using this measured difference in time of arrival of the two signals, the navigator then uses either tables or loran charts to obtain one **line of position.** The selector switches are then set to the characteristics of another loran pair, a second line of position determined, and a **fix** obtained. See Fig. 2. The time required to obtain such a fix is between 2 and 3 min. The accuracy of the

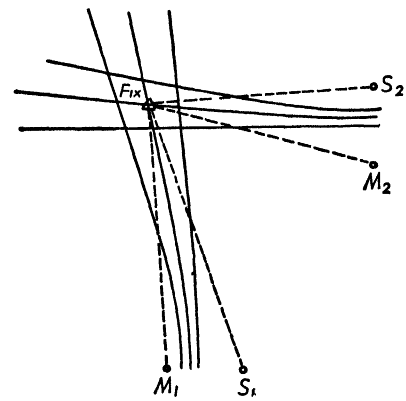

Fig. 2.

determined fix is of the same order of magnitude as that obtained from good **celestial navigation** and, of course, is independent of the state of visibility.

Standard loran may be used for homing purposes in the manner described in the articles on hyperbolic and GEE navigation. Among the many advantages of loran over the various "old-fashioned" systems are the facts that the determined fix is independent of any navigational instruments (such as **compass, chronometer, radio** equipment, etc.) and that the ship can proceed along a loran line with nothing operating other than the loran receiver. Furthermore if anything is wrong with the timing sequence of a particular station the monitors on shore will pick it up and the station will be shut down. This means that any loran fix obtained is good, since nothing will be received if the station is at fault.

It should be realized that loran depends for its effectiveness upon the transmission of **electromagnetic waves.** The characteristics of the waves received may be influenced by a variety of causes between the transmitter and the receiver. Among other troubles is found the interference between ground and sky waves, combined with the fact that the height of the reflecting layer of the sky waves varies.

In the attempt to increase the range of loran beyond that at present attainable with standard, several other systems have been developed with some successes for each. In the so-called SS (Skywave-Synchronized) loran the distance between stations is increased to 1200 or 1300 miles so that the effects of the ground wave are negligible. Several sky waves arrive at the receiver with the equipment designed to bring these into synchronism. Unfortunately there is no way of avoiding the errors introduced by the variability in the height of the reflecting layer. The minimum errors of about nine tenths of a mile occur when the lines cross at right angles and, to bring this condition to certain desired regions of the earth, the stations may be arranged at the corners of a large square, with pairs of stations at the opposite corners of the "SS Quadrilateral." This system was used with some success by the RAF in operations against Germany.

Still another type of loran takes advantage of the long-distance transmission of low-frequency radiation. The pulse lengths must be much longer in this LF loran than in standard, and there is a corresponding decrease

in the accuracy of time difference measurement. However, both the daylight range and the range over land appear to be as great as that for nocturnal conditions with the Standard, and at extreme distances the accuracy of fix determination seems to be nearly as good as the Standard. One great advantage of LF loran is that the waves never penetrate the reflecting layer, and the signal shapes at long distances are much less confused than with the Standard system. (W.K.G.)

LORENTZ-FITZGERALD CONTRACTION. A hypothesis proposed by Fitzgerald and extended by Lorentz to yield an explanation of the negative result of the **Michelson-Morley experiment.** Fitzgerald suggested that when a body moves through space, it experiences a compression or shrinkage in the direction of the motion. Lorentz showed how such an effect might be expected on the basis of the electromagnetic theory

Speed (miles per second)

Graph showing falling off of length with speed. The percentages are of the "static length."

and the electrical constitution of matter. That is, he deduced that when a body moves through space, its dimension parallel to the line of motion should become less by an amount dependent upon its speed. If the speed of the body is v, and that of light is c, then the contraction is in the ratio $\sqrt{1 - \frac{v^2}{c^2}} : 1$. For the earth moving in its orbit (about 18.5 miles per sec.), this contraction amounts to about one part in 200,000,000, which, on the diameter of the earth, would be about 2.5″. Small as this is, it accounts exactly for Michelson and Morley's result by making the source of light and the mirror draw closer together when the system is moving lengthwise. It is the only satisfactory explanation of that result if we regard light as traveling through a stationary **ether.** Viewed from a different angle and expressed in different terms, this hypothesis is now embodied as one of the basic principles of **relativity.** (L.D.W.)

LORICA. A structure enclosing the body in many species of **rotifers.** Formed of thickened integument. Also a shell or test surrounding the body in certain species of **Protozoa.** (A.W.L.)

LORICATA. 1. A group of ciliate (cilia) **protozoans** protected by a test. 2. A group of **rotifers** in which the body is protected by a shell. 3. The **Crocodilia,** a division of the reptiles. 4 A suborder of edentate mammals including the **armadillos** and **pangolins.**

A similar name, Loricati, is used for a group of fishes.

The term is now obsolete, in spite of its former wide application, and is rarely met in modern treatises on classification. (A.W.L.)

LORIQUET. **Parrot.**

LORIS. Mammalia, Primates. Animals of the warmer part of southeastern Asia and the East Indian islands. **Lemurs.** They have large staring eyes and from their very slow movements have also been named slow lemurs. The lorises are forest animals of nocturnal habits. The slender loris is known as *Loris gracilis,* the slow loris is *Nycticebus tardigradus.* (A.W.L.)

LORY. **Parrot.**

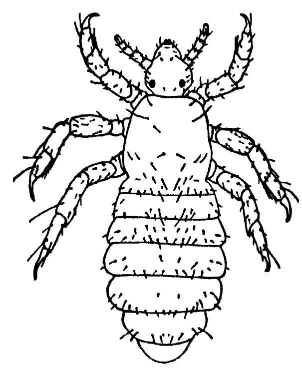
LOSCHMIDT NUMBER. **Avogadro's Law.**

LOTUS. **Water-Lilies.** Nymphaeaceae.

LOUD-SPEAKER. **Speaker.**

LOURI. **Plantain Eater.**

LOUSE. Insecta. An external parasitic insect found on warm-blooded animals, both birds and mammals. Two kinds of lice occur, the bird or biting lice and the



The head louse of man.

true or sucking lice. The former make up the order **Mallophaga** and the latter the order **Anoplura.**

As the names suggest, the bird lice have biting mouth parts and the sucking lice have piercing and sucking mouths. Bird lice eat bits of feathers and hair and cuticular scales while true lice suck blood. The true lice and a few species of bird lice live on mammals.

Three species of true lice, the head louse, *Pediculus humanus capitis,* crab louse, *Phthirus pubis,* and body louse, *Pediculus humanus corporis,* are parasitic on man. Head lice can usually be removed with a fine-toothed comb and the other species yield to mercurial ointments. The body louse is sometimes dangerous as a carrier of typhus fever.

Many other species of lice infest domestic animals and wild species. (A.W.L.)

LOUSE FLY. Insecta, Diptera. True flies specialized to live as external parasites on birds and mammals. They include the **sheep tick** (*Melophagus ovinus*), **bat ticks,** and **bee lice** as well as certain winged species which are recognizable as flies. Found chiefly on owls and other birds of prey. (A.W.L.)

LOVE BIRD. **Parrot.**

LOW. A region over which atmospheric pressure is lower than the surrounding area; i.e, an abbreviation for region of low pressure. Cyclonic winds blow around a low. (P.E.K.)

LOW-REFLECTION FILMS ON GLASS. The problem of troublesome reflections from glass surfaces, such as those from windshields, show windows, clock faces, and lenses, has been recently solved by the superposition of transparent films of suitable material and thickness. The action of these films depends jointly upon two different optical principles.

1. Reflection of light occurs only at an interface between two different media. The ratio of the quantity of the light reflected by any reflector to that of the light incident upon it is called the reflection factor, or the reflectance, of that reflector. In the case of a glass

surface covered with a transparent film, the reflection takes place partly at the outer surface of the film and partly at the interface between film and glass. It may be shown that the total reflectance of such a combination is a minimum when the absolute **refractive index** of the film is equal to the square root of that of the glass. Therefore it is desirable to find a film material which fulfills this condition as nearly as possible and at the same time makes a durable coating adhering firmly to the glass. The materials which at present appear most satisfactory in these respects are calcium fluoride (CaF_2) and lithium fluoride (LiF). Water would be excellent: wet glass reflects very little light (which accounts for the near invisibility of a glass object under clear water); but a water film soon evaporates.

2. All of the above remarks apply, irrespective of the thickness of the film. If now the film be made of a thickness about ¼ of the wavelength of the (normally) incident light, the reflectance is further reduced almost to zero by **interference**. The portions reflected by the film-glass interface and by the outer surface of the film are in such case in opposite phase to each other, and their effect is therefore subtractive instead of additive. A film of thickness 0.0001 mm. (or about 4 millionths of an inch) thus cuts out much of the reflection of light having wavelengths near 0.0004 mm., which includes the most abundant components of visible daylight. And if, further, the film is made of such a material as calcium fluoride or lithium fluoride, the amount of reflection is vastly reduced as compared with that from the untreated glass surface. Details of the chemical methods of applying low-reflection films to glass will be found in numerous technical papers.

It also follows that, since less light is reflected from glass provided with such films, more light is transmitted. This feature has proved of value in the treatment of lenses in optical instruments. (L.D.W.)

LUBBER'S LINE. Compass.

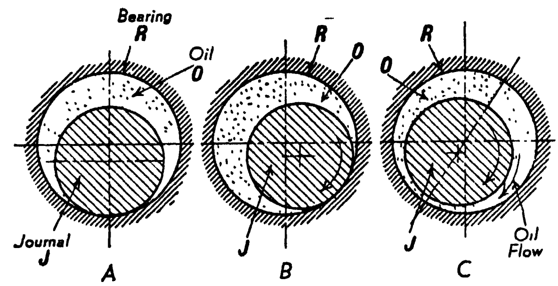
LUBRICATION. Lubricants are employed in engineering practice for two reasons: (1) to diminish friction between the moving surfaces of machine parts; and (2) to decrease friction between a cutting tool and the material to be cut, and at the same time serve to dissipate the heat developed in the machining operation. When the heat-dissipating function is of primary importance, the lubricant is usually referred to as a coolant.

Lubricants may be classified either by state, as liquid, semi-solid, or solid, or by origin as mineral, vegetable, or animal. Animal lubricants are obtained from the fat of common animals and can be classified as hard fats (stearin) and soft fats (lard) or naturally occurring combinations. They can be separated into further subdivisions of hardness and softness. Vegetable lubricants include rape seed oil, sperm oil (whale oil), cottonseed oil, soybean oil, castor oil and linseed oil. They vary in properties from solid to liquid, depending on their origin. Because animal and vegetable lubricants are more complex, chemically speaking, they are also more unstable, and the simpler mineral oil lubricants are usually preferred for machine applications.

Mineral oils are refined from crude oil by separating and purifying the various heavy components of the crude. Some crude oils (Pennsylvania) contain less gum-forming and asphaltic components than do others (Texas). For this reason the methods of treatment vary widely. The various fractions of the crude oil are usually separated by distillation, and undesirable components are removed by special processing such as acid treatment. After refining to obtain improved properties various special chemicals may be added, such as anti-oxidants, anti-gumming compounds and substances to change the "oiliness" characteristic. In the latter class are compounds which tend to concentrate at the surface rather than in the main bulk of the oil so that a small amount of the added constituent may have an effect quite disproportionate to its actual volume.

There are a few special cases where contamination by the oil may be detrimental to a product and the product itself may be used as the lubricant. Such cases include the manufacture of edible oils and some chemicals of an oily nature such as concentrated sulfuric acid (oil of vitriol).

The mechanism of lubrication in a bearing is shown diagrammatically in the figure. At A, the clearance space between the journal and bearing is filled with oil, and the journal rests on the bearing surface in metal-to-metal contact. (The load on the journal acts vertically downward.) As the journal begins to rotate in the direction shown by the arrow, the journal rolls upward to the right, as shown at B. Since oil adheres to the surface, however, the rotation under suitable circumstances builds up a separating oil film between the journal and the bearing, causing the journal to move to the left and take the position shown at C.



If the oil film shown at C separates the journal and bearing surfaces sufficiently so that no metal-to-metal contact (induced by the minute irregularities in the surfaces) can occur, the induced friction in the bearing is dependent largely upon the force necessary to shear the oil film, and thick-film or perfect lubrication is said to prevail. When metal-to-metal contact exists for all or part of the time, thin-film or imperfect lubrication is present, and the character of the contacting surfaces and the nature of the materials used for journal and bearing are important. The latter characteristics are important in thick-film lubricated bearings, however, since metal-to-metal contact may prevail during starting and stopping conditions. Thick-film lubrication is difficult to attain in oscillating or reciprocating bearings, since the oil film is continually undergoing changes in character and size because of the reversal of the contact surface motions.

The coefficient of friction f in thick-film lubricated bearings may be estimated from the following:

$$f = .002 + \frac{473}{10^{10}}\left(\frac{Zn}{p}\right)\left(\frac{D}{c}\right)$$

where Zn/p is the *bearing modulus*, D is the diameter of the journal or bearing in inches, and c is the total clearance in inches, or difference in diameter between the bearing and the journal. This expression is valid for small- and medium-sized bearings, up to about 3 or 4" in diameter, with length-diameter ratios varying from .75 to 2.8. For thin-film lubricated bearings, the coefficient of friction f may be estimated from the following:

$$f = K\sqrt[4]{p/V}$$

where p is the unit pressure on the bearing, in pounds per square inch of projected area (length times diameter), V is the surface velocity of the journal, in feet per minute, and K is a constant, varying from .006 for a well-lubricated, carefully attended bearing, to .045 for reciprocating bearings in unfavorable locations, given

only casual or indifferent maintenance, with a restricted or intermittent supply of lubricant.

Bearings may be lubricated in many ways. Intermittent lubrication is accomplished by using grease or oil and the lubricant is usually applied by an operator or through an oil hole, oil cup, or grease cup. Limited lubrication insures a continuous supply of a limited quantity of the lubricant, and is effected by a drop feed oil cup which permits a constant supply of oil through an adjustable needle valve or by a pad or wick which presses against the journal as it rotates, and which permits the oil to feed by capillary action to the surfaces in contact. Continuous lubrication insures an adequate supply of oil to the bearing surfaces and is effected in numerous ways. Ring- and chain-oiled bearings have a loose ring or chain resting on the journal which brings oil from a reservoir in the bearing housing to the top of the journal as it rotates. In bath lubrication, the journal is partly or wholly submerged in a pool of oil. Splash lubrication is used on reciprocating mechanisms, as in internal combustion engines where the shaft is inclosed and the reciprocating member can dip into a reservoir of oil at each stroke. Pressure lubrication employs a circulating system where the oil is pumped from a reservoir to the bearing and returns by gravity to the reservoir. (See **Hydrocarbons.**) (H.C.H., D.E.M.)

LUDER LINES. **Temper Rolling.**

LUDIO. **Guenon.**

LUDWIG'S ANGINA. **Stomatitis.**

LUES. **Syphilis.**

LUMBAGO. Acute pain in the back due to local infection or **sprain** of the back muscles. (R.S.M.)

LUMBAR PUNCTURE. **Cerebrospinal Fluid.**

LUMBER. Lumber is timber which has been sawed into boards and planks (see also **Wood**). If the logs are cut into quarters, and then sawed across the annual rings, the resulting product is known as quarter-sawed lumber. Boards which are sawed tangential to the annual rings are flat-sawed, and most lumber is so produced. Lumber is known as rough lumber, surfaced lumber, or worked lumber, depending on whether it is rough as it comes from the mill, dressed by a planer, or specially cut to make matched, lapped, or patterned lumber. On the basis of quality, lumber is graded into two main divisions, select and common. The former class is used mainly for special interior trim, and is more expensive than common lumber, since in select lumber the number, size, and type of defects permissible are restricted. There are four grades of select lumber. Grade A must be free from defects; grade B allows a few defects or blemishes; grade C allows that small number of defects and blemishes which may be covered by paint; and grade D allows that number of defects and blemishes which do not detract from the finished appearance. Grades A and B are suitable for natural finishes, and C and D for painted finishes. Grade A lumber is very difficult to obtain. Usually it is wanted in small quantities, which can be obtained by cutting out suitable portions of Grade B lumber. There are few lumber requirements but which may be satisfactorily executed in Grade B lumber, so when one wishes to have the best it is customary to specify, not A, but "B or better." Common lumber is graded as No. 1 common, No. 2 common, etc. The grading and selection of lumber cannot be exact, and hence there can be no definite demarcation between grades. Nos. 1 and 2 common may generally be used for house framing and other purposes with little or no waste, and this only in the extent the defects permit. Most wooden construction is with No. 2 or No. 3 common lumber.

The common unit of measurement of lumber is the board foot, which is the volume of wood in a board 12″ wide, 1′ long, 1″ thick. It is $\frac{1}{12}$ of a cu. ft. However, the purchaser of a board foot will get $\frac{1}{12}$ of a cu. ft. only in rough lumber, since it is customary to charge for finished lumber upon the basis of the rough board which was used. Thus a piece of $1'' \times 8''$ dressed lumber will usually measure about $\frac{7}{8}'' \times 7\frac{1}{4}''$, but if one contracted for 100 such boards, each 10′ long, he would be billed with the board feet in the rough lumber before planing. In the example quoted, the board feet are $100 \times 10 \times \frac{2}{3} = 667$ (1 ft. of 1×8 board has $\frac{2}{3}$ the volume of 1 ft. of 1×12 board). Standard commercial practice in this country is to market lumber in even lengths, as in 6, 8, 10, 12, 14, and 16 ft. Generally the cost per unit is the same for all lengths, but premium may be required for extra long lengths. (F.T.M.)

LUMEN. The internal cavity of a hollow organ. Usually applied only to tubular organs such as the blood vessels. The lumen is also a unit of measurement in photometry, being defined as the quantity of light or luminous flux received upon a unit surface, all points of which are at a unit distance from a concentrated source of one spherical candle intensity. (A.W.L.)

LUMINESCENCE. Broadly this term refers to the emission of light due to any other cause than high temperature. A firefly, for example, illustrates bioluminescence; certain chemical reactions give out light (chemiluminescence); and some electrolytic **rectifiers** are the source of galvanoluminescence. Triboluminescence is observed upon vigorously grinding certain solids, notably ordinary sugar.

A large variety of substances become luminescent when stimulated or "excited" by suitable radiation or by emissions such as cathode or beta rays. This phenomenon is apparently quite complex and is exhibited in various aspects. In some cases the light is emitted only so long as the exciting emission is maintained; it is called fluorescence. The screen of a **fluoroscope** thus responds to x-rays. In other cases the luminescence persists after the excitation is removed and it is then called phosphorescence. Thus zinc sulfide, under certain conditions, glows brightly for a time after exposure to daylight or lamplight, but the luminosity decays rapidly and disappears, usually within a few minutes. Some materials exhibit thermoluminescence; that is, they become luminescent, after exposure to excitation, upon being raised to a sufficiently high temperature. **Resonance radiation** may be regarded as a type of fluorescence in certain gases.

Stokes pointed out that when luminescence is excited by radiation, the frequency of the luminescence is usually less than that of the incident radiation. This is of course always true when visible luminescence is excited by ultra-violet, x-rays, or gamma rays.

Numerous theories regarding luminescence have been proposed, by Lenard, Kowalski, Perrin, Baly, and others. They agree mostly in assuming that the emission of luminescence is due to the removal of electrons from molecules by the energy of the exciting rays and the release of part or all of the energy upon their return. The **quantum theory** of radiation and electronic processes has done much in recent years to clarify certain aspects of the phenomena. (L.D.W.)

LUMINOSITY OF A STAR. The intrinsic brightness of a star may be expressed either in terms of its **absolute magnitude** or in terms of the sun's brightness as unity. The luminosity of a star is defined as its intrinsic brightness in terms of the brightness of the sun as unity. That is to say if our sun were replaced by a

star of luminosity 100 the light received by the earth would be 100 times as great. (W.K.G.)

LUMINOUS EFFICIENCY. **Photometry.**

LUMINOUS INTENSITY. **Photometry; Candle Power.**

LUMMER-BRODHUN SCREEN. **Bench Photometers.**

LUMP SUCKER. Pisces, Teleostei. *Cyclopterus.* Coastal fishes (**Pisces**) of the colder seas of the northern hemisphere. They have an adhesive organ used to attach them to rocks. The body is short and stout. (A.W.L.)

LUNAR DISTANCE. For a determination of terrestrial **longitude** the Greenwich time must be known. Prior to the invention of chronometers and the subsequent development of radio broadcasting of time, the determination of Greenwich time at sea was very complicated. For many centuries it was realized that the position of the **moon** relative to the stars might be considered as a clock hand.

Up to 1912 the American **Ephemeris,** and corresponding publications of other nations, published the distance of the center of the moon from the center of the sun, the four brighter **planets,** and certain bright stars, for every three hours of Greenwich time. Only those objects were used which were within convenient distance of the moon at the given time. All that was necessary for a navigator to determinue his Greenwich time at any instant was to measure with his **sextant** the distance between the bright limb of the moon and a tabulated "lunar distance star." Then, after applying necessary corrections, by interpolation from the tables he could find the Greenwich time corresponding to the instant of observation.

While this problem is fundamentally very simple in theory, in practice the method will not yield very accurate results. In the first place, the published lunar distances were **geocentric** in character and referred to the center of the moon. The problem of correcting the observations for **parallax, refraction,** semi-diameter of the moon, etc. (known as "clearing the observation") was quite complicated and subject to numerous errors. Furthermore, the motions of the moon could not be predicted with accuracy greater than several seconds of arc. Finally, it must be realized that the moon is moving, on the average, with a motion of only about 11″ in 20 sec. of time. Eleven seconds of arc is about the limit of accuracy of a single sextant observation, and hence 20 sec. of time is about the limit of accuracy of a determination of Greenwich time by the method of lunar distance. An error of this magnitude would introduce an error of about 5 miles in a longitude determination for a ship on the **equator.** (W.K.G.)

LUNAR INTERVAL. **Tides.**

LUNG. **Respiratory System.**

LUNG BOOK. A respiratory organ of **spiders** and some other **arachnids.** It consists of many thin plates or leaves in a small chamber on the abdomen which opens by a narrow aperture. Air circulating between these leaves supplies oxygen to the blood inside them. (A.W.L.)

LUNG FISH. A fish with an air bladder opening from the **pharynx** which can be filled with air gulped through the mouth and serving as a lung. Although some members of the other orders are able to breathe air, the term applies specifically to species found only in **Australia** (*Neoceratodus*), Africa (*Protopterus*), and South America (*Lepidosiren*), constituting the order or subclass Dipnoi. The dipnoids live in transient streams and swamps. Some species pass the dry season in cells which they form in the muddy bottom as the water dries up. They resemble the amphibians in some details of structure. (See also **Fossil Fishes.**) (A.W.L.)

LUNULE. 1. A crescentic mark in the pattern of any animal. 2. A depression in front of the umbo on the shell of some **bivalve** mollusks. (A.W.L.)

LUPANINE. **Alkaloids.**

LUSTER. This term is used by mineralogists to describe the appearance of the surface of a mineral, usually a crystal face, in reflected light. The principal types of luster are: metallic, adamantine, vitreous, resinous, greasy, pearly. The degrees of luster may be defined as: splendid, shining, glistening, or dull. Schillerization is a peculiar form of sub-metallic luster observed in different directions in certain minerals such as schiller-spar, **diallage, hypersthene,** etc. (R.M.F.)

LUTECIUM. Symbol: Lu. Atomic number: 71. Atomic weight: 174.99. No isotope, but of single atomic form: 175. Type of compound: Lu_2O_3. Color of salts: Colorless. Discovered by Urbain in 1907. A member of the **yttrium** sub-group of the rare earth metals. (R.K.S.)

LUTH. Reptilia, Testudinata. A large marine **turtle,** *Dermachelys coriacea,* reaching a length of six feet. Its **carapace** is formed of bony plates connected together but not joined to the spinal column or ribs. Also called the leathery turtle. Its flesh is not palatable. (A.W.L.)

LYCOPHORE. A larval form of tapeworm with ten hooks for locomotion. It lodges in **annelids** and **mollusks. Cestoda,** subclass Cestodaria. (A.W.L.)

LYCOPIN. **Pigments in Plants, Aminoacids and Proteins.**

LYCOPODIALES. Club mosses. The order Lycopodiales contains about 500 species, most of which are included in two genera, *Lycopodium* and *Selaginella.* The species of *Lycopodium* are trailing plants often called ground pines, or ground hemlock, as well as club mosses. Many of them are common plants of dry open places in the temperate zone. The plants have long creeping stems growing on the surface of the ground or several inches beneath it. From this prostrate stem short **dichotomously** branched roots extend down into the ground, and erect branches grow upward. The stems are covered with many small, pointed, dark green leaves. In the more primitive species the reproductive structures or **sporangia** are found in the **axils** of ordinary leaves. In other species the sporangia are borne in the axils of modified leaves which are aggregated at the tip of an erect branch, forming a slender cone or strobilus. The many **spores** borne within the sporangia are all alike and for this reason *Lycopodium* species are said to be homosporous. The spores are disseminated by the wind, and in time develop into gametophytes. The **gametophytes** of *Lycopodium* species are extremely small tuberous bodies which grow slowly and reach maturity only if they are invaded by an endophytic **fungus.** Generally the gametophyte or prothallus develops underground. In the upper surface of the prothallus both **antheridia** and **archegonia** are found. Each antheridium contains many straight, biciliate **sperms.** These swim to the egg, with which one unites, forming a **zygote.** From this the new **sporophyte** develops. At first the sporophyte depends on the gametophyte for its food substances. Thus it obtains nutriment by means of a special absorbing structure called a suspensor which grow into the tissue of the gametophyte.

Lycopodium plants are widely used as material from which to make Christmas wreaths. For this purpose the entire plant is often ripped from the ground. The spores of *Lycopodium* are also gathered and sold under the name of Lycopodium powder. Formerly these spores were used in making explosive mixtures and for flash lights.

The genus *Selaginella,* containing some 400 species, is most abundant in the tropics. A few species of small plants are found in temperate regions. In the tropics there are both terrestrial and epiphytic species. The general habit of the plant is much like that of *Lycopodium.* The sporangia are formed in the axils of leaves at the tips of the branches, forming terminal strobili or cones. At the base of the **sporophylls** there is also a small scale, called a ligule, of unknown function. The sporangia are of two kinds, one, a **megasporangium,** containing four large spores, called megaspores; the other a **microsporangium** containing many small spores or microspores. Species of *Selaginella* are therefore heterosporous, a character which distinguishes them from *Lycopodium* species. The microspores, while still within the sporangial wall, start to develop and become multicellular bodies or microgametophytes. In each microgametophyte are formed many biciliate sperms. The megaspore also develops without leaving the sporangium. Its contents divide and form a mass of cells so great that the wall of the megaspore is ruptured. Archegonia are formed in this mass of cells protruding from the cracks in the megaspore wall. The eggs within the archegonia are fertilized by the sperms. At once development begins and a new sporophyte is formed. First formed is the suspensor, a small absorbing organ which pushes into the gametophyte tissue. Stem and roots form later. Often these structures are well developed while still within the sporangium wall. From an evolutionary standpoint this life cycle is very significant. The microspores correspond to the pollen grains in the Spermatophytes. The embryo, surrounded by gametophyte tissue, gives a clue to the possible origin of the seed.

Several species of *Selaginella* are grown in cultivation because of their delicate appearance. Usually they require so much moisture around them that it is difficult to keep them alive in ordinary rooms. One xerophytic species, *Selaginella lepidophylla,* is sometimes seen in cultivation. The plant, a native of the drier regions of America, when dry forms a tight little ball. On receiving sufficient moisture this ball unfolds, forming a flat plant whose much-branched stems spread out on the surface of the ground. Large numbers of these plants are gathered and sold under the name of resurrection plants. (See also **Paleobotany.**) (R.M.W.)

LYCOPSIDA. Lycopsida are **vascular** plants with the following characteristics: The **stele** is a solid cylinder; the leaves are small and spirally arranged on the stem; no breaks, or leaf gaps, occur in the central cylinder; and the **sporangia** are borne on the upper surface of the leaves. Lycopsida are considered the more primitive types of vascular plants. The members of the order Lycopodiales are Lycopsida. (R.M.W.)

LYDITE. Basanite.

LYMPH. A clear fluid which circulates in the tissue spaces of vertebrates and passes into the venous system by way of a tubular **lymphatic system.** It is derived from the liquid plasma of the **blood** but is more watery and contains no red corpuscles. It serves as an intermediary between the blood itself and the **tissues** of the body.

Lymph is found lying free in the serous sac cavities of the body, i.e., the **peritoneum, pleura,** and the spaces in the **brain** filled with **cerebrospinal fluid,** which may also be classified as lymph, although it differs in composition from the fluid found in the lymph vessels.

Lymph is derived from the plasma of the blood either by filtration, diffusion, or **osmosis** through the capillary walls or by active secretion of endothelial cells making up capillary walls. Its composition is very similar to the blood plasma.

The function of lymph is to bring nourishment to the tissue cells and to return waste matter and other toxic material to the blood stream by way of the lymphatic vessels, or directly into the blood stream through the capillary walls. Lymph has been compared with the body fluids of invertebrates, commonly designated as **hydrolymph** and **haemolymph.** (A.W.L., R.S.M.)

LYMPH GLAND, LYMPH NODES. Lymph.

LYMPHATIC SYSTEM. A tubular system supplementing the **blood** vascular system of vertebrates. It collects fluid, chiefly lymph, from the tissue spaces and returns it to the venous circulation.

The smaller tubules of the system resemble **capillaries** and the larger ducts, called lymphatics, are similar to **veins,** although of more delicate structure in relation to their size. Like veins, they have valves which aid in promoting flow through the movements of the surrounding muscles. They are irregular in diameter, forming reservoirs at some points and dilating in the amphibians, reptiles, and birds to form lymph hearts whose pulsations propel the lymph toward the heart. The smaller vessels converge like blood vessels to form larger trunks. In man the chief vessels are the thoracic duct, and the right lymphatic duct, which empty into the large veins at the sides of the neck. Along the course of the lymph vessels are groups of lymph nodes. They serve as filters which localize and retard the spread of toxic and infective elements that are being returned to the blood stream. The lymph nodes also serve as centers for formation of **lymphocytes** which form one of the main divisions of blood cells.

Besides returning to the general circulation waste products from the cells the digestive lymphatics absorb nourishment from the products of **digestion** in the intestine, returning these food products to the blood stream. (A.W.L., R.S.M.)

LYMPHOCYTE. A variety of white **blood** cell or leucocyte which is manufactured by **lymph nodes.** Lymphocytes are classified as large and small and together they make up about 25–30% of the white blood cells under normal conditions. This relationship is disturbed **in** disease. (R.S.M.)

LYMPHOGRANULOMA INGUINALE (Lymphopathia venereum). A specific venereal disease characterized by a transient primary sore followed by **adenitis** of the lymph nodes in the groin, inguinal **buboes, suppuration,** and **fistulae.** The disease is transmitted by sexual intercourse. The etiological agent is a filterable **virus.** (D.M.H.)

LYMPHOSARCOMA. A malignant **tumor** arising in lymph glands, or in an organ which contains lymph tissue. The gastro-intestinal tract, and the spleen, bone marrow, the entire lymphatic system may be involved. The disease is always fatal, but may run a relatively long course. X-ray treatment gives temporary relief. (D.M.H.)

LYNX. Mammalia, Carnivora. Moderately large **cats** of the northern hemisphere, characterized by conspicuous ear tufts and a fringe of long fur about the throat. Among the several North American species most are called wildcats or bobcats, and the Canada lynx, *Lynx canadensis,* alone is known as the lynx. Several species of lynx also occur in Europe and Asia. (A.W.L.)

LYRA. (The harp.) (Map, page 380.) This **constellation,** while small in size, contains a number of most interesting objects for an observer with a telescope, whether the instrument be large or small. The constellation is most easily distinguished by the equilateral triangle with the star **Vega** at one of its apexes.

Vega is an interesting star for a variety of reasons. In the first place, it is the brightest star in the northern celestial hemisphere. It lies almost in the direction in which the **sun** and all of the **planets** are moving due to **solar motion.** At present, this star is a long ways from the pole of rotation of the **celestial sphere,** but, due to **precession** this star will be the pole star about 12,000 years hence.

The star Epsilon Lyrae is one of the most famous multiple stars in the entire sky. A field glass will show this star to be double, and a four-inch telescope on a good night will show that each component is also double.

Several other interesting doubles are to be found in the constellation. Also in this constellation is the famous ring **nebula,** which, while not impressive in a small telescope, is a very interesting object in an instrument larger than a 6″.

In zoology, the term lyra designates a sound-producing or stridulating apparatus of certain **spiders.** It consists of a group of spines projecting over a concavity in the surface to which they are attached. Various other forms of stridulating organs are found associated with the pedipalps and chelicerae of different species of spiders; all consist of structures formed for the production of vibrations. (W.K.G., A.W.L.)

LYRE BIRD. Aves, Passeriformes. *Menura.* A large bird (**Aves**) with an ornamental tail in the male sex which simulates the form of a lyre. The several species are Australian. (A.W.L.)

LYRIDS. The Lyrids are **meteor showers** which are observed about April 20 of each year. The orbit of the **radiant point** was definitely associated with the orbit of **comet** 1861 I. by Weiss. Records of showers from this radiant are found back as far as 687 B.C. The report written by the Chinese in 15 B.C. indicates that during the Lyrids shower of that year "after the middle of the night, stars fell like rain." Several other accounts of striking showers during April are on record, in particular we find many newspaper accounts of the Lyrid shower of 1803, which was observed over the United States from North Carolina to New Hampshire. The Richmond, Va., *Gazette* of April 23, 1803, gives a long and vivid account of the shower occurring on the morning of April 20, stating that "from one until three those starry meteors seemed to fall from every point of the heavens, in such numbers as to resemble a shower of sky rockets."

A few scattered members of this shower are observed coming from the radiant point in the **constellation** of **Lyra** every year, but there has not been any very striking display since 1803. Since there have been striking showers in the past, the assumption is made that there is a large swarm of meteors at some undetermined point along the orbit, and that we may be treated to another brilliant display during some April in the future. (W.K.G.)

LYRIFORM ORGAN. A sensory organ, probably an organ of smell, found in **spiders.** These organs occur on most segments of the legs and on the under surface of the body. They consist of a series of slits and are associated with special nerve endings. (A.W.L.)

LYSINE. Aminoacids, Polypeptides, and Proteins.

LYSIS. 1. The gradual decline of the symptoms of disease, referring especially to the gradual abatement of fever. 2. The dissolution of cells, e.g., bacteria, or red blood cells, changing them from solids to liquids. (D.M.H.)

M

M SERIES. **X-Ray Spectra.**

M TYPE MARKER. **Radio Range.**

MAAR. A volcanic explosion crater without a prominent volcanic cone. (R.M.F.)

MACADAM ROAD. **Highways.**

MACAQUE. Mammalia, Primates. **Monkeys** of several Asiatic and one African species. They are related to the mangabeys but are stouter and have a slightly longer muzzle. The tail varies from long to rudimentary. These monkeys make up the genus *Macacus.* Among the included species are the bonnet monkey, lion-tailed monkey, pig-tailed monkey, and magot. (A.W.L.)

MACARONI. **Wheat.**

MACASSAR OIL. **Fixed oils.**

MACAW. **Parrot.**

MACE. **Nutmeg.** *Myristica fragrans.* Myristicaceae.

MACHINE FORGING. **Forging.**

MACHINE SCREW. **Screw Fastenings.**

MACHINE TOOL. As based upon common usage, a machine tool is any power-driven non-portable machine which is designed primarily for shaping and sizing metal parts, either by chip removal or abrasion, from raw materials such as castings, forgings, bar and tube stock, plates and pressed parts. Machines for producing these raw materials, such as forging machines, rolling mills, or die-casting machines, are not classified as machine tools. Metal-cutting machines such as punches and shears, and metal-bending machinery, are also excluded from the machine tool classification. Several other definitions of the term machine tool are in use by the Department of Commerce and the Treasury Department of the United States Government, which are somewhat broader than the preceding explanation. The most important machine tools are those used for boring, broaching, drilling, gear tooth formation, grinding, hobbing, milling, planing, turning and tapping, and will be described under these heads. (See **Lathes, Turret Lathes,** and **Screw Machines.**) (H.C.H.)

MACHINES. The term machine applies traditionally in physics to any one of those simple devices—lever, inclined plane, etc.—which might with greater propriety be called "elements of mechanism." These elementary machines fall into two general classes, those dependent upon the vector resolution of forces (inclined plane, wedge, screw, toggle joint), and those in which there is an equilibrium of torques (lever, pulley, wheel-and-axle). Their detailed explanation is to be found in any textbook of high school physics. For each of the several types, there is a factor known as the "mechanical advantage," which theoretically represents the ratio of the force exerted by the device to the force acting upon it; though on account of friction and elasticity, the actual ratio of the force may differ somewhat from this theoretical value. For a lever, it is equal to the ratio of the "arms"; for an inclined plane, with the force acting parallel to the plane, it is the cosecant of the angle of inclination; etc. Ordinarily a more practicable measure of the mechanical advantage is the ratio of a small displacement produced by the operator on the machine to the resulting displacement of the load by the machine. Thus, if the handle of an automobile jack is moved 1″, in lifting the car 0.002″, the mechanical advantage is 500.

The principles of **efficiency** (ratio of output energy to input energy) are well illustrated by the action of machines. No mechanism can operate without loss of energy through friction or otherwise; hence the efficiency of a machine is always less than unity. Otherwise, it would be possible to realize **perpetual motion.** (L.D.W.)

MACKEREL. Pisces, Teleostei. Marine fishes **(Pisces)** with compressed spindle-shaped bodies and a widely flaring forked tail. The large family Scombridae which they make up includes the important food fishes of moderate size called **mackerels,** *Scomber scombrus,* and a number of moderate to large game and food fishes. The latter are the **king fish,** sierra or pintado, *Scomberomorus regalis,* **bonitos, albacore,** and tunny, more commonly called the **tuna,** *Thunnus thynnus.* One of the smaller genera, *Pneumatophorus,* is called the thimble eye or chub mackerel. (A.W.L.)

MACKEREL SKY. Both altocumulus and cirrocumulus clouds often appear arranged in uniform bands similar in appearance to a mackerel's back. The reference pertains particularly to altocumulus. (P.E.K.)

MACLAURIN'S FORMULA. **Expansion of Functions in Series.**

MACRODASYOIDEA. **Gastrotricha.**

MACRONUCLEUS. A large nucleus in the bodies of many 1-celled animals, accompanied by one or more small nuclei known as micronuclei. The macronucleus is apparently the controlling center for the ordinary activities of the animal. It develops under certain conditions from a subdivision of the micronucleus. (See **Cell.**) (A.W.L.)

MACROSCOPIC. Derived from the Greek, meaning broad and visual. Used by **petrographers** to describe the features of a rock which are large enough to be seen by the naked eye, hence the antithesis of microscopic. A better synonym is megascopic, from the Greek, meaning large and visual. (R.M.F.)

MACROSTRUCTURE. The internal structure of metals as observed in a ground or polished section with the naked eye or at low magnification. The surface is usually deeply etched to develop flow lines, **dendritic** structure, weld structure, segregation, porosity, **laminations,** laps, seams, and other structural discontinuities.

The macrostructure of castings is characterized by dendrites, while forgings or rolled products generally have flow lines, which are indicative of the plastic deformation which the part underwent during its production. In steel the flow lines result from alignment of non-metallic inclusions as minute stringers in the direction of elongation of the part. The flow lines developed in forgings are useful in checking die design and forging practice. The quality of tool steel and other high-grade bar stock is often checked by etching

cross-sections and examining the macrostructure. (See **Microstructure.**) (R.H.H.)

MACULOSE. A term proposed by Holmes in 1919 to denote a group of spotted **contact-metamorphosed** rocks, including mottled **slates, schists,** and **hornfels,** as distinguished from those exhibiting well-defined **foliated** structure. (R.M.F.)

MAD TOM. Pisces, Teleostei. **Catfishes** of small size belonging to several species of the genus *Schilbeodes.* They occur throughout the Mississippi River system, the Great Lakes region, and the eastern states generally. (A.W.L.)

MADDER FAMILY. Rubiaceae. A family comprising some 4500 species, particularly abundant in tropical regions. Some species are found in temperate regions, and a few in Arctic climates. The family includes trees, shrubs, and herbs having opposite entire or sometimes toothed leaves with **stipules,** the latter often large and conspicuous. The flowers are perfect, regular and **epigynous,** and 4- or 5-parted. Few members of the family are important. Species of *Gardenia,* natives of tropical Old World regions, are frequently grown for their fragrant showy flowers. *Rubia tinctorium,* the madder plant, was formerly a very important source of the dye madder, also called alizarin. Now, however, the dye is prepared synthetically. Gambier, *Uncaria Gambii,* a climbing plant native in tropical Asia and the Oceanic Islands, yields quantities of pyrogallol (see **Phenol**) **tannin,** extracted with boiling water from the leaves and young shoots. This is used in tanning leathers, often mixed with other **tannins.** It is also used as an astringent in medicines.

Ipecac, *Cephaelis Ipecacuanha,* a native of South American tropics, is a shrubby plant, the roots of which are six millimeters thick. From the dried roots and the lower part of the stem the drug ipecac is obtained. Used in small doses, ipecac is a stimulant; in large doses it is an eliminant, causing vomiting, sweating, and elimination through the kidneys and bowels. It is a very efficient means for clearing an overloaded stomach. **Quinine** and **coffee** are two other important products from members of this family. (R.M.W.)

MADREPORITE. A perforated plate on the surface of the body of **echinoderms.** The perforations lead into the water vascular system. (A.W.L.)

MAFIC. Femic.

MAGDALENIAN. Paleontology of Man.

MAGENTA. Dye.

MAGGOT. The soft-bodied **larva** of many species of two-winged **flies.** They are often white but some species are brightly colored. No organs of locomotion are present. Most maggots hatch from the egg in the midst of an abundant food supply of decaying organic matter or living plant or animal tissues and are able to move about sufficiently for their needs by wriggling the body. (A.W.L.)

MAGIC EYE TUBE. Tuning Indicators.

MAGMA. The term for molten material. A natural, complex, liquid, high-temperature, **silicate** solution ancestral to all **igneous rocks,** both intrusive and effusive. The locus of a magma is within the **lithosphere** (crust) under great pressure and an impenetrable cover which helps the magma to retain its original gases and water vapor in solution. The origin of magma is not known but it is generally assumed that separate magma chambers may exist within the lithosphere. (R.M.F.)

MAGMATIC STOPING. A term proposed by **R. A.** Daly in 1906 for a process by which large intrusive rock bodies, such as **batholiths,** might be able to take the space which must have been previously occupied by other rocks. This process assumes that the pre-existing rocks are shattered, or stoped, at the roof of the **magma** chamber and sink to lower levels in the magma, where they are melted and assimilated. The outer margins of the magma are assumed to be kept molten by the aid of 2-phase convection currents as well as by the relatively rapid foundering of the wall rocks and their assimilation in depth. When the magma congeals at the top of the chamber so as to show the angular fragments which have been stoped from the walls of the chamber, these fragments are called **xenoliths.** (R.M.F.)

MAGMATIC WATER. Water and water vapor given off by volcanoes proves that water is an important constituent of all **magmas.** (R.M.F.)

MAGNAFLUX. Magnetic Particle Inspection Test.

MAGNESITE. The mineral magnesite is **carbonate** of **magnesium,** $MgCO_3$. It is a hexagonal mineral, but usually found massive. It has a **rhombohedral** cleavage; conchoidal fracture; brittle; hardness, 3.5–4.5; specific gravity, 3; luster, vitreous to silky; color, white, gray, yellow, or brown; transparent to opaque. Most magnesite is believed to have been derived from the action of carbonated waters upon rocks rich in magnesium. Magnesium-bearing waters, on the other hand, may have in some cases acted upon **calcite** or **dolomite.** Magnesite deposits are known in Greece, Austria, Norway, India, Australia, and South Africa. In the United States magnesite is found in California and Nevada, some of which deposits seem to be of original sedimentary character. Magnesite is in demand for the manufacture of refractories and various compounds of magnesium used in medicine or for other purposes. (E.S.C.S.)

MAGNESIUM. Symbol: Mg. Atomic number: 12. Atomic weight: 24.32. Density: 1.74. Hardness: 2. Melting point: 651° C. Boiling point: 1110° C. Isotopes: 24 (77.4%), 25 (11.5%), 26 (11.1%).

Magnesium is a silver-white metal, malleable and ductile when heated; unattacked by dry **oxygen,** by water or **alkalis** at room temperature; when heated to about 800° C. reacts in air or steam and emits a brilliant white light of high actinic power; reactive with acids including **carbonic** at room temperature; reactive upon heating with **nitrogen, phosphorus, arsenic, sulfur, chlorine,** in some cases with such vigor as to constitute a hazard. Recognized by Black in 1755, and isolated by Davy in 1808.

Magnesium is used in increasing amounts (1) as an alloy with **aluminum** in light, strong construction, e.g., **airplanes,** and also used (2) in photographic flashlight powders, incendiary bombs, signal flares, (3) as a deoxidizer in the casting of metals, (4) as a "getter" in radio tubes, (5) as a reagent in organic chemistry, e.g., **Grignard reaction.**

Magnesium occurs generally in rocks, especially **limestone** (average 8% MgO) and **igneous rocks** (average 3.5% MgO); as the important mineral **dolomite** (magnesium calcium carbonate mixtures), notably in the Alps, and as **magnesite** (magnesium carbonate, $MgCO_3$), obtained commercially in Austria, Greece, Russia, and the states of California and Washington; in ocean water as the metal second in abundance to **sodium** (about 1 part of magnesium to 10 parts of sodium), in salt deposits, lakes, and brines, notably Stassfurt, Germany, and the state of Michigan, mainly as chloride or sulfate; present in natural hard waters of the earth's surface; present in chlorophyll (see **Pyrrole and Related Compounds**). Magnesium metal is obtained by **electrolysis** of fused magnesium chloride.

Acetate: Magnesium acetate ($Mg(C_2H_3O_2)_2 \cdot 4H_2O$), white solid, soluble, formed by reaction of magnesium carbonate and **acetic acid,** and then crystallizing.

Arsenates: Magnesium ammonium arsenate ($MgNH_4AsO_4$), white precipitate, by reaction of soluble magnesium salt solution and **sodium** arsenate in the presence of excess **ammonium** hydroxide, upon igniting yields magnesium pyroarsenate ($Mg_2As_2O_7$), white solid.

Borate: Magnesium borate ($Mg_3(BO_3)_2$ or $Mg(BO_2)_2$), white precipitate, by reaction of soluble magnesium salt solution and **sodium** borate, used as a preservative.

Boride: Magnesium boride (Mg_3B_2), brown solid, by reaction of **boron** oxide and magnesium powder ignited.

Bromide: Magnesium bromide ($MgBr_2 \cdot 6H_2O$), white solid, soluble, formed by reaction of magnesium carbonate and **hydrobromic acid,** and then crystallizing. Is present in many salt brines, and in traces in ocean water, constituting the source of bromine.

Carbonates: Magnesium carbonate, magnesia alba ($MgCO_3$), white solid, insoluble, formed by reaction of soluble magnesium salt solution and **sodium** carbonate or bicarbonate solution. Present in carbonate minerals and rocks, **magnesite** (more or less pure magnesium carbonate), **dolomite** (magnesium calcium carbonate mixtures), dolomitic **limestone.** When ignited yields magnesium oxide and **carbon dioxide;** when treated with acids yields the corresponding magnesium salt and carbon dioxide, but with **carbonic acid** yields soluble magnesium bicarbonate. Used as a heat refractory and insulating material, and as a source of magnesium compounds; magnesium bicarbonate ($Mg(HCO_3)_2$), colorless solution, by reaction of magnesium carbonate and carbonic acid, yields, upon boiling, magnesium carbonate white solid and carbon dioxide; magnesium ammonium carbonate ($MgCO_3 \cdot (NH_4)_2CO_3 \cdot 4H_2O$), white precipitate (soluble in ammonium chloride solution) by reaction of soluble magnesium salt solution and excess ammonium carbonate.

Chlorides: Magnesium chloride ($MgCl_2 \cdot 6H_2O$), white solid, soluble, formed by reaction of magnesium carbonate (or hydroxide, or oxide, or metal) and **hydrochloric acid,** and then crystallizing, loses hydrogen chloride when heated, yielding magnesium oxychloride. Used as a dressing and filler for cotton and woolen fabrics, in paper manufacture, in cements, refrigerating brines, in ceramics, and as a source of magnesium for its insoluble magnesium compounds and magnesium metal; anhydrous magnesium chloride ($MgCl_2$), white solid, soluble, formed (1) by heating magnesium chloride crystals in a current of dry **hydrogen chloride,** (2) by heating magnesium ammonium chloride. Melting point 712° C. Used as the **electrolyte** in manufacture of magnesium metal; magnesium ammonium chloride ($MgCl_2 \cdot NH_4Cl \cdot 6H_2O$), white solid, soluble, when heated yields anhydrous magnesium chloride residue; magnesium potassium chloride, **carnallite** ($MgCl_2 \cdot KCl \cdot 6H_2O$), white solid, soluble, when heated fuses to anhydrous mixture magnesium potassium chloride; magnesium oxychloride, white solid, insoluble, formed (1) by heating magnesium chloride crystals, (2) by mixing magnesium chloride solution and magnesium oxide. Used as a cement when mixed with fillers, such as wood flour, sand powder, marble powder, cork, talc, for flooring.

Chromate: Magnesium chromate ($MgCrO_4 \cdot 7H_2O$), yellow solid, soluble, formed by reaction of magnesium carbonate and **chromic** acid solution and then evaporating.

Citrate: Magnesium citrate, citrate of magnesia ($Mg_3(C_6H_5O_7)_2 \cdot 4H_2O$), white solid, soluble, formed by reaction of magnesium carbonate and **citric acid,** and then evaporating. Used in medicine and in effervescent beverages.

Fluoride: Magnesium fluoride (MgF_2), white precipitate, by reaction of soluble magnesium salt solution and **sodium** fluoride solution. Used in ceramics.

Fluosilicate: Magnesium fluosilicate ($MgSiF_6$), white solid, soluble, formed by reaction of magnesium carbonate and **hydrofluosilicic acid,** and then evaporating. Used in hardeners for concrete, and in ceramics.

Hydroxide: Magnesium hydroxide, "milk of magnesia" ($Mg(OH)_2$), white precipitate, by reaction of soluble magnesium salt solution and **sodium** hydroxide solution. Used in medicine as a suspension in water ("milk of magnesia"), and in sugar refining.

Hypophosphite: Magnesium hypophosphite ($Mg(H_2PO_2)_2 \cdot 6H_2O$), white solid, soluble, formed by reaction of magnesium carbonate and **hypophosphorus** acid, and then evaporating. Used in medicine.

Iodide: Magnesium iodide ($MgI_2 \cdot 8H_2O$), white solid, soluble, formed (1) by reaction of magnesium carbonate and **hydriodic acid,** and then evaporating, (2) by heating magnesium metal and iodine. Used in medicine.

Lactate: Magnesium lactate ($Mg(C_3H_5O_3)_2 \cdot 3H_2O$), white solid, soluble, formed by reaction of magnesium carbonate and **lactic acid,** and then evaporating. Used in medicine.

Nitrate: Magnesium nitrate ($Mg(NO_3)_2 \cdot 6H_2O$), white solid, soluble, formed by reaction of magnesium carbonate and **nitric acid,** and then evaporating. Used in pyrotechnics.

Nitride: Magnesium nitride (Mg_3N_2), yellow solid, with moist air or water yields ammonia and magnesium hydroxide, formed by heating magnesium to a high temperature in **nitrogen** or **ammonia** (**hydrogen** gas evolved), or air (when a quantity of magnesium powder is ignited and then left undisturbed until cool, magnesium nitride is formed in the inner part of the mass).

Oleate: Magnesium oleate ($Mg(C_{18}H_{33}O_2)_2$), yellow solid, insoluble, formed by reaction of soluble magnesium salt solution and **sodium** oleate. Used in varnish driers.

Oxalate: Magnesium oxalate ($MgC_2O_4 \cdot 2H_2O$), white solid, insoluble, formed by reaction of soluble magnesium salt solution and **ammonium** oxalate solution.

Oxide: Magnesium oxide, magnesia, "burnt magnesia" (MgO), white solid, reacts slowly with water to form magnesium hydroxide, absorbs carbon dioxide from the air to form magnesium carbonate, is readily soluble in acids, insoluble in alkalis; formed (1) by heating magnesium carbonate to high temperature (**carbon dioxide** gas evolved), (2) by heating magnesium hydroxide, nitrate, sulfate, or oxalate, (3) by burning magnesium metal in air or **oxygen** (emission of brilliant white light of high actinic power). Used as a heat refractory and insulating material, in compounding rubber, in cosmetics, as a filler for paper; magnesium peroxide (MgO_2), white solid, insoluble, formed by reaction of soluble magnesium salt solution and sodium peroxide. Used in bleaching woolen and silk fabrics, and as antiseptic.

Phosphate: Magnesium ammonium phosphate ($MgNH_4PO_4$), white precipitate, by reaction of soluble magnesium salt solution and **sodium** phosphate in the presence of excess ammonium hydroxide, upon igniting yields magnesium pyrophosphate ($Mg_2P_2O_7$), white solid.

Salicylate: Magnesium salicylate ($Mg(C_7H_5O_3)_2 \cdot 4H_2O$), white solid, soluble, formed by reaction of magnesium carbonate and **salicylic acid** in water. Used in medicine.

Sulfate: Magnesium sulfate, "Epsom Salt" ($MgSO_4 \cdot 7H_2O$), white solid, soluble, formed by reaction of magnesium carbonate and **sulfuric acid,** and then evaporating, removable from natural brines or salt deposits. Used as a source of magnesium for its insoluble compounds, as a dressing and filler for cotton and silk goods, and in dyeing and printing and fireproofing cotton, as sizing for paper, in cosmetics and lotions, and in medicine.

Sulfide: Magnesium sulfide (MgS), formed (1) by heating magnesium sulfate and **carbon** to a red heat, (2) by heating magnesium and **sulfur** to ignition (Hazard I).

Tungstate: Magnesium tungstate ($MgWO_4$), white precipitate, by the reaction of soluble magnesium salt solution and ammonium **tungstate.** Used as a luminescent paint, and fluorescent x-ray screen. (R.K.S.)

MAGNESIUM ALLOYS. Magnesium was first made and some of its mechanical properties determined in 1830, but until about 1910 its only use was in the form of flashlight powder, ribbon and sheets and for the deoxidation of certain non-ferrous alloys, especially those containing nickel. The American development dates from 1915. Because of their lightness, about ¼ the weight of steel and ⅔ that of the aluminum alloys, and also because of their easy machinability the magnesium alloys are being used to an increasing extent.

Commercial magnesium and many of its alloys are resistant to ordinary types of atmospheric corrosion but may be seriously corroded in bad industrial atmospheres or along the sea coast, especially if in direct contact with salt water. Many methods of chemical treatment to increase the corrosion-resistance have been developed, of which a typical one is a mixture of sodium dichromate and nitric acid. For severe conditions, the chemically treated alloys are protected by paint, varnish or enamel.

For most working and operating conditions, the fire risk is unimportant as the heat will be dissipated because of the relatively high thermal conductivity before the burning point is reached. A fire hazard exists if a machining operation produces very fine chips or powder and is always present in grinding operations. This hazard is eliminated by grinding under oil or by adequate removal of the fine particles by suitable ventilation.

Designation *	Dowmetal C	Dowmetal H	Dowmetal O-1	Dowmetal FS-1
Condition	Heat treated and aged	Heat treated	Heat treated and aged	Hard rolled
Form	Castings	Castings	Extruded shapes	Sheet
Approximate chemical composition	Al 9.0 Zn 2.0 Mn 0.2	Al 6.0 Zn 3.0 Mn 0.2	Al 8.5 Zn 0.5 Mn 0.2	Al 3.0 Zn 1.0 Mn 0.2
Typical physical properties

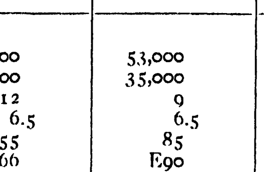
(R. S. WILLIAMS, M.I.T.)

With one or two exceptions, all magnesium alloys contain aluminum in amounts from 2.5–12%. All contain manganese in amounts from 0.1–0.3%. Many carry zinc in amounts from 0.5–3% and a very few have small percentages of cadmium or silicon. Intensive studies of the effects of other alloying elements are in progress. The alloys are available in the form of ingot, castings, forgings, sheet, extruded shapes, tubes and wire. Sand castings vary in tensile strength from 14,000–30,000 lbs. per sq. in. while die casting produces alloys with strengths up to 33,000 lbs. per sq. in. Castings may be heat-treated by annealing at 330–400° C. (626–752° F.) followed by air-cooling. The tensile strength increases to 29,000–34,000 lbs. per sq. in. with an increase in ductility and toughness. The heat-treated castings may be further strengthened by aging (heating at about 175° C. (340° F.) to 39,000 lbs. per sq. in., but the ductility and shock-resistance are decreased. Forging or extrusion will increase the tensile strength to 32,000–47,000 lbs. per sq. in. depending on the composition and treatment and with an increase in ductility. The elastic modulus of the alloys is rather low, 6,500,000 as compared to about 30,000,000 for steel, so that rigid structures must be built with somewhat heavier sections than would be indicated by calculations based on tensile strength alone.

MAGNET. In ancient times it was known that stones containing magnetite (see **Iron**) had qualities which were not the property of other stones. It was found that they would attract iron, and when freely supported would turn so that their axis would take a north-south direction. These lodestones were the earliest magnets, but now are natural curiosities only, since the magnets



Graphical magnetic field of a bar magnet.

used in compasses, instruments, magnetos, and all the various array of equipment which embodies a magnetic field produced by a magnet, are artificially constructed of hardened steel, magnetized by a strong magnetic flux. This type of magnet may be said to be a permanent magnet, in contrast to the **electromagnet.**

A magnet is a body possessing the property of at-

tracting magnetic substances. The so-called permanent magnet should be used where a constant magnetic field is to be produced, since a well-made permanent magnet loses its magnetism very slowly, and then only up to a certain point, after which it is said to be aged. Thereafter it maintains a constant degree of magnetism unless subjected to strong de-magnetizing effects. Manufacturers of permanent magnets for precision instruments artificially age them during the process of manufacture. A bar which has been magnetized is found to have poles. These are centers where magnetic attraction is strongest. If the magnet is free to turn, the pole which points northerly is called a north pole, and the other a south pole. Like poles repel each other with a magnetic force, and unlike poles attract each other. The earth is a large magnet having magnetic poles somewhere near, but not coincident with, the geographic poles. Since unlike poles attract each other, and the north pole of a magnet is taken as that which points northerly, it is the earth's south magnetic pole which lies near the north geographic pole. A magnet, delicately made, and freely suspended, becomes a **compass.** (F.T.M.)

MAGNETIC ANALYSIS. **Mass Spectograph.**

MAGNETIC BEARING. **Bearing.**

MAGNETIC CIRCUIT. A magnet, or a coil of wire carrying a current, is the seat of an influence which extends outward from it and is called a **magnetic field.** The flux from a bar magnet or from a straight electromagnet issues from one end of the magnet or coil, bends around, and re-enters at the other end. This can be exhibited by exploring the region with a compass needle. If there is provided an iron frame or ring extending from one pole of the magnet or coil around to the other, and in case of the coil, running clear through it, the magnetic flux is not only concentrated largely in the iron but is much greater in total amount than if the induction is entirely in the air. Even a short air gap in the iron reduces the flux considerably.

The analogy of such a magnetic path to an electric circuit is easily seen. The magnetic flux corresponds to a current. The magnet or coil corresponds to a battery, and provides magnetomotive force just as a battery supplies electromotive force. The amount of flux produced by a given magnetomotive force depends upon the dimensions and material of the "magnetic circuit," e g., the length and cross-section of the iron ring followed by the flux and the permeability of the iron; just as the dimensions and material of the electric conductor determine its resistance. This attribute of the magnetic circuit (corresponding to resistance) is called its reluctance.

These ideas are expressed quantitatively for the purpose of practical calculations. The magnetomotive force $\mathfrak{M}$ is commonly given in "ampere-turns." Thus, a coil of 50 turns carrying a current of 4 amperes has a magnetomotive force of 200 ampere-turns. Another unit of magnetomotive force sometimes used is the "gilbert," equal to $5/2\pi$ or 0.794 ampere-turn. The flux ϕ is expressed in lines or "maxwells." Just as the resistance of an electric circuit is defined as the ratio of the electromotive force to the current, so the measure of the reluctance $\mathfrak{R}$ of a magnetic circuit is the ratio of the magnetomotive force to the flux. We then have the relation

$$\phi = \frac{\mathfrak{M}}{\mathfrak{R}},$$

a sort of magnetic Ohm's law, known as Bosanquet's law.

There are approximate formulae, used in electrical engineering, for calculating $\mathfrak{M}$ and $\mathfrak{R}$, and hence ϕ, from the specifications of a coil, its core, air gaps, etc. Such formulae are extensively used in designing transformers, generators, motors, etc. (See **Electromagnet.**) (L.D.W.)

MAGNETIC DAMPING. **Lenz's Law.**

MAGNETIC DEFLECTION. **Cathode-Ray Tube.**

MAGNETIC COMPASS. **Compass.**

MAGNETIC FIELD. The region surrounding a **magnet** or an **electric current** is endowed with peculiar properties, the most familiar manifestation of which is the **torque** experienced by a small magnet, such as a compass needle, when placed in such a region. For any point of the field, there is only one direction in which the small magnet will come into stable equilibrium; and when this takes place, the direction in which the north pole of the magnet points is called the direction of the field. Upon exploring a magnetic field by moving the small magnet about in it, it is found that the field direction in general follows curved lines of force. If the field is due to the current in a conductor, these lines form completely closed curves enclosing the conductor; if due to a magnet, they apparently enter the iron at the south pole and emerge at the north pole, inferring that they complete themselves through the iron as they do through a coreless, current-carrying helix.

In any magnetic field there is at each point a certain magnetic intensity, a vector whose direction is that of the field. If one pole of a very long, slender bar magnet of unit pole strength is inserted into the field, that pole is acted upon by a force which, expressed in dynes, is a measure of the magnetic intensity. The unit magnetic intensity is the **oersted** (formerly the **gauss**). An instrument used for measuring the intensity is called a **magnetometer.** (See **Magnetic Flux.**)

Just as there is an **electric potential** at every point of an electric field, a **magnetic potential** exists at every point of a magnetic field. The difference in the magnetic potential at two points is measured by the work necessary to move a unit magnetic pole against the field from one point to the other. This difference is sometimes called a magnetomotive force, in analogy to **electromotive force.**

The lines of magnetic intensity around a current-carrying wire are circular, having the plane of the circle perpendicular to the axis of the wire. The direction of the whorls of force is determined by the "right-hand rule." When the wire is grasped by the right hand, the fingers encircling the wire, and the thumb pointing along the wire in the direction of the current, the fingers encircle the wire in the direction of the lines of force. This rule is used to determine in which direction the north pole would lie in a helix or solonoid of wire, for, instead of having a straight wire encircled by magnetic whorls, the wire itself is bent into a circular form by being wound in a solonoid or helix. The lines of force will then produce an axial magnetic field, so that one end of the solonoid is equivalent to a north pole, the other to a south pole. (L.D.W., F.T.M.)

MAGNETIC FLUX. The magnetic flux through any closed figure, such as a circle, a rectangle, or a loop of wire, is the product of the area of the figure by the average component of magnetic induction (see **Magnetism**) normal to that area. Thus, if a rectangle 5 cm. $\times$ 8 cm. is placed in a region where there is a uniform magnetic induction of 2500 **gauss,** and at an angle of 30° with the lines of induction, the magnetic flux through it is 2500 gauss $\times$ 40 cm.^{2} $\times$ sin 30° = 50,000 gauss-cm.^{2} or "maxwells." The magnitude of this quantity is often conventionally represented by imagining the lines of induction to be so spaced that the number of them through a given area is equal to the number of gauss-cm.^{2} or maxwells of flux through that area The flux in the above example would be commonly expressed as 50,000 "lines." When a coil has several (n) turns and each turn has approximately the same flux (ϕ) through it, the effect is the same as for a single

loop with the flux $n\phi$ through it. This product, which is called the "linkage," is expressed in "maxwell-turns" or "line-turns."

The magnetic flux or the linkage through a loop or a coil may be measured by putting into the circuit a ballistic (undamped) galvanometer and then suddenly removing the flux (or the coil). If the resistance of the whole circuit and the constant of the galvanometer are known, the flux may be calculated from the "throw" of the galvanometer. (L.D.W.)

MAGNETIC INDUCTION. **Magnetism; Gauss.**

MAGNETIC INTENSITY. **Magnetic Field; Oersted.**

MAGNETIC MATERIALS. The electrical industry is dependent on four basic types of materials, good conductors of electricity, high-resistivity conductors capable of withstanding high temperatures, insulators, and magnetic materials. In recent years the greatest developments have been in insulators and magnetic materials with resultant improvements in motors, generators, transformers, and instruments of all kinds.

The ferromagnetic elements are iron, nickel, and cobalt. Of these iron is the only one which has important magnetic applications in pure, or commercially pure form. All three elements, and many others which themselves are non-magnetic are used in special alloys in which certain magnetic characteristics are developed to a high degree. It is even possible, by alloying, to develop magnetic material from certain nonmagnetic elements.

There are two distinct groups of ferromagnetic materials, those which are easily demagnetized, and those which are not. These are often designated as soft and hard magnetic materials. In many respects iron is an excellent soft magnetic material. It attains the highest saturation value of magnetic induction found in any material with the exception of certain cobalt alloys. (**See Magnetism.**) However, its maximum permeability (maximum ratio of magnetic induction to magnetizing force) is surpassed by other materials. When used as a core in a field induced by a.c. the so-called "iron losses" are relatively high. Iron losses consist of energy losses related to the area of the hysteresis loop, and of eddy-current losses caused by induced current circuits within the metal. High values of residual induction (*OR* on the typical hysteresis curve on page 759) and coercive force (*OC*) are indications of high hysteresis loss. A low value of electrical resistivity results in high eddy current losses. However, other factors such as the thickness of the sheets in laminated cores, and to a leser degree grain size also affect eddy current losses. Values for commercial quality magnetic iron are compared with other representative soft magnetic materials in the following tabulation. By special heat treatments and the use of specially purified iron much higher values of permeability and lower hysteresis losses can be obtained.

Soft Magnetic Alloys	Saturation Intrinsic Induction, B Gausses	Maximum Permeability B/H	Resistivity Microhm Cm.	Hysteresis Loss * Ergs/cc/Cycle	Residual * Induction, Br Gausses	Coercive Force Hc * Oersteds	Maximum External Energy

* In the case of magnetically soft materials, these values are for a magnetizing force, H, of 10 kilogausses

With a good grade of silicon electrical steel the hysteresis loss can be cut in half and the eddy-current loss reduced even more because of the high resistivity compared with iron. This results in much more efficient operation of **alternating-current** equipment. A special type of silicon steel known as Hipersil having marked directional properties has been developed recently. A reduction of 25% in the weight of a transformer may be made without reduction in performance provided the design takes advantage of these directional properties.

Certain high-nickel alloys of the Permalloy type have very high permeabilities at low and moderate inductions and give low hysteresis losses. For many special applications in instruments and communications equipment these higher cost alloys are economically justified. Power transformers, motors and generators, etc., are designed for silicon electrical steels.

In the use of any of these materials for a-c applications, it is desirable to reduce the thickness of individual laminations to reduce eddy-current losses. For special applications at higher than usual power frequencies, extremely thin strip is used, approaching 1/1000" thick. The most common thickness at 60-cycle power fre-

quencies is about 14/1000". In the communications field where the use of very high frequency current greatly aggravates the problem of eddy-current losses, alloys of the Permalloy type are used. They are produced in powdered form, given a very thin insulating film, and compacted under high pressure into a suitable core shape. While this is a product of **powder metallurgy,** it is unusual in that no sintering is required. (A final heating is applied to relieve the stresses caused by pressing and thus greatly improve the magnetic properties.)

In the production of magnetically soft materials it is important that elements such as carbon and sulfur which disturb the continuity of the base-metal crystal structure be reduced to low residual amounts, and that the material be used in a strain-free condition. High annealing temperatures resulting in coarse grain structures are used. These conditions are, for the most part, reversed when magnetically hard materials are sought. These materials must be capable of reaching high inductions, but upon removal of the direct magnetizing force the magnetic flux remaining in the circuit should be high, therefore a hysteresis loop of large area is desired. A good over-all measure of the quality of a permanent magnet is the "maximum external energy." This is the maximum value which can be obtained for the product of the coordinates of a point on the curve between B_r and H_c (line RC on page 759).

In order to obtain a high external energy value, high carbon and alloy contents are used and the steels are quenched to a high hardness. Processing and heat-treating temperatures are kept as low as possible and no attempt is made to relieve the severe internal stresses set up by formation of **martensite.**

Magnet of fair quality can be made of ordinary high-carbon steels, however, the advantages of the chromium and tungsten types of alloy steels are apparent. There are many special grades containing cobalt, three of which are included in the table. Still greater improvement in coercive force, which is a measure of resistance to demagnetization, is attained in the Alnico compositions which are **precipitation hardening** type alloys. These compositions are hard and brittle as cast and must be finished by grinding. Small-size magnets can be produced by **powder metallurgy** to high dimensional accuracy. The magnetic properties are equivalent to those of the cast alloys and the mechanical strength is greater, thus the principal limitations are size and cost. (R.H.H.)

MAGNETIC MOMENT. **Magnetism.**

MAGNETIC PARTICLE INSPECTION TEST (MAGNAFLUX). A rapid non-destructive test for fatigue cracks, grinding checks, weld defects, stress-corrosion cracks, seams, and other surface and subsurface defects in steel and other magnetic alloys.

The piece to be inspected is magnetized by means of a solenoid or by-passing a heavy current through the piece itself. At cracks or other discontinuities, local flux-leakage fields are formed. A magnetic powder applied to the magnetized piece will be attracted strongly to the areas of flux leakage, forming a pattern which reveals the location and extent of the defects. The powder may be applied dry by dusting on the work from a porous bag or shaker (dry method), or it may be suspended in a light oil which may be flushed over the work or used as an immersion bath (wet method).

Magnaflux inspection can be used to advantage on steel bars, shapes, plates, or castings before fabrication, on finished parts, and on parts which have been in service. Steels of "aircraft quality" must meet Magnaflux inspection specifications.

Non-magnetic metals such as austenitic stainless steels and the non-ferrous alloys can be examined for defects by a related process known as "Zyglo." The part is dipped into a penetrating fluorescent liquid, rinsed, dried, and powdered. Under the capillary action of the powder the liquid marks the surface at cracks, seams, or other defects. The piece is then viewed under "black" (ultra-violet) light which excites fluorescence. (R.H.H.)

MAGNETIC PENDULUM. A bar magnet poised on a pivot or suspended by a thread in a magnetic field having a horizontal component will, if disturbed and released, oscillate in a horizontal plane as a magnetic pendulum. This arrangement is commonly employed in the **magnetometer** method of measuring the earth's magnetic field intensity, or in comparing field intensities in different localities. The period of oscillation of such a pendulum. This arrangement is commonly employed in magnet, the horizontal component H of the magnetic field intensity, the **moment of inertia** I of magnet and supports with respect to the oscillation axis, and (if a suspending fiber is used) the torsion coefficient K of the fiber. For small amplitudes the period is

$$T = 2\pi \sqrt{\frac{I}{MH + K}}.$$

With a pivoted magnet, $K = 0$; while if the bar is unmagnetized, $M = 0$, and the formula degenerates into that for a **torsion pendulum.** The moment of inertia I may be determined experimentally in the same manner as with a torsion pendulum, but using $MH + K$ in place of K. In order to find K alone, the magnet is replaced by a non-magnetic bar having the same moment of inertia, and the torsion pendulum method applied. (L.D.W.)

MAGNETISM. Centuries ago, minerals were discovered which exhibited strong attraction for iron and served as compass needles. These "lodestones" are in fact iron ores, usually Fe_3O_4. It was found that a steel bar stroked with such a natural magnet becomes itself a magnet with poles dependent upon the direction of stroking. With care the poles may be strongly localized in limited regions, almost points, and the forces between poles are then found to obey **Coulomb's law** of inverse squares. Two unit poles at a distance of 1 cm. in a vacuum attract or repel each other with a force of 1 dyne. When placed in a **magnetic field,** a bipolar magnet experiences a torque proportional to the field intensity and to the sine of the angle between the axis of the magnet (line joining poles) and the field direction. The maximum torque per unit field intensity (which obtains when the magnet and the field are at right angles) is the magnetic moment of the magnet.

When a substance having magnetic properties is placed in a magnetic field, the field intensity gives rise to a magnetizing force H within the body, and the substance acquires a certain magnetization I, depending upon H and upon the susceptibility I/H of the substance. The resulting magnetic induction, $B = H + 4\pi I$, is a quantity much used in magnetic theory. If the field intensity is gradually built up from zero, the induction may be represented by a curve with H and B as coordinates. As magnetization proceeds, the curve approaches a straight line inclined at 45° (if B and H are on same scale); which means that I approaches a steady value, a

condition called saturation. The ratio B/H is at any stage the magnetic permeability of the substance. If now the field is diminished, it is found that a certain reverse intensity OC, called the coercive force, is usually required to reduce the induction to zero. This is due to **hysteresis.** Some alloys of iron show extraordinary peculiarities; for example, permalloy (22% iron, 78% nickel) has enormous initial permeability, while perminvar (iron, nickel, and cobalt) has almost constant permeability for different fields, so that the graph OS is practically straight. (See **Magnetic Materials,** and typical hysteresis curve on page 759.)

Substances may exhibit magnetic properties not only in different degrees, but in radically different ways. There are three fairly distinct classifications: paramagnetic, ferromagnetic, and diamagnetic substances. The many paramagnetic substances, and the small group of ferromagnetic substances (iron, nickel, cobalt, gadolinium, and some alloys), both have positive susceptibility (I increases with H), but their magnetization curves are different and the phenomena are attributed to quite different causes. Any ferromagnetic substance becomes paramagnetic at a sufficiently high temperature (see **Curie-Weiss Law**). With diamagnetic substances, such as copper, silver, and bismuth, the susceptibility is negative and the permeability slightly less than 1; so that their magnetization curves lie in the fourth quadrant.

The physical nature of magnetism has been the subject of much speculation and research. It appears now that paramagnetism is probably due to the orbital motion of electrons in the atom, there being an excess of electrons revolving one way over those revolving the other; that in the atoms of ferromagnetic substances the number of electrons spinning one way on their axis is unequal to the number spinning the other way, while relatively large groups called "domains," made up of atoms having parallel magnetic moments, act together when the substance is magnetized and somehow add enormously to the induction; and that diamagnetism arises from the **precession,** in the applied field, of atoms which are not even paramagnetic, but which thus give rise to a feeble magnetization opposed to the field. The magnetic moments of paramagnetic atoms appear to be made up of very small units called magnetons, and the processes causing changes in magnetization take place in accordance with **quantum** conditions. (See also **Barkhausen Effect, Barnett Effect, Magnetic Circuit, Magnetic Flux, Magnetostriction, Electromagnetism.**) (L.D.W.)

MAGNETITE or MAGNETIC IRON-ORE (LODESTONE). The mineral magnetite, ferroferric oxide, Fe_3O_4, is **isometric,** commonly occurring in **octahedrons, dodecahedrons,** and massive, granular, laminated, etc. It is brittle with an uneven fracture; cleavage is not distinct, but with pressure an octahedral **parting** may develop; hardness, 5.5–6.5; specific gravity, 5.18; luster, metallic to dull; color, **iron** black; **streak,** black. It is opaque and strongly magnetic; when possessing polarity is known as lodestone. Magnetite is a common mineral in the **igneous rocks,** especially those of the ferromagnesian varieties, and is found in many **metamorphic** types. It is associated with **corundum** in **emery.** In northern Sweden are what may be the largest magnetite deposits in the world, believed to have been formed by segregation in the **magma.** Magnetite is also found in Norway, in the Urals, Italy, Switzerland, Australia and Brazil. In the United States the Pre-Cambrian rocks of the Adirondacks contain large beds of magnetite. This mineral is found also in New Jersey, Arkansas, Utah, and in Canada in Quebec and Ontario. The lodestone or natural magnet is found in Siberia, the Harz Mountains, the Island of Elba, and at Magnet Cove, Arkansas. The name magnetite is said to be derived from the district of Magnesia, near Macedonia. There is, however, a fable that it was named for a shepherd, Magnes, whose iron-bound staff and shoes with iron nails stuck to the ground in which magnetite was present.

This mineral is an important ore of iron, containing 72% of metallic iron. (E.S.C.S.)

MAGNETO. The magneto is a device for producing alternating currents of high voltage properly synchronized for distribution to the spark plugs of an engine of the spark ignition (Otto cycle) type. The same function may generally be admirably performed by a coil-and-battery system, but the compactness and light weight of the magneto, and its reliability, have caused it to be widely used for *ignition.* The magneto is but seldom seen in that most familiar example of spark ignition, the automobile engine, because various electrical requirements of the automotive vehicle besides ignition have promoted the use of systems embodying a substantial storage battery which can also supply electric current to an ignition system. Such are termed coil-and-battery systems. (See **Ignition System.**)

The magneto has a single function—ignition. Except for spark plugs, wiring harness, and switch, it is a complete ignition system. Nowadays it is to be found on stationary engines, tractor engines, boat engines, and others where the ignition system is to be independent of other electrical services; and on the aircraft engine, where its proved reliability is highly respected.

In reality the magneto is an electric generator, induction coil, interrupter, and distributor, all consolidated in one small compact unit. Three different systems of generation of the low voltage electrical pulses are found. These, which are illustrated in Fig. 1, may be called (1) the armature type, (2) the inductor type, and (3) the

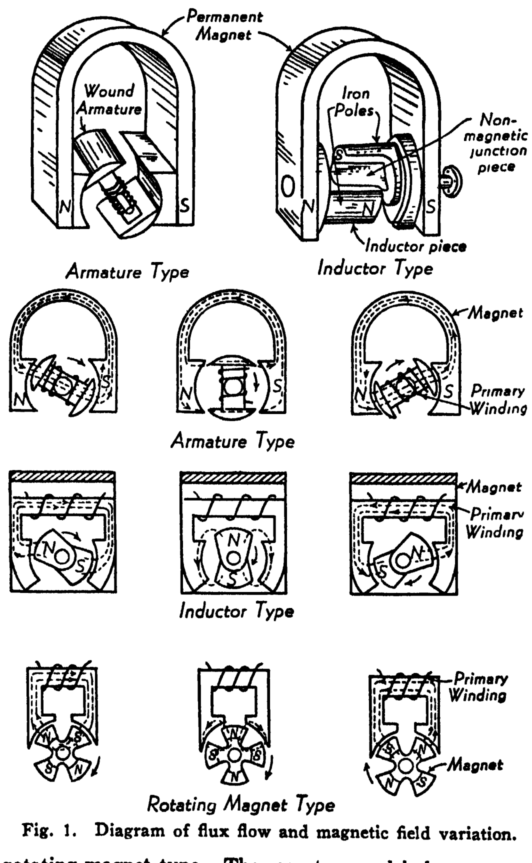

Fig. 1. Diagram of flux flow and magnetic field variation.

rotating magnet type. The armature and inductor types have stationary permanent magnets. In one a wire-wound armature is rotated between pole shoes, as in a

dynamo machine, and in the other a soft iron "inductor," or flux changer, is rotated between the pole shoes.

The magnetizing influence which a magnet can exert on a magnetic circuit is called magnetomotive force. It is the "voltage" of a magnetic circuit. Flux in a magnetic circuit is equivalent to current in an electrical circuit. It may be represented by imaginary lines of force, as in Fig. 1. The stronger the magnetomotive force of a circuit, the greater will be the flux. The material of the magnetic circuit may be composed of anything through which the magnet can force flux, even air, but is mainly ferrous because of the excellent magnetic "conductivity" of this material, especially soft iron. Only the smallest of air gaps can be permitted because of the high "reluctance" of such to convey flux. If the amount of flux associated with a coil is varied by any process whatsoever, an electromotive force is induced in the coil. In all magnetos motion of the rotor induces a change of flux linkage through the primary coil winding. The method of varying flux linkage is shown in Fig. 1. Flux lines are shown dotted, with assumed direction of flux being from a north to a south pole. The diagrams are self-explanatory, although possibly some comment will be helpful in tracing the magnetic circuit of the inductor type. In the figure it is seen that the rotating soft iron inductor has *N* and *S* pole pieces which remain magnetically in contact with the poles of the permanent magnet, although continuously rotating. The *N* and *S* inductors are magnetically separated by the middle section of the inductor being non-magnetic (brass). Consequently the flux lines leaving the *N* pole of the magnet pass through the *N* end of the inductor, thence to the pole shoe and through the soft iron core of the primary winding to the other pole shoe, then across the air gap into the *S* end of the inductor, back to the *S* pole of the permanent magnet and through the magnet to the starting point.

The voltage induced in the primary winding is insufficient to jump a spark across the gaps of the **spark plugs**, but if a circuit breaker (called interrupter or breaker) is connected in the coil circuit to open the previously short-circuited coil at the instant the flux change reaches maximum (not coincident with maximum flux density), the resulting surges of primary coil current apply extra magnetomotive force to the magnetic circuit. Then, if a secondary coil of a great many turns is wound around the primary coil, extremely high voltages will be induced in it. It is these voltages which provide the "pressure" necessary for a jump spark. The secondary coil lead could be connected directly to the spark plug of a single cylinder engine. A 4-cylinder, 4-cycle engine needs 4 precisely timed sparks every 2 revolutions of the crankshaft. Consequently, the magneto rotor speed, the number of poles, and the interrupter design must all be correlated so as to produce the 4 high voltage surges. There must, in addition, be a rotary switch to receive these surges from the secondary winding and direct them in proper succession to the 4 spark plugs. This is called the distributor and is usually an integral part of the magneto. The distributor must be geared to rotate at one-half crankshaft speed. The distributor rotor (finger, brush) makes its connection with the magneto secondary through the drive shaft. The distributor case is molded of high-grade insulation with conducting inserts to which are connected the wires which carry the voltage to the plugs. In some distributors the rotor "brushes" the contact points as it passes them, whereas in others the current must jump a small gap between the moving finger and the stationary contact point.

The primary circuit must be broken as many times per single revolution of the rotor as there are permanent or induced poles on the rotor. The break is mechanically accomplished by a cam. Usually the cam is mounted directly on the rotor shaft. In a 4-cycle engine the number of firings required per revolution is one half the number of cylinders. The required magneto shaft-crankshaft speed ratio is the number of cylinders divided by twice the number of poles on the rotor. Fig. 2 shows typical breaker points. The movable point is mounted on a spring. Points are made of platinum

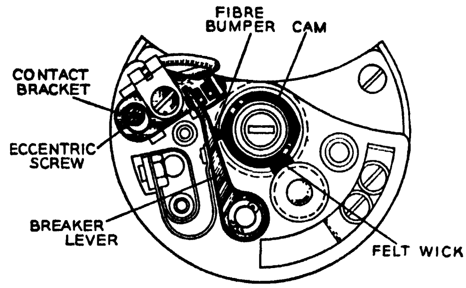

Fig. 2. (*American Bosch Corp.*)

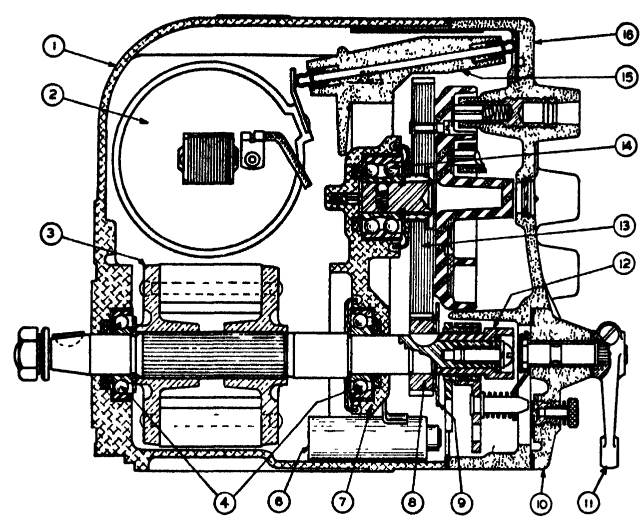
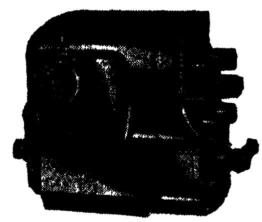
iridium alloy, and have a condenser connected across them to eliminate arcing and burning from self-induction in the primary circuit, and also to assist in bringing primary current to zero rapidly, thereby increasing the voltage produced by the secondary winding.

Illustrating a standard type magneto for 6-cylinder engine ignition, Fig. 3 shows an external appearance and a section through a rotating magneto-type of magneto. As the auxiliary view consisting of a circuit diagram shows, the 2-pole inductor rotor rotates between pole shoes A and B in order to create reversal of magnetic flux through the coil. The inductor rotor shaft which is mounted on ball bearings (4) rotates at 1½ times crankshaft speed, producing 2 sparks for every 360° of inductor rotor travel. The condenser (6), coil (2), and breaker assembly are stationary, although the latter may be shifted by arm (11) so as to advance or retard the timing of the spark relative to piston position. One end of the primary coil is connected to the breaker, and a lead from the secondary coil is carried to the distributor plate (16) for connection to a contacting brush which establishes contact with a circular, pick-up conducting ring in the distributor rotor. The distributor rotor shaft is mounted on ball bearings (14) and is driven at half crankshaft speed by the 1:3 ratio between the drive gear (8) and the distributor gear (13). A connection is made internally in the molded insulating material of the distributor rotor from the pick-up ring to a small inset segment in the distributor rotor. This segment is located at a greater radial distance from the distributor shaft than is the pick-up ring. Six brushes extending from sockets in the interior of the distributor plate bear against the face of the distributor rotor which, as it rotates, permits the small segment to make contact with one brush after another until all 6 brushes have received sparks. The brushes are connected to sockets on the exterior of the distributor plate. The high-tension cable to the spark plugs is inserted into these sockets.

Magnetos are employed regularly in modern aircraft engine ignition. That field of use poses operating problems not encountered elsewhere, some of which are worthy of description. Since inductor and rotating magnet types have no high voltage lead-off from the rotor, they are favored over the armature (shuttle) type. A typical magneto system is pictured in Fig. 4. Two magnetos are provided for the engine (9 cylinder, radial, indicated by the wiring harness) so that two independent sources of ignition will exist. Each cylinder has two spark plugs, each plug being connected separately to a different magneto. The magnetos are mounted on the engine crankcase and gear driven by it. The ignition switch, which is at the pilot's control, is turned to short circuit the breakers in order to stop





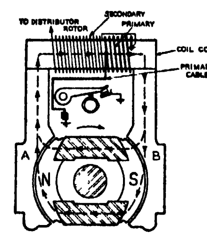


Fig. 3. (*Fairbanks-Morse & Co.*)

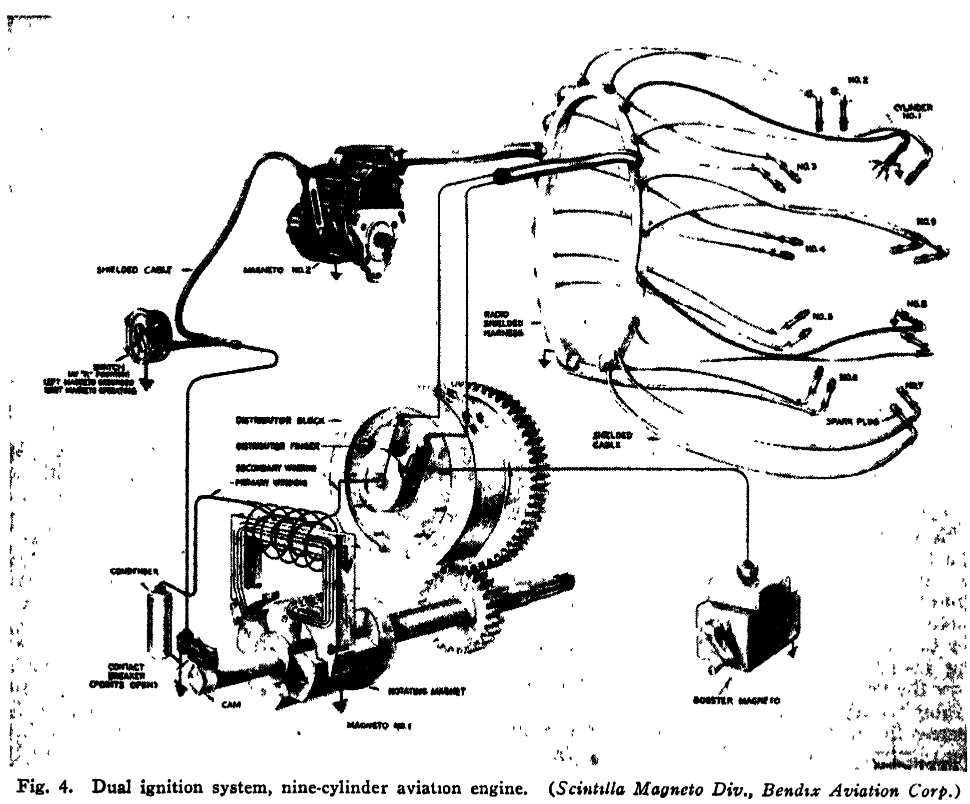

Fig. 4. Dual ignition system, nine-cylinder aviation engine. (*Scintilla Magneto Div., Bendix Aviation Corp.*)

the engine. In some cases, during cranking of the engine the magneto rotor speed is too slow to produce a satisfactory spark. A supplementary high voltage source known as a booster may be used during cranking, or an impulse coupling of the magneto rotor to the engine may be supplied. The booster magneto is usually hand-cranked and is connected to the spark plug through a distributor finger which trails the normal finger so as to retard the spark enough to prevent engine "kickback" during cranking. The impulse coupling is a spring-like mechanical linkage between the engine and magneto shafts which will wind up and let go at just the right moment to spin the magneto shaft fast enough to generate the necessary spark voltage. After the engine has started and reached a predetermined speed where normal magneto action is adequate, a centrifugal weight-actuated lock renders the impulse device inoperative. The ignition lag necessary to reduce kickback of an engine which normally operates on about 20° advance of spark before top dead center can be built into the distributor finger design used with a booster magneto (or vibrating coil and battery), or into the impulse coupling. The case on which the breaker is mounted, if permitted some small angular adjustment, can become a means of retarding the spark, for if the breaker shaft were rotating at crankshaft speed, a 5° rotation of the case in the direction of rotation of the cam would delay the spark 5° of crankshaft travel. Some magnetos have this spark-retarding feature, as do the breakers on most all coil and battery systems, but it is uncommon in aircraft ignition.

A single-unit dual magneto consists of a magneto unit containing 1 rotating magnet, 2 coils, and a double breaker assembly driven from an accessory drive shaft. There are 2 separate distributor assemblies, which are often driven by gearing from the rotor shaft.

As shown in Fig. 5, the condensers and coils are located in the breaker housing. There is some saving in weight

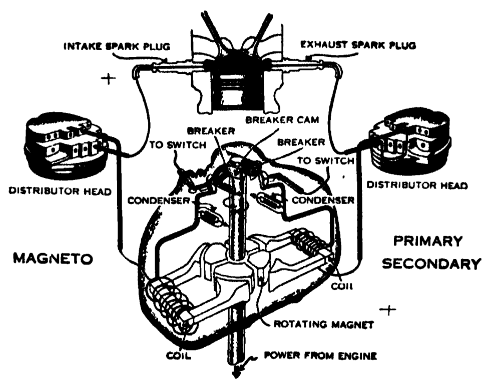

Fig. 5. Single-unit dual magneto.

over 2 complete magnetos, and the reliability of ignition appears to be nearly equivalent to the double magnetos

The ignition system of aviation engines could be much like that for any other service, except for the following service conditions:

1. The growing importance of radio communication to navigation and piloting requires special attention to prevent broadcasting of interference static from the ignition system.

2. Increasing demands for high altitude equipment have accentuated the effect of corona loss, ionization flashover, etc.

3. The need in high-power engines for a system that will fire successfully even though the normal insulation throughout the ignition system is greatly impaired.

Radio communication is relieved of interference by shielding the ignition equipment, especially the wiring and spark plugs, by enclosing it in metallic tubing or sheathing. This sometimes necessitates modifications of the magneto which would not otherwise be practical. High altitudes promote corona discharge from ignition systems over the high-tension (high-voltage) components. This not only leaks off energy needed in the spark plugs, but also, through the formation of ozone, accelerates the deterioration of wiring harness insulation. Flashovers may take place. Since these difficulties are aggravated as higher altitude flights become common, means have been sought for their elimination. One method is to supercharge the ignition system—that is, enclose the troublesome parts in an airtight casing and supply an air pump to maintain in it dry air at pressures that suppress corona difficulties. This is particularly suitable for modifying existing engines and their magnetos. Other methods involve relocation of magnetos so as to shorten the high-tension lines. Special high-altitude magneto systems have been devised, of which one will be described.

Corona can be suppressed if high-tension circuits are eliminated. But the high tension is necessary at the spark plugs. This difficulty is overcome in the high-altitude system by delaying the creation of high tension until the timed ignition pulse has reached the vicinity of the spark plug. There, the high-tension pulse needed by the spark plug is produced by a small transformer coil. The magneto is low tension, as are the distributor and wiring harness. There is a simplification and lightening of these parts, but a transformer coil is needed for each spark plug. This high-altitude, low-tension magneto ignition system is diagrammed in Fig. 6.

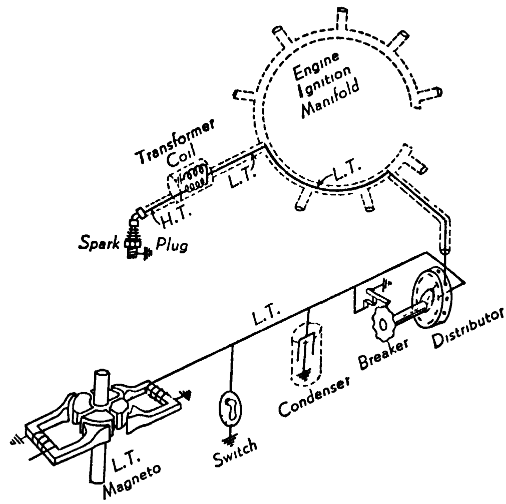

Fig. 6. Diagram of magneto ignition suitable for high altitudes (9 cyl. radial engine).

In modern aircraft engines of high-power rating there is a tendency for an electrical shunting of spark plug gaps by formation of lead compounds over the insulator surface, carbon tracking, and moisture on the terminals. From 8000 to 10,000 volts is normally required at the gap, but leakage paths may so accumulate as to cause irregular firing, especially where many hours' service between spark plug changes are expected. Magneto ignition systems using a high frequency condenser discharge to activate the plugs are being installed experimentally on large aircraft engines. The system is made low tension as far as the spark plug. Special plug designs are used, having the transformer coil integral in the spark plug bushing. From a magneto a charging pulse, created by the magneto breaker, is passed through a rectifier to charge a large condenser. A synchronized contactor (like a breaker, but acting by closing the circuit) and distributor unit discharges high-frequency, low-voltage transient current through the spark plug primary coil. A high-

frequency, gap-jumping voltage is induced in the plug coil secondary. The high frequency discharge is not so readily shunted by leakage paths, and it is claimed that the high frequency system will continue to fire plugs that would have shorted out in an ordinary high tension system. (F.T.M.)

MAGNETOMETER. An apparatus used for measuring moderate magnetic field intensities, or sometimes the magnetic moments of magnets; frequently both. The standard laboratory equipment is set up in two ways, giving two results from which may be calculated both the magnetic field intensity (or rather, its horizontal component H) and the magnetic moment M of a short bar magnet forming part of the equipment. The terrestrial magnetic intensity is usually measured in this way, and Gauss employed this method in verifying the magnetic inverse-square law.

In the first arrangement, the magnet is used as a **magnetic pendulum,** whose **moment of inertia** I is known and whose period of oscillation T is measured. It is

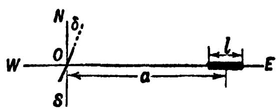

Diagram of magnetometer; δ is the deflection of the needle at O, due to magnet in the "end-on" position at distance a.

usually suspended by a fiber of known torsion coefficient K; in some cases K is small enough to be neglected. From the magnetic pendulum formula we obtain the product

$$MH = \frac{4\pi^2 I}{T^2} - K. \qquad (1)$$

The magnet is then arranged to deflect a small compass needle. The needle is at O, the magnet at a considerable distance a from it, and commonly east or west of and aligned upon it (see figure). If the length of the magnet is l, the deflection δ of the needle is given by

$$\tan \delta = \frac{M}{H} \frac{32a}{(4a^2 - l^2)^2},$$

from which

$$\frac{M}{H} = \frac{(4a^2 - l^2)^2}{32a} \tan \delta. \qquad 2)$$

The second members of (1) and (2) contain only measurable quantities, and are therefore known. Hence, by multiplying (1) and (2) we get M^2, and by dividing (1) and (2) we get H^2; from those results M and H follow. Instruments embodying these principles are regularly used by the U. S. Coast and Geodetic Survey. (L.D.W.)

MAGNETOMOTIVE FORCE; **Magnetic Circuit.**

MAGNETON. **Magnetism.**

MAGNETO-OPTICAL ROTATION. Some substances are in themselves optically active, that is, they rotate the polarization plane of **polarized light** passed through them. In 1845 Faraday discovered that glass and other substances devoid of this property acquire it when placed in a strong magnetic field. This is the so-called Faraday effect. The light must traverse the substance along the lines of force. The direction of the rotation is reversed if the field is reversed, but is the same with respect to the observer whether the light is going or coming, so that a beam passing one way and reflected back has its rotation thereby doubled (which is not the case with natural activity). Some substances produce right-handed, some left-handed rotation in light traveling in the direction of the field. In any case, except for ferromagnetic substances, the rotation per unit thickness is for a given wavelength proportional to the field intensity, its value per cm. per oersted intensity being called the Verdet constant. Some typical values of the constant, with sodium light, are: flint glass, 0.061′; water, 0.013′; air, 0.000007′. For ferromagnetic substances the rotation is proportional to the magnetization (see **Magnetism**) rather than to the intensity, as shown by Kundt. The rotation increases with diminishing wavelength.

Another type of magnetic rotation was observed by Kerr in 1877. A beam of plane-polarized light vibrating either in or perpendicular to the plane of incidence has its polarization plane rotated upon reflection from the polished pole-piece of a strong magnet. The polarization is at the same time rendered slightly elliptical. (L.D.W.)

MAGNETOSTRICTION. The term literally implies magnetic contraction, but is generally understood to include a number of closely allied phenomena relating to ferromagnetic substances under magnetic influence.

1. When an iron rod is subjected to a gradually increasing longitudinal magnetic field, it at first increases slightly in length (Joule effect) and later the length diminishes; when the magnetic intensity has reached about 250 oersteds, the rod has returned to its original length, and further increase of intensity causes it to contract (Villari reversal point). Nickel contracts rapidly at first and then remains nearly constant, while some iron-nickel alloys lengthen without reversal. The following phenomena are also recognized. 2. The Guillemin effect: the tendency of a bent ferromagnetic rod to straighten in a longitudinal field. 3. The Wiedemann effect: the twisting of a rod carrying an electric current when subjected to a magnetic field. 4. The Villari effect: a change of magnetic induction within an iron rod under longitudinal stress (inverse Joule effect).

Magnetostriction has been put to practical use in the magnetostrictive resonator, essentially an iron rod maintained in longitudinal elastic vibration by a high-frequency current in a helix wound upon it, and used, through the joint operation of the Joule and Villari effects, to control the frequency of the current, somewhat after the manner of the familiar **piezo-electric** (crystal) **resonator.** (L.D.W.)

MAGNETRON. This is a vacuum tube which functions under the joint action of an externally applied magnetic field and the electric field between its anode and cathode. In its common form it consists of a cylindrical **cathode** (a straight wire filament) and a coaxial anode structure. In some tubes the **anode** is a single cylinder while in others it is split lengthwise for all or part of its length. These tubes are widely used in ultra high frequency oscillator circuits where the conventional **vacuum tubes** would be completely inoperative. The electric field is created by applying a high d-c potential between the filament and anode structure while the magnetic field is applied longitudinally by external permanent or electro-magnets. When the tube is properly connected to a resonant **line** it can be made to operate as an **oscillator** for certain values of the applied fields. A magnetron of suitable dimensions may be made to generate frequencies measured in thousands of megacycles (wavelengths of a few centimeters). (L.R.Q.)

MAGNIFYING POWER. Crudely defined, the magnifying power of an optical instrument is the ratio of the apparent size of an object as seen through the instrument to the apparent size of the same object as seen without the instrument. To define "apparent size of an object" in terms which will permit of rigorous discussion requires certain assumptions. We may define the apparent size of an object as the angle which the object subtends at the eye, or as the size of the image which the lens of the eye forms of the object on the retina of the eye (retinal image). Using this definition we shall

find that the apparent size of the rising moon is actually less than that of the moon when up on the meridian in spite of the fact that the rising moon always "looks" much larger than when it is up away from objects with which direct comparison can be made.

Even with the assumption of apparent size defined as above, the significance of the term magnifying power depends upon the type of instrument which is under consideration. For a **telescope,** used to view distant objects, the magnifying power may be directly defined as the ratio of the size of the retinal image obtained with the instrument to the size of the retinal image obtained without any optical aid. When a positive **eyepiece** is used the magnifying power may be shown to be directly equal to the ratio of the focal length of the object glass of the telescope to the focal length of the eyepiece. For example, a telescope with an object glass of 10 feet focal length will have a magnifying power of 60 when used with a positive eyepiece of 2″ focal length. It should be noted that changing the eyepiece will change the magnifying power of the telescope; e.g., if an eyepiece with one-half inch focal length were used with the above telescope, the magnifying power would be 240. Hence, the question regarding the magnifying power of a telescope with interchangeable eyepieces is meaningless unless the particular eyepiece is specified for the particular telescope. In telescopes, binoculars, field glasses, etc., purchased from dealers in optical supplies, usually the eyepieces are not interchangeable and the magnifying power specified by the maker depends upon the lenses supplied with the instrument. In case negative eyepieces are used with a telescope a so-called "effective focal length" must be known for the eyepiece before the magnifying power can be calculated.

In the case of a **microscope,** either simple or compound, the magnifying power is usually defined as the ratio of the retinal image obtained for a given object while using the microscope to the retinal image that would be obtained of the same object without the instrument with the object at a standard distance from the eye, usually 250 mm. For a compound microscope the magnifying power is approximately equal to 250 times the length of the tube, divided by the product of the focal lengths of the objective and eyepiece, the three lengths all expressed in millimeters. The magnification effected by a projection instrument, such as an enlarging camera or a stereopticon, is logically expressed as the ratio of the diameter of the real image formed on the screen to the diameter of the object itself. If the focal length of the projecting lens is f and its distance from the screen is d, this magnetification is approximately equal to $\frac{(d-f)}{f}$. (W.K.G., L.D.W.)

MAGNITUDE. Stellar Magnitude.

MAGPIE. Aves, Passeriformes. Moderately large long-tailed birds (**Aves**) related to the crows. The common North American species, *Pica pica,* ranges from Alaska to Arizona and eastward into Iowa. It is a black and white bird. The yellow-billed magpie, *P. nuttalli,* flies only in California. The European and Asiatic species of magpies are more brightly colored.

The magpies build very large untidy nests and are noted for their curiosity, adaptability, and noisiness. (A.W.L.)

MAHOGANY. *Sweitenia Mahagoni* and other species. Meliaceae. The name mahogany belongs properly to a group of trees which are found in Central America and the West Indies, and to a few related species growing in tropical Africa. These, species of the genus *Sweitenia,* are large trees with **pinnately** compound leaves like those of ash trees and small flowers in **panicles** in the leaf **axils.** The term mahogany is also frequently and mistakenly applied to many dark red woods, not mahogany.

The trees grow in a variety of habitats, often in most inaccessible places, so that it is very difficult to get the cut logs to the market. Mahogany is usually classified according to the region from which it comes, as Cuban mahogany, Honduras mahogany, etc.

The first mahogany to appear in Europe was brought in as ballast in a ship, the heavy logs being very suitable for that purpose. In port it was necessary to remove these in order to get in more cargo. So it was offered to English woodworkers. At first it was rejected as too hard to work and of little use, being heavy and dark-colored. Gradually it found favor, until it became a highly prized wood for fine furniture making. The first mahogany used in cabinet work was Spanish mahogany, *Sweitenia Mahogoni.* For a long time mahogany from San Domingo held first rank and was eagerly sought after. It was a very hard dark wood which could be given a very high polish, and was very durable. The supply is now nearly exhausted. Cuban mahogany is another variety which gives a dark red wood, and which finishes with a very fine glossy surface. In this, as in some other varieties, the wood is frequently marked with very small white pores of chalk-like substance. With age the wood of these varieties gradually darkens; it does not, however, lose its beautiful smooth finish. Other species of *Sweitenia* are shipped from Panama, from Mexico, and from South American countries.

The heavy logs of mahogany are removed from their native forests and shipped to American or foreign markets. In some varieties the logs are short and thick; often they are not perfect, having cracks or imperfections caused by branching. Some of the larger logs may be hewn square before removing from the forest, making them lighter and easier to handle. Specially valuable are those logs which when cut show a wavy grain or other irregularities. Even more valuable are blocks of mahogany which come from a large forking of the stem; from these the beautifully grained crotch mahogany is obtained. This is usually cut into thin **veneers.** In drying, mahogany shrinks very little, and once dry, is very durable, twisting or warping very little.

African mahogany is becoming increasingly valuable. It is obtained from large trees of the genera *Khaya* and *Entandrophragma,* both members of the same family as mahogany, and yielding woods very similar to it. Often appearing as mahogany are certain species of the genus *Cedrela,* which includes Spanish **cedar,** native trees of Central and South America. Many entirely unrelated woods, such as birch, maple, and even softwoods like whitewood, are frequently stained to simulate mahogany. True mahogany need not be stained. (R.M.W.)

MAHSEER, MAHASIR. Pisces, Teleostei. A large fresh-water fish (**Pisces**), *Barbus mosa,* of the Oriental region, related to the carps. It attains a length of 6′. (A.W.L.)

MAIDENHAIR TREE. *Ginkgo biloba.* Ginkgoales. The maidenhair tree is the sole surviving member of an order of **Gymnosperms** which in **Mesozoic** times was very abundant and widely distributed. Doubt exists whether the tree grows wild in any region today, though many people state that it does on the mountain slopes of China. It has been cultivated in the temple gardens of China and Japan for centuries. In late years it has been widely planted in the New World

The tree often has a tall slender pyramidal shape when young; others, and especially older specimens, are wide-spreading. The branches are of two kinds: a long shoot which grows rapidly in length and which is composed mostly of woody tissue; and short shoots or spurs which elongate very slowly. These short shoots have a large pith, a thick **cortex** and very little wood. A short shoot may sometimes (especially in the case of injury to the

long shoot) become a long shoot. The leaves of the ginkgo tree are somewhat variable in shape. Those on the long shoot are wedge-shaped and deeply notched, those of the short shoot broadly wedge-shaped and little or not at all notched. The veins are furcate, forked, as in the ferns. It is to the leaves that the tree owes its common name, Maidenhair tree, since their shape suggests that of the maidenhair fern. The trees are **dioecious**, the two types of flowers being borne on different trees. The male **strobilus** is composed of many **sporophylls**, each with two **sporangia**. The female flowers are also numerous. Each consists of a long slender **peduncle** or stalk bearing two **ovules**. In most cases one of those aborts early. The pollen grains, which consist of three small disk-shaped cells and one relatively large one, are carried to the ovule by the wind. There it forms a pollen tube which digests its way through the tissue surrounding the **gametophyte**. A pollen tube which has nearly reached the gametophyte contains two large **sperms**, each of which has a spiral coil of cilia at its anterior end. One of these sperms passes to one of the large eggs contained in the female gametophyte, and joins with it. The nucleus of the sperm unites with that of the egg, which is then said to be fertilized. The ovule containing the fertilized egg enlarges. When mature it is about an inch in diameter and green. Its outer covering is fleshy and has a curious rancid odor which is very noticeable when the fruit is crushed. Within this fleshy coat is a dry covering surrounding the gametophyte and the embryo plant. The seeds germinate readily, forming a long tap root and a short erect shoot. Young plants are rather susceptible to low temperatures, requiring some protection in the northern states. (R.M.W.)

MAIZE. Corn.

MALACHITE. The mineral malachite is a **basic carbonate** of **copper** corresponding to the formula $CuCO_3 \cdot Cu(OH)_2$. It is **monoclinic**, crystals tending to be acicular, but usually found massive. It is a brittle mineral; hardness, 3.5–4; specific gravity, 3.9–4.03; luster, vitreous to silky or dull; color, green; streak, green; translucent to opaque. Malachite is an alternation product found associated with other copper-bearing minerals. It is a rather common mineral and is found quite widely distributed. Large quantities have been found in the Ural Mts.; it is also found in Germany, France, England, the Belgian Congo, Rhodesia, and Australia. In the United States beautiful radiated masses of fibrous crystals have been found in Berks County, Pennsylvania. It has been found in Tennessee at Ducktown, and in Arizona, Nevada and Utah. Malachite besides being an ore of copper has been used for various ornamental purposes. The word malachite is derived from the Greek meaning, a *mallow*, because of its green color. (E.S.C.S.)

MALACOLITE. Diopside.

MALACOSTRACA. Crustacea.

MALARIA. A disease transmitted by the bite of infected anopheline mosquitoes, characterized clinically by recurrent paroxysms of chills, fever and sweating. In the mosquito the parasite develops on the stomach wall and in the salivary glands, while in man it grows in the red blood cells. Man, monkeys, birds, fish and cattle are subject to the disease.

Malaria is widespread in tropical and subtropical countries. Probably no other disease has disabled and killed as many people throughout the world. The combined deaths in all parts of the world where the disease occurs is probably 2,000,000 each year. In the United States, where malaria is prevalent in the southern states only, there are nearly a million cases and 5000 deaths; in India, 100,000,000 cases and 1,000,000 deaths occur annually. On the battle fronts of World War II, malaria has been one of the major problems.

In man, malaria is produced by four specific parasites which are not infectious for the lower animals. *Plasmodium vivax, P. malariae, P. falciparum* and *P. ovale.* They are transmitted by various species of anopheline mosquitoes, and undergo definite development in the mosquito necessary for their survival.

Vivax or *tertian malaria* is by far the most common type. The incubation period is about 6 days, and paroxysms of chills and fever appear on the 14th day after the bite of an infected mosquito. They continue to recur every other day, as the parasite completes its 48-hour cycle of development. During the paroxysm, the patient first goes through a "cold stage" during which he has chilly sensations, his skin is blue, his teeth chatter and there is violent shaking. After an hour, the "hot stage" is ushered in, with a rapid rise in temperature to as high as 107° F.; the skin is hot and dry and the patient complains of severe headache. The fever lasts about 2 hours, and is followed by the "sweating stage," during which there is profuse perspiration, the temperature falls to normal, the headache disappears, and although weak and drowsy, the patient feels well.

P. ovale produces a disease practically identical with tertian malaria.

Quartan malaria, produced by *P. malariae*, has an incubation period of 18 to 40 days. The paroxysms occur every 72 hours, and are longer and somewhat more severe than those accompanying tertian malaria.

Falciparum or *estivo-autumnal malaria* is a more severe disease than the other types, and is the cause of practically all deaths due to malaria. The paroxysms occur irregularly after a 12-day incubation period. They are severe, and accompanied by high temperatures. The so-called cerebral, algid, hemorrhagic and pernicious types of malaria represent forms of falciparum malaria with different localizations of the parasite. In the cerebral type, the onset is rapid with delirium and coma, and death may occur in several hours without return to consciousness. "Black-water fever" or hemorrhagic malaria is a type in which hemolysis or dissolution of the red cells occurs, and dark urine due to the presence of hemoglobin is an outstanding feature. In the algid form, there are vomiting, diarrhea, and subnormal temperature.

The treatment of malaria with **quinine** is one of the oldest examples of specific chemotherapy in medicine. Quinine has been used as a preventive in countries where malaria is endemic, and is given orally or hypodermically in the acute disease. Because of the shortage of quinine, a synthetic drug, **atabrin**, is now used, both as a preventive, and alone or in conjunction with quinine as a curative drug during the acute attack. A course of treatment with atabrin and quinine extends over one week. Although these drugs control the paroxysms of malaria, the complete eradication of the parasites is extremely difficult to accomplish. The disease therefore tends to recur again and again, even though adequate treatment be given. A malarial infection confers a low-grade very brief immunity after the acute attack has subsided.

The control of malaria is a matter of the eradication of the mosquito vector. Wherever anopheline mosquitoes breed, they must be diligently sought out and killed. This involves drainage of swamps, and clearing out of all possible breeding places. In a malaria area houses must be adequately screened, and people should not be out of doors in the evenings when anopheline mosquitoes do most of their biting. The application of mosquito-repellents to exposed areas of skin is also effective. (D.M.H.)

MALEIC ACID. Acids, Carboxylic.

MALEO. Aves, Galliformes. A peculiar bird (**Aves**) of Celebes and neighboring East Indian islands. The head and neck are covered with naked red skin and the crown bears a black prominence resembling a helmet. The plumage is mostly black but that of the breast and belly is salmon colored. The large eggs are buried in hot sand. (A.W.L.)

MALIC ACID AND MALATES. Malic acid, hydroxysuccinic acid ($H_2 \cdot C_4H_4O_5$ or $COOH \cdot CH_2 \cdot CHOH \cdot COOH$) is a white solid, melting point 133° C., decomposes at 150° C., soluble in water, alcohol, or ether. **Calcium** malate, on account of its slight solubility, is of importance in the separation and recovery of malic acid. Calcium malate plus dilute **sulfuric acid** yields malic acid plus calcium sulfate and the latter may be separated by **filtration.** Malic acid may be obtained by evaporation of the filtrate. Malic acid may be obtained (1) from some natural products, e.g., the free acid in the juice of unripe apples and gooseberries, often in conjunction with citric or **tartaric acid**; potassium hydrogen malate is present in rhubarb and currants; calcium malate in sugar "sand" by evaporation of the sap of the sugar maple, (2) by synthesis. Malic acid is a dibasic acid, that is, two series of **salts** and **esters** are known. On heating under pressure to 200° C., it is converted into fumaric acid. Malic acid is used in medicine and in the production of various salts and esters.

Ester: Ethyl malate $\begin{array}{l} CH_2 \cdot COOC_2H_5 \\ | \\ CHOH \cdot COOC_2H_5 \end{array}$ boiling point 253° C. (R.K.S.)

MALIGNANT. A term used to describe (1) an infection or disease which is especially virulent and rapidly grows worse, (2) **tumors**—cancer and sarcoma—which are non-encapsulated, spread to distant structures, and usually result fatally. (D.M.H.)

MALIGNITE. This rock is best described as a **nephelite syenite** with larger proportions of **iron** and **magnesia** than is usual in **alkali** rocks. It has received its name from the type locality on the Maligne River, Province of Ontario, Canada. (E.S.C.S.)

MALINGERER. One who pretends sickness deliberately. (R.S.M.)

MALKOHA. Aves, Cuculiformes. A **cuckoo** of Ceylon. (A.W.L.)

MALLEABILITY. Metals, Physical Properties of.

MALLEABLE CAST IRON. Malleability is understood, in most cases, to be that property which makes it possible to hammer, press, roll, etc., a metal to some finished shape. However, in the case of malleable cast **iron,** the malleable product denotes a casting which is much stronger and possesses shock resisting qualities to a much greater extent than gray cast iron. A malleable iron casting is produced from an iron casting which in the untreated state is hard and brittle. This casting is caused to have as large a silicon content as possible, since it has been found that this element promotes the change from the hard casting to the malleable form during the heat treatment.

The malleabilizing of iron castings is the conversion of cementite **carbon** into a finely dispersed graphite form, although a part of malleabilizing may result from burning out of the surface layer of the carbon by heating the casting in the presence of the oxidizing agent. The hard castings are annealed to the malleable form by packing them in an annealing box surrounded by an oxidizing agent. Crushed iron oxide and mill scale have been used for this packing, but the malleable product may be produced even if an inert packing, such as sand, be used. However, since some increase in strength is obtained by packing in an active material, castings are so treated. After packing, the boxes are placed in an annealing furnace, and held at a temperature of about 800° C. for 3–5 days, after which they are slowly cooled, and are malleable. There are two types of product:—white-heart and black-heart malleable iron. The latter is made by conducting the annealing operation at a higher temperature and shorter period of time than for the white heart, and it is more satisfactory when large, thick castings are to be annealed. (F.T.M.)

MALLOPHAGA. The **bird lice** or biting lice, constituting a small order of insects. They have flattened bodies with many spines directed backward, short legs, and biting mouths. Wings are lacking. Most species live as external parasites on birds but a few are found on mammals. (A.W.L.)

MALLOW FAMILY. Malvaceae. The plants of this family include herbs, shrubs and trees (the latter tropical), and are rich in mucilaginous substance. The leaves are alternate, and in most cases **palmately** lobed and veined, with small deciduous **stipules.** The flowers are regular and perfect, often large and showy, and variously borne. They have five (or rarely, fewer) more or less united **sepals,** five petals, and numerous **stamens,** which characterized the family by having their filaments joined to form a tube which surrounds the **styles.**

The most important member of this family is the **cotton** plant, whose fibers outrank in commercial importance all others. Okra or Gumbo, *Hibiscus esculentus,* a native of tropical Africa, is another member of importance. It is a coarse annual plant with large veiny leaves and showy axillary flowers. The slender 5-ribbed pods are used in soups, or when young, are cooked and used in salads. Okra has also been used as a source of fibers for paper manufacture. Another member of some importance is *Althaea officinalis,* the Marsh Mallow. The underground rootstock of this plant is not only rich in mucilage, but is also used medicinally in ground form, the bark being removed before grinding.

Many members of the family are grown as ornamental plants, among them being the Hollyhock, *Althaea rosea,* the so-called flowering maples, *Abutilon* sp., species of *Malva,* the true Mallows, and the Rose of Sharon, *Hibiscus syriacus,* which becomes a large bush or even a small tree, with showy pink or white flowers. (R.M.W.)

MALONIC ACID. Alcohols and Ethers.

MALPHIGIAN TUBULES. Small tubules closed at one end and connected with the alimentary tract at the other. They occur in the spiders and other **arachnids, centipedes** and millipedes, and **insects,** and function as excretory organs. The tubules vary greatly in form and number in different species. (A.W.L.)

MALT. Barley.

MALTA FEVER. Undulant Fever.

MALTOSE. Carbohydrates.

MALUS'S LAW. A law applying to the intensity of **polarized light** as affected by the polarizing apparatus. If a beam of plane-polarized light is passed through a **Nicol prism,** for example, the intensity (flux density) of the emergent beam falls off, as the prism is rotated, from a maximum value when the transmission plane of the prism coincides with the plane of vibration of the light, to zero when it is at right angles to that direction. The intensity varies as the square of the cosine of the angle through which the prism has been thus rotated. The same law applies to the effect of a

glass reflector, reflecting always at the polarizing angle, as the plane of reflection is rotated around the stationary, polarized incident beam. (L.D.W.)

MAMMALIA. Animals characterized by warm blood and hairy vestiture. The young of most species develop in the body of the mother and all are nourished by milk secreted by special glands. The teeth are of four kinds, incisors, canines, premolars and molars (**Dentition**). A class of the phylum **Chordata**, including the creatures popularly called animals without further qualifications.

The mammals are one of the dominant forms of animal life. The most important domestic species belong in this class and man himself is a mammal, hence their economic importance cannot be overemphasized. They are the source of most of the animal products used by man and include also some harmful species of predators and rodents.

The classification of the mammals is briefly as follows:

Subclass Prototheria. Egg-laying mammals.
Order **Monotremata.** The duck-bill (**Platypus**) and spiny ant-eater (**Echidna**) of the Australian region.
Subclass Eutheria. Young developed at least partly in the body of the mother.
Division Didelphia. Pouched mammals. Young born in an early stage of development and carried in a pouch on the abdomen of the female until able to walk.
Order **Marsupialia. Kangaroos** and **wallabies, opossum, koala,** and others.
Division Monodelphia. Placental mammals. Young connected with the body of the mother throughout embryonic development by a special structure called the **placenta.**
Section **Unguiculata.** Clawed animals.
Order **Insectivora.** Small furry animals, mostly nocturnal. They eat insects and smaller animals and some vegetable matter. **Shrews, moles,** etc.
Order **Dermoptera.** The flying **lemurs** of the Oriental region.
Order **Chiroptera.** Winged mammals. The **bats.**
Order **Carnivora.** The flesh-eating species, with large canine teeth and sharp-edged molars. **Lion** and **tiger, weasels, bears, skunks, seals, walruses,** etc.
Order **Rodentia.** Gnawing animals. Incisor teeth like chisels. **Rabbits, squirrels, rats, mice, porcupines,** etc.
Order **Edentata.** Toothless or with imperfect teeth. The **sloths, armadillos** and **ant-bears.**
Order **Pholidota.** Scaly ant-eaters or **pangolins.**
Order **Tubulidentata.** The **aard-varks.**
Section **Primates.** With nails instead of claws or hoofs. Appendages often differentiated as arms and legs. Thumb and great toe opposable to the other digits or anatomically similar to such appendages.
Order **Primates.** The **monkeys, baboons, apes,** man, and other related species.
Section **Ungulata.** The hoofed animals and related forms with heavy nails on the appendages.
Order **Artiodactyla.** The even-toed ungulates. The axis of the foot is through two digits. **Swine, cattle, sheep, deer, camels** and other species.
Order **Perissodactyla.** Odd-toed ungulates. Axis through the middle digit of the foot. **Horses, rhinoceroses, tapirs** and related species.
Order **Proboscidea. Elephants.** Nose and upper lip prolonged to form a trunk or proboscis.
Order **Sirenia.** Aquatic species. **Dugongs** and **manatees.**
Order **Hyracoidea.** Small animals resembling rodents. The hyraces or **conies.**
Section **Cetacea.** Highly specialized marine animals.
Order **Odontoceti.** The toothed **whales.** Sperm whales, **porpoises, dolphins,** and related forms.
Order **Mystacoceti.** Species with baleen or whalebone in place of teeth. Right whales, rorquals, and baleen whales. (A.W.L.)

MAMMARY GLAND. A large gland which secretes milk for the nourishment of the young of **mammals.** Mammary glands are structurally related to the sweat glands. They are normally functional only in the female although they develop as rudiments in the male sex. In most species the ducts of the glands open on a prominence, the teat or nipple, from which the young suck the milk, but in egg-laying mammals the milk is merely licked from the surface upon which it exudes and in some of the pouched mammals the young are temporarily attached to the teats within the pouch by an oral sucker and the milk is discharged into their mouths. (A.W.L.)

MAMMARY ORGAN. An organ developed in some of the **bryozoans** which nourishes the embryos during their attachment to the parent. (A.W.L.)

MAMMATO-CUMULUS. Clouds.

MAN. Paleontology of Man.

MANAKIN. Aves, Passeriformes. Brightly colored birds (**Aves**) of Central and tropical South America. **Chatterers.** (A.W.L.)

MANATEE, MANATI. Mammalia, Sirenia. Completely aquatic animals with a horizontally flattened oval tail, no hind limbs, and fore limbs developed as flippers. They are superficially similar to the whales but differ in many details of structure and are apparently derived from different ancestral stock. They live only in shallow coastal waters and estuaries and eat aquatic plants. Also called sea cows.

The several species of the genus *Manatus* are distributed on both shores of the Atlantic and in the Oriental and Australian regions. *M. latirostris* is found in Florida. (A.W.L.)

MANDIBLE. A structure associated with the mouth and used for biting, or if used differently, evolved from a biting organ. The term is applied to the pair of biting organs derived from jointed appendages in the **arthropods,** and, in the sucking mouths of some **insects,** to the slender piercing structures which have been shown to have the same origin. It is also used for the lower jaw of **vertebrates** and for a prominent bone of that jaw which makes up the entire structure in the mammals but is associated with other bones in the jaws of fishes (**Pisces**), **amphibians** and **reptiles.** The two parts of the beak in birds are known as the upper and lower mandibles. (A.W.L.)

MANDIBULAR GROOVE. A groove in the **carapace** of some **crustaceans** just behind the **mandible.** It may accompany the **cervical groove,** in which case it is located farther forward. (A.W.L.)

MANDREL. An arbor with a taper of about .001″ per in., upon which hollow cylinders are held for turning and facing the exterior surfaces. (H.C.H.)

MANDRILL. Mammalia, Primates. A peculiarly ugly species of African **baboon,** *Papio maimon.* (A.W.L.)

MANEUVERABILITY. That quality in an aircraft which determines the rate at which its altitude and direction of flight can be changed. (F.T.M.)

MANGABEY. Mammalia, Primates. *Cercocebus.* An African **monkey** of a small group of species also called the white-eyelid monkeys. They are slender animals with a fairly long muzzle and long tail. Related to the macaques. (A.W.L.)

MANGANESE. Symbol: Mn. Atomic number: 25. Atomic weight: 54.93. Density: 7.2. Hardness: 5. Melting point: 1260° C. Boiling point: 1900° C. No isotope, but of single atomic form: 55.

Manganese is a silver-white metal, not notably hard (becomes hard on alloying with **carbon**), brittle, capable of taking a brilliant polish but readily oxidized upon heating, reacts with water upon boiling, soluble in dilute acids. Discovered by Scheele in 1774.

Manganese occurs chiefly as **pyrolusite** (manganese dioxide (MnO_2)) in the Caucasus Mountains of Russia, India, Brazil, the Gold Coast of Africa, and the United States. 1. Treating pyrolusite **in a blast furnace** with **iron** ores and **carbon** furnishes ferro-manganese (78% Mn) and speigeleisen (12–33% Mn), both used in the production of steel. 2. Pure manganese may be obtained by ignition of the oxide with aluminum powder, or by electrolytic method from the sulfate. Small percentages of manganese are added to steel as a deoxidizer, and large percentages, say 12%, produce a very tough steel. An alloy of 20% manganese, 20% nickel, 60% copper possesses good resistance to corrosion, and by heat treatment develops greater hardness and strength than any other copper alloy. 3. When pyrolusite is heated with sodium carbonate and nitrate, sodium manganate is formed, which is then extracted with water. This is the substance from which manganese compounds are commonly obtained.

Acetate: Manganese acetate ($Mn(C_2H_3O_2)_2 4H_2O$), pale pink crystals, soluble.

Chlorides: Manganese chloride, manganous chloride, manganese dichloride ($MnCl_2 \cdot 4H_2O$), rose-red crystals, soluble to practically colorless solution by reaction of **hydrochloric acid** on manganese oxides, hydroxide, carbonate, sulfide and subsequent crystallization; manganese tetrachloride, manganese perchloride ($MnCl_4$), green solid.

Dithionate: Manganese dithionate (MnS_2O_6), by reaction of manganese dioxide suspension with **sulfurous acid.** With **sodium** carbonate yields sodium dithionate solution and manganese carbonate precipitate.

Hydroxide: Manganese hydroxide, manganous hydroxide ($Mn(OH)_2$), white precipitate but rapidly turning brown in the air by oxidation to manganic hydroxide, formed by reaction of manganese salt solution and **sodium** hydroxide solution; manganic hydroxide ($Mn(OH)_3$), brown solid.

Manganates: Sodium manganate (Na_2MnO_4) and potassium manganate (K_2MnO_4), green soluble solids, formed (1) by oxidation of other forms of manganese by heating with **sodium** carbonate and nitrate, and (2) regulated reduction of permanganate. Manganate solution is readily oxidized to permanganate in the presence of acid.

Nitrate: Manganese nitrate, manganous nitrate ($Mn(NO_3)_2 \cdot 6H_2O$), rose-red crystals, soluble to practically colorless solution.

Oxides: Manganese monoxide, manganous oxide (MnO), grayish-green solid, formed (1) by heating of manganese **oxalate,** hydroxide or carbonate in the absence of air, (2) by reduction of higher manganese oxides by heating with **hydrogen;** manganese sesquioxide, manganic oxide (Mn_2O_3), brownish-black solid, by heating manganese dioxide at 700° C.; trimanganese tetroxide, mangano-manganic oxide (Mn_3O_4), brownish-black solid, by heating any oxide of manganese at 1000° C.; manganese dioxide, manganese "peroxide" (MnO_2), black solid, by heating manganese nitrate to 200° C., used as pyrolusite in dry cell batteries, and to color glass and ceramic ware, also in the preparation of a dryer for paint and varnish oils, and in the chemical laboratory for the preparation of **chlorine** from **hydrochloric acid;** manganese heptoxide (Mn_2O_7), red oil, dangerously explosive, formed by reaction of potassium permanganate and concentrated sulfuric acid.

Permanganates: Sodium permanganate ($NaMnO_4$) and potassium permanganate ($KMnO_4$), purple-black soluble solids, the latter readily crystallized, formed by oxidation of acidified manganate solution. Permanganate solution, purple, is readily reduced to manganous in the presence of acid, e.g., by the reaction of ferrous salt.

Sulfate: Manganese sulfate, manganous sulfate ($MnSO_4 \cdot 4H_2O$), pink solid, soluble to practically colorless solution.

Sulfide: Manganese sulfide, manganous sulfide (MnS), pink precipitate by reaction of manganous salt solution and **ammonium** sulfide solution. (R.K.S.)

MANGANITE. The mineral manganite is a hydrous **oxide of manganese** corresponding to the formula MnO(OH), it occurs in prismatic **orthorhombic** crystals, sometimes in massive columnar forms. It is a brittle mineral; hardness 4; specific gravity 4.2–4.4; luster, submetallic; color, steel gray to iron black; streak, red-brown to almost black; opaque. Manganite is of secondary origin and it may itself alter to **pyrolusite.** It is usually associated with other manganese minerals. It is found in the Harz Mts., Germany; Sweden; Cornwall and Cumberland, England; and in the United States in Michigan. It is an ore of manganese. (E.S.C.S.)

MANGEL-WURZEL. Beet.

MANGO. Mangifera indica. Anacardiaceae. The mango is a long-lived tree, often developing a massive trunk and widely spreading branches. Its **lanceolate** leaves are evergreen and about 4″ long. The flowers are numerous, small, pink and borne in **racemes.** The ovoid fruits, 1–5″ in diameter, are 1-seeded berries having a thick rough greenish rind and a pleasantly aromatic orange-colored flesh esteemed by many. This fruit is eaten fresh or in salads. Unfortunately, fruits frequently occur which are not at all agreeable, because of the fibrous nature of the flesh and the unpleasant sour taste.

Reproduction is either by seedlings, which do not always come true, or by grafting. The tree is extensively cultivated in tropical regions, and is now grown in Florida, southern California, and tropical America. For successful growth hot moist weather is necessary, followed by a short dry period for successful ripening of the fruit. (R.M.W.)

MANGOSTEEN. Garcinia. Guttiferae.

MANGROVE. *Rhizophora Mangle.* Rhizophoraceae. The mangrove is a moderate-sized tree which grows on low, often submerged, coastal lands. It is found, for instance, in all tropical American coasts. The leaves of the plant are opposite, entire, dark green, and rather tough. The flowers are borne in small clusters and are perfect, with four **sepals,** four pale yellow linear petals, four to twelve **stamens** and single 2-celled inferior **ovary.** Only one **ovule** develops. The seed usually germinates while the fruit is still attached to the tree. A long thick **hypocotyl** grows from the fruit, and attains a length of 5–10″ and a diameter less than ¾″. Eventually an **abscission layer** develops, so that the fruit, in which the young seedling is well advanced in germination, falls to the soft muddy ground, in which

the new tree will grow. Because the lower part of the hypocotyl is heaviest, it strikes the ground first and so sinks into a position most favorable for further growth. Should it fail to penetrate into the mud, the upper and lighter portion of the germinated fruit causes it to float until a favorable environment is reached. In a favorable location the hypocotyl puts out many roots, which anchor the young plant; then the **epicotyl** quickly grows. It is characteristic of the mangrove that from the stem and branches there grow out arching prop roots which soon form an intricate mass in which is deposited silt and all sorts of debris floating in the water. Because of this the mangrove causes a gradual building up of the land around it, until eventually the black slimy mud in which it grows gives place to a low coastal land which gradually becomes usable by man.

In addition to its land-forming function, the mangrove has other uses. The wood is dark red or reddish-brown, fine-grained, and hard; it is used in charcoal making. The bark contains **tannin** and so is employed in tanning hides. From the young shoots a reddish dye may be obtained, which, however, is of little value. (R.M.W.)

MAN-HOLE. A man-hole is a means of ingress and egress to a region, ordinarily and normally not occupied by humans, but occasionally necessitating inspection or repair by them. Sewers, tanks, boiler drums, and many other structures are equipped with one or more man-holes which are often only of sufficient size to permit a man to crawl through with considerable difficulty. Normally these openings are closed by man-hole covers. (F.T.M.)

MANIA. A state of extreme excitement or exaltation. Mania is characterized by violence, hallucinations, delusions, and often requires restraint to protect the patient as well as others. Mania occurs as an acute toxic reaction to drugs and certain infections, or as a part of the picture in psychoses, particularly those of the manic-depressive type. (D.M.H.)

MANIC-DEPRESSIVE PSYCHOSIS. A severe mental illness characterized by alternating phases of excitement with elation and profound depression. Between these episodes the individual is normal in a typical case. Occasionally patients experience only one attack; in others, the alternating episodes become continuous.

The cause of this psychosis is unknown. There is a definite hereditary tendency and women are more often affected than men. The manic-depressive is almost always an extrovert and often is of the short, stocky type of body build. This disease is little understood, but is thought to be related to a disturbance in the emotional life, usually based on fears, uncertainties and insecurity. It is a more complete and serious personality disorder, and unlike a simple **psychoneurosis**, results in abnormal behavior.

The manic phase is usually preceded by a mild depression for a few days. Then, gradually, excitement begins. At this stage the patient is buoyant, full of self-confidence, liberal with his money, aggressive and boastful. As his excitement increases he becomes talkative, argumentative, full of schemes and pranks. His good humor is sustained until he is crossed in his wishes, when he becomes angry and vociferous in abuse. He quickly recovers his good spirits, and is able to be extremely active for days with little sleep, and declares he never felt better in his life. This period is classified as one of hypomania. It passes imperceptibly into the period of **mania**, when the mounting excitement reaches a pitch of joyous exaltation, accompanied by rapid uninterrupted speech, with continuous flight from one subject to another, singing, dancing, aggressive sexual behavior, and sometimes violent destructive motor activity. Throughout the episode, the patient remains oriented as to his environment. **Hallucinations** rather in the nature of transitory illusions occasionally occur. Delusions usually of the grandiose wish-fulfillment type may occur, and ideas of persecution are not rare. The average duration of manic attacks is 6 months.

The depressive phase in a large per cent of individuals appears after several manic episodes a few years apart. It begins with a mild depression of spirits. The patient lacks confidence in himself and feels inadequate. Gradually he slips into a severe depression. He sits with his head hung down, his body stooped; his attitude is one of hopelessness, despondency and profound unhappiness. Thought and speech are slow; ideas of guilt, remorse and **hypochondriasis** predominate. Ideas of persecution may be present, but hallucinations are uncommon. In extreme forms, there is complete absence of motor activity, and stupor may develop. Sometimes threats and attempts at suicide are carried out. In some patients the depressive state is combined with mania, and instead of joy coloring the manic phase, loud grief and woe predominate.

Both the manic and the depressive stages of this psychosis often represent defense reactions on the part of the patient—unconscious defences against his fears, or insecurity. The elation is an over-compensation, an effort to bluff himself into believing he is not afraid. This mechanism in mild form is used frequently by normal people, but in the manic it becomes a fixed pattern which he cannot escape. The depressive phase, also, is an unconscious defense in the form of a withdrawal from the active life which is full of disappointment and insecurity.

The prognosis for a single manic or depressive episode is good, but recurrences are common. Treatment during these episodes is symptomatic—restraining and attempting to quiet the manic, and caring for the depressed individual, protecting him from suicide, giving him an adequate diet and tube-feeding if necessary. During the normal intervals between the psychotic episodes, psychotherapy directed toward discovering the patient's emotional problems and helping him to adjust himself to them, offers the most hopeful method of preventing future attacks. (D.M.H.)

MANIFOLD, ENGINE. With particular attention to the **internal combustion engine** in the multi-cylindered form, the manifold is that part which distributes a common fuel-air mixture uniformly to each of the several **cylinders**, or which gathers up the exhaust gases after they issue from the cylinders and combines them into one exhaust stream. Since the great majority of internal combustion engines are multi-cylindered, and further, since the purpose of multi-cylinders is to provide more uniform flow of power, the manifolds must be well chosen and correctly patterned, or else they will tend to offset the advantage of the multi-cylinder arrangement.

Considering problems of manifolding from the standpoint of gasoline engines, in which they are most difficult, the condition which the manifold must meet is that of equal distribution of fuel and air to the different cylinders without permitting any segregation of the heavier fuel particles, and without creating much pressure drop by friction. The inlet manifold is attached at its discharge end to the inlet ports of the cylinders, and at its other end to the outlet of the carburetor. A carburetor does not perfectly vaporize and mix a fuel with air so that an equal distribution of the volume of the fluid passing through the manifold is not necessarily an equal distribution of the fuel to the separate cylinders because of the inertia of the heavier fuel particles; therefore bends have to be carefully laid out, and any factors which might tend to deflect the stream unevenly into one limb of the manifold should be eliminated. Inlet

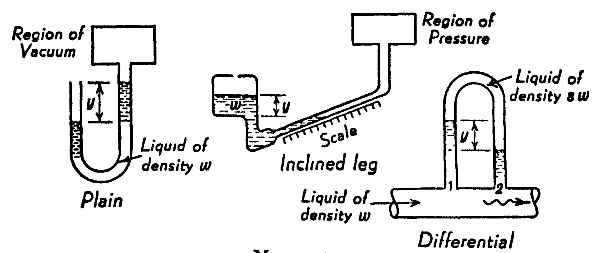
manifolds may be either updraft or downdraft, depending on the relative location of carburetor and cylinders. It is much simpler to maintain uniform mixture in a downward moving stream than in the upward. Many manifolds are provided with what is known as a hot spot, which is a portion of the manifold upon which the heavier gasoline particles will strike, and which by the heat it contains will immediately vaporize these heavier particles. In an ordinary T-shaped manifold, the hot spot should be placed at the top of the vertical stem, where it will form a target for the ascending droplets of gasoline. While shape of the inlet manifold is a matter of great importance, the material of it is not, since the inlet manifold is kept cool by the inflowing mixture. It should be tight and smooth internally.

The exhaust manifold conveys a stream of heated gas which may, at times, cause it to reach red-hot temperatures, and it must be constructed of a material capable of resisting such conditions, and be provided with some means of expanding and contracting with variation of temperature. Some large engine exhaust manifolds are water-jacketed. The ideal exhaust manifold has a separate lead from each cylinder, each lead being streamlined into a common stack or exhaust pipe at some distance from the cylinder. If this is not possible, the manifold should be divided into sections so that two cylinders will not exhaust into the same section simultaneously. Where the noise of the exhaust is not objectionable, or is less objectionable than the back pressure created by the exhaust manifold, exhaust may either be freed directly from the ports, or from short, straight exhaust stacks discharging directly to the atmosphere. (F.T.M.)

MANILA HEMP. *Musa textilis.* Musaceae. The Manila Hemp plant is a perennial herb having an underground **rhizome** from which the very large leaves rise directly. The apparent stem, which may be as much as 20′ in height, is composed of the tightly overlapping, broad leafstalks. The flower stem grows up through the center of the column formed by the leaf-bases and bears inconspicuous flowers covered by reddish bracts. The fruit is green, banana-like and filled with numerous seeds. The native home of the plant is the Philippine Islands.

To obtain the fibers the so-called stem of leaf-bases is cut down and at once cut in long narrow strips. By drawing these over a dull knife the fibers are cleaned of most of the non-fibrous substance surrounding them, leaving uniform strands 6–10′ or more long. The fibers are white to buff-colored and lustrous, coarse and very strong. They are extremely durable, little affected by water, and hence much used for making cables, hawsers and marine cordage. The finer strands may be spun into thread and from that coarse cloths woven. Manila waste and worn-out manila products are used in making a very tough paper known as manila paper. The plant is extensively cultivated, especially in the Philippine Islands. The cultivated plant yields a better grade of fiber. Another name given to the fiber is **abaca.** (R.M.W.)

MANOMETER. Pressures which are so small that the Bourdon tube **pressure gauge** is not accurate, are conveniently measured by a liquid manometer. This instrument is one which balances fluid heads in a glass tube so that readings may be taken by comparing the registry of menisci on a scale mounted alongside the tube. In its simple form, it consists of a U-tube, one end of which is open to the atmosphere, and the other to the region where the pressure is to be measured. If the pressure is different from atmospheric, the liquid with which the manometer is partially filled will stand higher in one leg of the tube than the other. As shown in the accompanying illustration, the manometer is connected to a vacuum, the balancing head on the low-pressure leg. Since the other leg is open, the pressure head y is either the vacuum or the gauge pressure. The magnitude is yw



Manometers.

lbs. per sq. ft. when y is measured in ft. and w in lbs. per cu. ft. To make the instrument more sensitive, one leg may be inclined at a large angle to the other so that a given vertical displacement of the meniscus will travel a considerably larger distance along the scale. Of course in this type the other leg must be of enlarged cross-section so that its level will not vary appreciably as the meniscus travels along the scale. The scale can be calibrated to read any desired pressure units.

Very small pressure differences are measured by differential manometers, a simple form of which is shown. Suppose that a liquid of specific weight w is flowing along a pipe and it is desired to measure the friction loss between points 1 and 2. An inverted U-tube is connected, having its upper portion filled with a non-miscible liquid of specific weight sw. The difference of pressures at points 1 and 2 will then be $wy\ (1—s)$. Very small differences of pressure may thus be indicated by a readable displacement y if s approaches unity; that is, if the two liquids are nearly of the same density. (F.T.M.)

MANTIS. Insecta. Orthoptera. A large **insect** of predacious habits. The body is moderately broad and bears four wings. The first segment of the thorax is long and rather slender, adding to the reach of the powerful raptorial front legs. The head is prominent and has large eyes.

From the fancied suppliant air of these voracious insects as they await their prey with the forelegs uplifted they are called praying mantises, and their owlish expression has given them the rarer name of soothsayers. The common species is *Mantis religiosa.* (A.W.L.)

MANTIS FLY. Insecta, Neuroptera. Small predacious insects superficially like the **mantis** in form. They make up the family Mantispidae and are also called mantispas. (A.W.L.)

MANTIS SHRIMP. Crustacea, Hoplocarida. Moderately large marine **crustaceans** with a pair of powerful grasping appendages formed like those of the mantis. They are named for their superficial resemblance to the shrimps on one hand and to the mantis on the other. (A.W.L.)

MANTISSA OF A COMMON LOGARITHM. **Logarithms.**

MANTLE. 1. A fold of the dorsal body wall of **mollusks.** It secretes the shell, forms a respiratory chamber, and in some species encloses the body. 2. The wall of the body of **tunicates,** beneath the enclosing tunic. 3. Folds of tissue forming a dorsal and a ventral flap which secrete the shell in the **brachiopods.** (A.W.L.)

MANTLE ROCK (REGOLITH). The term mantle rock is applied to all of the loose unconsolidated ma-

terial which is found at the surface of the earth and covers, more or less completely, the solid rock beneath.

Regolith, derived from the Greek word meaning a cover and stone, is essentially synonymous with mantle rock. (R.M.F.)

MANUBRIUM. 1. A projection at the axis of the body of a **medusa** on which the mouth opens. In some species the reproductive bodies (**gonads**) develop in the manubrium. 2. A handle-like process, such as the uppermost piece of the **sternum.** (A.W.L.)

MANUCODE. Aves, Passeriformes. A name applied to a few smaller **birds of paradise** of several islands of the Australian region. Derived from the generic name *Manucodiata* which is in turn a corruption of a Malay name. (A.W.L.)

MANUL. Mammalia, Carnivora. A wild **cat,** *Felis manul,* of Siberia, Mongolia and Tibet. It is about the size of the domestic cat and varies from buff to silver-gray in color. Also called Pallas' cat. (A.W.L.)

MAP. A drawing which describes portions of the earth's surface is called a map. Since there are many different purposes for which maps are used, different kinds of maps are made. For example, there are the topographic maps, land subdivision maps, general geographic maps, geologic maps, etc. The features which are expressed on a map will vary with the degree of specialization of use of the map, even to the point of excluding all features except those which are to be emphasized. For example, railway maps show little other than the line of the railway and the towns along its route. Since the surface of the earth is in three dimensions, it is necessary to use some special method of showing the altitude of the surface. Otherwise the drawing would be capable of showing only breadth and length of an area. A topographic map is one on which the altitude is shown by some conventional means, usually contour lines or hachures. Other features of the landscape, such as bluffs, woodland, streams, marshes, may be included on the topographic map by generally accepted symbols. The standard symbols of the U. S. Geological Survey are more often used than any others. (See **Contour.**)

A planimetric map is one which shows natural and artificial features of the earth's surface. **Contours** are not drawn on this map. A hydrographic map is a map showing the shore line and the configuration of the bottom of a body of water (see **Hydrographic Surveying**).

A map may be oriented or interlocked with adjacent plats by giving the direction of either true or magnetic north on the map, or by placing thereon some of the meridians and parallels of the earth. The former method is suitable to maps of small areas, the latter for depicting the larger areas, states, and countries. Maps of large areas must show the surface of a sphere, as that is the shape of the earth. It is not possible to represent accurately a spherical surface on a flat surface, therefore some approximation, or some method of representation which is correct in some, but not all respects, must be employed in mapping large areas so that the effect of curvature is not neglected. (See **Map Projections and Charts.**)

Most maps are of no value in **navigation** and some of them are actually dangerous to use for this purpose since they emphasize some features in such a manner as to be misleading. As an extreme case we have Mark Twain's balloon pilot, who lost his way because a state boundary was crossed without the change in color of the land that was indicated on the map!! **Charts** should always be used for navigational purposes.

The scale of a map is the fixed ratio between corresponding distances on the map and on the territory which the map portrays. Scales are numerical or graphical. A numerical scale may be given in terms of one inch on the map equals a certain whole number of feet or miles on the ground; or it may be stated as one unit on the map equals a certain number of the same units on the ground. When the latter method is used, the scale is in fractional form having a numerator equal to unity. This is called the representative fraction. A graphical scale is a subdivided reference line drawn on the map to the same scale as that used in plotting the map. The subdivisions are marked in terms of the units of measurement of the numerical scale. A graphical scale should always be given if distances are to be scaled because the materials on which maps are made are subjected to changes in linear dimensions due to climatic conditions. A graphical scale is also necessary for use in connection with scaling distances from a photographic reproduction of an original map when the size has been changed. (F.T.M., W.K.G., C.W.C.)

MAP PROJECTIONS. The numerous methods for representing the surface **of** the **earth** on a plane are known as map projections. The term originated from the geometric-projection methods of drawing lines from some point out through the surface of the earth to a developable surface. The surfaces most commonly used in the geometric projections were the **plane,** the **cylinder,** and the **cone.** In most cases, the distortions introduced by the strictly geometric projections are intolerable for modern purposes, and the term map projection has been expanded to include all sorts of purely mathematical methods for representing the surface of the earth on a plane. The pattern of lines on the **map** or **chart** representing meridians of **longitude** and parallels of **latitude** form what is known as the **graticule** of the projection.

The growth of geopolitics and the increase of air travel have provided powerful stimuli to the general subject of cartography and many ingenious map projections have been devised. It is impossible to include anything like a complete list of modern maps and charts, but particular attention is directed to those which are of value in modern **navigation** such as: **Mercator, gnomonic, polyconic, cylindric, Lambert** and **stereographic** projections. (W.K.G.)

MAPLE SUGAR. Sugar.

MARAL. Mammalia, Artiodactyla. A Persian **deer,** *Cervus elephas maral,* of the red deer group. (A.W.L.)

MARBLE. Technically speaking this term should only be applied to metamorphosed, recrystallized **limestones** and **dolomites.** It is generally used as a trade term, however, for any crystalline **calcium** carbonate rock of pleasing pattern and color when cut and polished. Some marbles are almost pure white, as in the case of the best statuary marble, but various impurities produce marbles of all colors, shades and patterns. In the northern Appalachians there is a great belt of marbles which, in Vermont, have been developed into one of the greatest marble-producing regions in the world. Here are quarried and mined a variety of marbles which compete with the Italian **travertines** and **breccias.** Including the more common stone, which is bluish gray, are such decorative types as red, verd antique, black, green and pink. Other producing states are Alabama, Massachusetts, North Carolina, Maryland and Virginia. The amount of marble produced in the United States in 1933 was equivalent in value to $6,236,508. (R.M.F.)

MARCASITE. The mineral marcasite, sometimes called white iron pyrites, is, like ordinary **pyrites,** disulfide of **iron** corresponding to the same formula, FeS_2. Marcasite, however, crystallizes in the **orthorhombic** system often yielding serrate, spear-shaped **twins,** hence the name "cock's comb pyrites" It is a

brittle mineral; hardness, 6–6.5; specific gravity, 4.85–4.90; luster, metallic; color, light bronze-yellow; streak, grayish-black; opaque. Marcasite alters very easily and may disintegrate with the formation of sulfuric acid and iron sulfate. Fossils replaced by marcasite are therefore often destroyed after being placed in collections. Marcasite is found in numerous places in Europe, Czechoslovakia, France, England, etc.; in Mexico, and in the United States in the lead districts of Illinois, Wisconsin and Missouri. The name marcasite is believed to be of Arabic origin and formerly was applied to common pyrite. (E.S.C.S.)

MARE. The female of the **horse** and related species with the exception of the asses. Females of these animals are called jennets. (A.W.L.)

MARE'S TAIL. Detached fragments of fibrous cirrus appearing in streaks with feather-like tufts at one end. (P.E.K.)

MARGAY. Mammalia, Carnivora. A wild **cat** of moderated size. It is reddish marked with black spots. Mexico to Paraguay. (A.W.L.)

MARIALITE. Wernerite.

MARIHUANA. Hemp.

MARINE BIOLOGY. The study of all living things found in the ocean and their interrelations.

The masses of water in the oceans are so great that all human knowledge of the living things within them must be a very small part of their story. Most investigations have been conducted in the shallower waters near the shores. Specially equipped ships have occasionally conducted extensive towing operations in deep as well as shallow waters but this work is hampered by the great expense involved and discloses only such forms of deep-sea animals as can be taken in relatively small nets. The recent use of the bathysphere by Beebe and Barton for direct observation down to a half-mile depth has shown that large fishes also occur in the abysses.

Many marine laboratories have been established primarily for the study of marine biology. Among them the station at Naples is famous. In the United States, stations are located at Woods Hole in Massachusetts, Cold Spring Harbor on Long Island, Friday Harbor on Puget Sound, and in other favorable places. The Bermuda Biological Station for Research, formally opened in 1932, is one of the most favorably located institutions for all oceanographic work. (A.W.L.)

MARINER'S COMPASS. Compass.

MARJORAM. Mint Family.

MARKHOR. Mammalia, Artiodactyla. A wild *goat, Capra falconeri,* of the Himalayas. It is a large and variable species with long horns, spirally twisted although in variable forms. (A.W.L.)

MARL. Marl is a loose earthy deposit of **calcium** or **magnesium** carbonate mixed with clay in varying proportions. It is usually gray but the color may be affected by the presence of other substances, such as **iron** oxides. Marls are believed to have accumulated in fresh-water basins as they are frequently found carrying shells of fresh-water **mollusks,** then called shell marl. If sand is present in any quantity it is then called sandy marl. There are considerable deposits of marl in the **Tertiary** formations of the Atlantic and Gulf States. (E.S.C.S.)

MARLIN. 1. Pisces, Teleostei. Large marine game fishes (**Pisces**) taken in the warmer waters of the Atlantic. Related to the swordfishes and sailfishes. 2. Aves, Charadriiformes. The marbled **godwit.** (A.W.L.)

MARMOSET. Mammalia, Primates. Small **monkeys** of Central and South America. They have only thirty-two teeth, four less than the other American monkeys, and the thumb is not opposable to the fingers. All digits but the great toe bear claws instead of nails. They constitute the family Hapalidae.

Most of these monkeys are called marmosets but the common Brazilian species, *Hapale jacchus,* is also known as the ouistiti and the group of long-tusked marmosets, *Mystax,* are called tamarins. One species, *Midas aedipus,* of the Isthmus of Panama, bears the French name pinché. (A.W.L.)

MARMOT. Mammalia, Rodentia. Stout-bodied burrowing animals of moderately large size. The common **woodchuck** or groundhog, *Marmota monax,* is a familiar North American species, and in the western states others occur, one of them, *M. caligata,* known as the whistler. In Europe and Asia the bobac, *M. bobac,* alpine marmot, *M. marmota,* golden marmot, and several other species occur. The fur is sparse and rather coarse but it is used to a limited extent. The flesh is edible. (A.W.L.)

MARQ SAINT HILAIRE. Celestial Navigation.

MARS. (See planetary tables, page 1109.) Mars, the "ruddy planet," is the fourth **planet** in order of distance from the sun. It has been observed from remote antiquity since its ruddy color and relatively rapid motion among the stars make it a very conspicuous object. Within the past 50 years there has been a great deal of speculation relative to the possibility of there being intelligent life on this planet, and, for this reason, there has probably been more printers' ink expended in pseudo-scientific articles about conditions on Mars than on any other astronomical object, with the possible exceptions of the sun and moon.

Since the **orbit** of Mars lies entirely outside of the orbit of the earth, the planet can never be seen in the crescent **phase.** However, at **quadrature,** Mars does present a distinctly gibbous-phase condition as seen with a telescope.

Mars is best observed at **opposition** for during this **configuration** it is on the **meridian** at midnight. The distance from the earth at an average opposition is about 78,200,000 kilometers (48,600,000 miles), but at a "favorable opposition" (i.e., with the earth at **aphelion** and Mars at **perihelion**) this distance is reduced to 55,700,000 kilometers (34,600,000 miles). These favorable oppositions occur at intervals of from 15 to 17 years.

The question regarding the possible habitability of Mars, or of any other planet, may be said to hinge upon two questions, not mutually exclusive: the **temperature** of the surface, and the existence and character of an **atmosphere.** The temperature of the surface of Mars has been a vexing one for a long time, but has apparently been definitely settled by the brilliant research both at the Lowell and Mt. Wilson observatories. Using independent methods, both agree that the temperature of the planet's surface is approximately 283° K. (50° F.) at the equatorial regions at noon—a condition well adapted for life as we know it on the earth. The question regarding the atmosphere of Mars cannot be said to be as definitely settled as the surface temperature. The **surface gravity** of the planet is such that the planet could retain an atmosphere of oxygen, nitrogen, and other heavy gases, and probably water vapor as well, but could not hold the light gases such as hydrogen and helium. The clarity with which the surface features of the planet can be observed and the absence

of any definite cloud effects seem to indicate conclusively that there is very much less atmosphere than we have on the earth. At the Mt. Wilson Observatory, using the most powerful instruments and most delicate tests, it has been shown that the amount of oxygen over the planet's surface cannot exceed a thousandth part of that over the surface of the earth, and that the planet's atmosphere and surface must be exceedingly dry.

Through even a moderately large telescope, Mars is a very beautiful object, with a number of large and permanent surface markings clearly visible. From the motion of these surface markings the rotation period of the planet has been definitely determined as about 24.5 hours. It has also been determined that the planet's equator is inclined to the plane of the orbit of the planet at about 24°. Both of these figures indicate that the day and night conditions and **seasonal** changes on Mars are comparable with those on the earth, with the exception, however, that the Martian year is about twice as long as the corresponding period on the earth.

The greater portion of the surface of Mars is reddish in appearance, but there are large and well-defined greenish-gray areas, and brilliant white caps at the polar regions. The reddish areas do not show any seasonal changes, and are believed to be desert areas, possibly similar in character to regions on the earth such as Sahara. The dark areas, unfortunately known as seas, show definite seasonal variation in color, having a more strikingly greenish tint during the summer than in the winter. The seasonal changes of these dark areas have been ascribed by many reliable authorities as due to some form of vegetation and there seems to be no need for rejecting this possibility, in spite of the low oxygen content of the atmosphere and scarcity of water. The changes in appearance of the polar caps with season is most striking. During the winter season in the northern Martian hemisphere the polar cap is extremely prominent, while no cap whatsoever appears at the south pole. As spring approaches in the north the north cap shrinks and the south cap grows until the north cap entirely disappears. It has long been believed that the polar caps are composed of snow, but whether this is actually frozen water or of some other form of frozen gas is not definitely known.

The question regarding the fine details on the surface of Mars, in particular the so-called canals, is still a puzzling one. In 1877 and again in 1879 Schiaparelli announced the discovery of a number of fine dark lines crossing the surface of the planet. During the next 50 years a great many observers searched for the canals with varying degrees of success. Schiaparelli, Lowell, E. C. Pickering, and a number of other observers saw the canals and were able to construct detailed maps of them. On the other hand, Barnard and a number of other excellent observers were never able to see any trace of the canals. All of the observers who have been able to see the canals agree that they show great variations in visibility and also that they show seasonal variations. Even taking this into account, it is difficult to understand why Barnard, one of the most skillful of observers, and working with the best instrumental equipment in the world, should never be able to see the canals at all. To date the canals have never been positively photographed, and until their reality is proved beyond serious doubt, it is futile to speculate regarding their origin or purpose.

Mars has two **satellites**, both discovered by Hall in Washington in 1877. They are both very small and relatively close to the surface of the planet. The inner one is so close that it revolves about the planet in about 7.5 hours, about ⅓ of the rotation period of the planet, and hence rises slowly in the west and sets in the east, contrary to all other celestial objects observed from Mars. This is the only case on record in the solar system where a satellite has a period of revolution shorter than the rotation period of the planet. (W.K.G.)

MARSH GAS. **Methane.**

MARSH TEST. **Arsenic.**

MARSH MALLOW. **Mallow Family.**

MARSUPIAL MOLE. Mammalia, Marsupialia. A pouched burrowing animal, *Notoryctes typhlops,* found in a very limited part of Australia. It is about the size of the true moles and resembles them in the soft fur, the rudimentary eyes, the enormously developed claws, and the lack of external ears. Also called the pouched mole. (A.W.L.)

MARSUPIALIA. The pouched mammals, including the kangaroos, opossums, and many less familiar forms. The order is characterized by the presence of a marsupium or pouch on the abdomen of the female in which the young complete their development. They are born in a very early stage. With the exception of the opossums of the Americas, all marsupials occur in the Australian region.

The principal forms in this order are the **kangaroos** and **wallabies, phalangers, wombats, bandicoots, dasyures, pouched mole,** and **opossums.** (A.W.L.)

MARSUPIUM. A pouch formed of a fold of skin on the abdomen of the female. The teats open into this pouch and the young, born in a very early stage of development, are transferred to it. They adhere to the teats by a temporary sucker and the milk is discharged into their mouths. (A.W.L.)

MARTEMPERING. **Steel.**

MARTEN. Mammalia, Carnivora. Slender animals with short legs and a moderately long bushy tail. Related to the weasels but larger. The several species live in the northern hemisphere.

Some of the most valuable furs marketed are those of martens, and all species bear fur of fine quality. The sable of northern Asia, *Martes zibellina,* and the marten of northern North America, *M. americana,* produce the most valuable fur, although that of the fisher is also good. The fisher, *M. pennanti,* formerly ranged over most of North America, but is now found only in the wilder northern areas. It is also called the pekan and the American marten is sometimes known as the American sable. (A.W.L.)

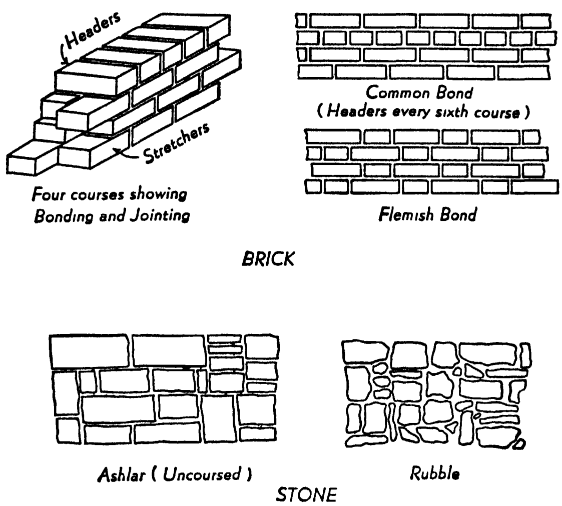
MARTENSITE. **Steel.**

MARTIN. Aves, Passeriformes. Any of several species of **swallows,** represented on all continents except Australia. They have the short beak and wide mouth of the swallows and either a forked or a square tail. They nest about houses, on cliffs, and in burrows and hollow trees. North America has one species, the purple martin, *Progne subis.* The male is glossy blue-black and the female somewhat duller. These birds commonly nest in the cornices of buildings or in bird houses where they live in colonies. (A.W.L.)

MASK. A peculiar hinged appendage associated with the mouth of the immature **dragon fly.** It can be extended to catch the animal's prey. A modified **labium.** (A.W.L.)

MASONRY. Masonry is a term applied to structures composed of individual units laid in and bound together by mortar. The common materials of masonry construction are brick, stone, and tile. Masonry is one of the most durable and permanent types of construction, since the materials which enter into it are but little affected by the elements. However, the quality of masonry construction depends on the mortar and caliber

of workmanship employed in its construction. Masonry is used chiefly in the walls of buildings, retaining walls, **piers**, buttresses, **arches**, **foundations**, and monuments. Brick masonry is used more frequently than any other type. Brick walls may be either solid or veneered. Veenered construction has strength imparted by a framework of wood or a rough masonry wall composed of concrete or tile blocks, over which is placed a layer of bricks which give weatherproofing and a finished appearance to the wall. The veneered wall is often superior to a solid brick wall. Solid brick masonry is



Masonry.

made of two or more layers of brick with the bricks running longitudinally, bound together with bricks running transverse to the wall. These brick arrangements are known respectively as stretchers and headers. The method of alternating stretchers and headers gives rise to different bonds, such as the common bond, the English bond, and the Flemish bond. There is not a great deal of difference between these bonds from the utilitarian standpoint, but the appearance of the finished wall is somewhat different, and these bonds have been developed to suit different tastes.

Blocks of cinder concrete, or of ordinary concrete, and blocks of hollow tile are known as building blocks. They are much larger in size than the ordinary bricks, and lay up much faster in the wall. Furthermore, cinder and tile masonry have but little water absorption compared to solid brick masonry. While these blocks are used alone for commercial walls such as factories, garages, etc., their use in the best grade of construction is limited to backing up brick veneer and to interior partitions and cellar walls.

Stone which is worked into the masonry may be dressed or rough. Stone masonry wherein the stones are dressed to flat surfaces is known as ashlar masonry. Stone masonry with irregularly shaped stones is rubble masonry. Both ashlar and rubble masonry may, by the selection of stones, be laid in course, but a great deal of stone masonry is uncoursed.

The strength of masonry walls is dependent upon the bond between the building material and the mortar, but not entirely so, since the complete filling of the space between adjacent bricks or stones with a mortar which hardens so interlocks the units that a strong masonry wall would be obtained even with no adhesion between mortar and brick. The irregularities of stone surfaces, and the artificially made grooves or recesses of building blocks, aid this interlocking action. (F.T.M.)

MASS. Few terms are used in physics with greater frequency and assurance than "mass of a body," and few are more difficult to define. Mass is often confused with weight, a mistake not helped by the use of the same names for the units of mass and of weight (e.g., gram). What appears to be the only inseparable attribute of mass is **inertia**; and, indeed, for the purposes of dynamics, inertia may be taken as the measure of mass. One body has twice as much mass as another body if it offers twice as much force in opposition to the same acceleration, no matter where the two bodies may be in the universe. The **relativity** theory teaches, however, that the inertia of a body, and hence its mass, is dependent upon its motion. If in any state we consider the body at rest, and call its mass in that state m_0 (the "rest mass"), then when the body is given a velocity v with respect to that state, the mass becomes $m = m_0(1 - v^2/c^2)^{-1/2}$, in which c is the velocity of light; so that at a speed of about 160,000 miles per sec., the mass of a body would be doubled. The concept of the "electromagnetic mass" of electric charges was developed by Maxwell (see **Electromagnetic Field**). (L.D.W.)

MASS ACTION, LAW OF. Equilibrium.

MASS CURVE. Impounding Reservoir.

MASS DIAGRAM. Earthwork.

MASS, LAW OF CONSERVATION OF. Matter cannot be created nor destroyed. This law holds within the experimental error of the most precise **chemical reactions**. However, matter is believed to be converted into energy according to the Einstein equation (energy equals mass times the velocity of light squared) in many of the atomic disintegrations. (See **Radioactivity.**) (R.K.S.)

MASS POTENTIAL. Potential.

MASS PRODUCTION. Measurement.

MASS RATIO. Rockets.

MASS SPECTROGRAPH. Any type of apparatus for sorting streams of electrified particles in accordance with their different **masses** by means of deflecting fields. If a particle of mass m (grams) carrying a charge E (e.m.u.) and moving with the **kinetic energy** EV corresponding to its passage through an accelerating potential drop V (volts), enters a uniform transverse **magnetic field** of intensity H (oersteds), it will follow a circular path whose radius is

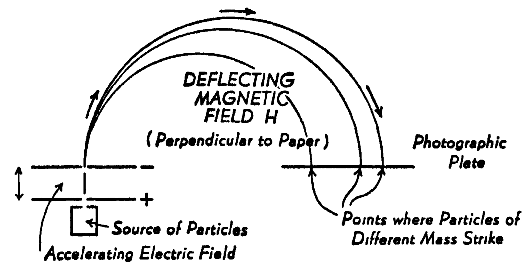
$$r = \frac{1}{H}\sqrt{\frac{2mV}{E}}.$$

H and V may be given known values, and r may be observed; then from the above formula, the mass

$$m = \frac{H^2r^2}{2V}E$$

may be calculated. If the particles are ionized molecules or atoms (e.g., positive rays), E will be some multiple of the electronic charge $e = 1.602 \times 10^{-20}$ (e.m.u.), so that particles of any one mass will move on different radii according as they happen to be singly, doubly, ... , multiply ionized; while all singly ionized particles moving on different radii will be known to have masses in proportion to r^2. The figure shows, in purely schematic form, one type of apparatus arranged for this purpose. (In the Aston spectrograph the particles pass through both an electric and a magnetic field, the separation produced by the one being offset by a convergence due to the other; in which case V need not be known.) By

means of such "magnetic analysis," much has been learned concerning the actual masses of atoms and other particles, and the **isotopes** of elements. (See **Chemical Composition.**) (L.D.W.)

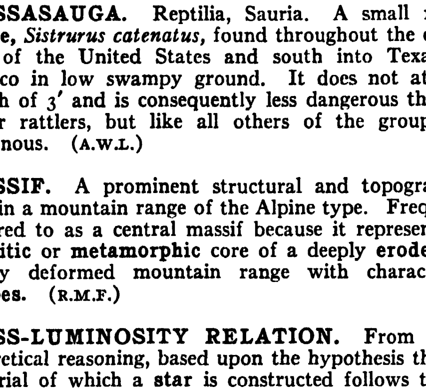


The particles follow semicircular paths and make spots where they strike the plate.

MASSASAUGA. Reptilia, Sauria. A small rattle-snake, *Sistrurus catenatus*, found throughout the eastern half of the United States and south into Texas and Mexico in low swampy ground. It does not attain a length of 3′ and is consequently less dangerous than the larger rattlers, but like all others of the group it is poisonous. (A.W.L.)

MASSIF. A prominent structural and topographical unit in a mountain range of the Alpine type. Frequently referred to as a central massif because it represents the **granitic** or **metamorphic** core of a deeply **eroded** and highly deformed mountain range with characteristic **nappes.** (R.M.F.)

MASS-LUMINOSITY RELATION. From purely theoretical reasoning, based upon the hypothesis that the material of which a **star** is constructed follows the gas laws, Eddington was able to show that there should be a relationship between the mass and the total radiation from a star. The details of the theory are far too complex to be included here, but it should be emphasized that the conclusions are based upon purely theoretical reasoning and not upon a statistical study of previously determined masses and **absolute magnitudes.** The results obtained from the theory are graphically represented by the curve shown in the accompanying figure. The curve was calculated from pure theory and



Mass-luminosity curve. (*From a diagram by Eddington.*)

the plotted points represent stars with observationally determined masses and luminosities. The agreement between theory and observation is remarkably close for **giant and dwarf stars of all spectral classes.** The only class of stars for which the theory completely fails to agree with observational results is the abnormal group known as the **white dwarfs.** (W.K.G.)

MASTAX. The chewing or grinding apparatus of the alimentary tract of **rotifers.** It is an expanded chamber with muscular walls in which chitinous jaws or trophi work together to break up the food. (A.W.L.)

MASTECTOMY. Surgical removal of the breast. The operation is usually performed for the removal of tumors, benign or cancerous. Simple mastectomy is removal of the breast alone. Radical mastectomy is often carried out if the tumor is a **cancer.** It consists of removal of the breast, the underlying muscles and the lymph glands in the axilla, in an effort to remove all tumor cells and thus prevent recurrence. (R.S.M.)

MASTER OSCILLATOR. This is the frequency setting **oscillator** of a radio **transmitter** consisting of the oscillator and at least one following amplifier stage. A very common usage is the master oscillator-power amplifier transmitter. Such circuits give greater frequency stability than a simple loaded oscillator but are not as good as the crystal controlled oscillator-amplifier arrangement. They are used primarily where an adjustable frequency transmitter is desired. (L.R.Q.)

MASTIC. Resins.

MASTIGOPHORA. One-celled animals whose bodies bear one or more **flagella** as organs of locomotion. A class of the phylum **Protozoa.**

This group contains a large number of species, some of great economic importance. Many of them contain chlorophyll and so carry on a type of metabolism like that of green plants. They may be green in color or blue, yellow, brown or red, due to other pigments associated with the green chlorophyll. Many species are colonial and some show a division of labor within the colony which foreshadows true multicellular organization. A few of the colonial species have collared cells like the sponges.

The **trypanosomes** which cause African **sleeping sickness** and various diseases of animals and the Leishmanias which cause kala azar and Oriental sore are the most important species economically.

The classification of the group is as follows:

- Subclass **Phytomastigina.** Usually with chlorophyll, living as plants.
  - Order **Chrysomonadida.** Very small. One or two flagella. Color yellow to brown, rarely green or bluish. Sometimes form pseudopodia.
  - Order **Cryptomonadida.** No pseudopodia. Color varied.
  - Order **Dinoflagellida.** Marine and some fresh-water forms. Body enclosed in a cellulose sheath, often beautifully sculptured.
  - Order **Phytomonadida.** Small rounded green species. Many colonial.
  - Order **Euglenoidida.** Usually elongate, with one or more flagella in a pit at the anterior end. With or without green color. Sometimes with a pigment spot (stigma) near the anterior end.
  - Order **Chloromonadida.** A few rare green species without a stigma.
- Subclass Zoomastigina. Without pigment bodies. Free-living and parasitic species.
  - Order **Pantostomatida.** With pseudopodia and flagella.
  - Order **Protomonadida.** One of three flagella. Sometimes form pseudopodia. Mostly parasitic. **Trypanosomes** and others.
  - Order **Polymastigida.** Three to eight flagella. Mostly minute, living in the alimentary tract of animals.
  - Order **Hypermastigida.** With numerous flagella. Living in the alimentary tract of insects. (**Isoptera**). (A.W.L.)

MASTITIS. Chronic or acute inflammation or infection of the breast. (D.M.H.)

MASTODON. **Fossil Mammals.**

MASTOIDITIS. An acute infection of the air cells of the mastoid process of bone behind the ear. This usually occurs as a complication of middle-ear infection (**otitis media**) which reaches the mastoid by direct extension. The symptoms are fever, pain, tenderness and swelling over the mastoid process, occurring during the course of an ear infection. Early treatment with **sulfonamides** or **penicillin** may control the infection completely, but if the process is extensive and associated with abscess formation and bone destruction, surgery will be necesary in addition to chemotherapy. Mastoiditis is dangerous because of the proximity of the infection to the brain and its coverings and the danger of spread to these structures. (D.M.H.)

MASTURBATION. Producing an orgasm in oneself by the hand or some other mechanical friction of the genital organs. It is more common than supposed, occurs in both sexes and often is quite common in childhood. The habit does not produce physical disorders or injury. It may have an injurious mental effect produced by the sense of guilt, the conflicts, and fears which may lead to the development of a **psychoneurosis.** (R.S.M.)

MASURIUM. Discovery announced by Noddack, Tacke and Berg in 1925 and presumably of atomic number 43. (R.K.S.)

MATCH. **Ignition.**

MATCHING. **Impedance Matching.**

MATÉ. *Ilex paraguayensis.* Aquifoliaceae. Maté yerba, or Paraguay tea, is a drink made from the leaves of a small evergreen tree found in the forests of Paraguay and southern Brazil. The branches of the tree are cut off and dried, after which the leaves are broken off, dried more thoroughly and ground to a powder. The drink is prepared by pouring boiling water over the powder, and has a pleasant mild odor and taste. As yet it has not gained great popularity as a beverage in the United States. It contains caffeine South American natives consume great quantities, using a curious instrument for the purpose—a tube at the lower end of which is a flattened spoon-shaped part, perforated to permit the liquid to pass. Through this instrument, called a bombilla, maté is sucked up. (R.M.W.)

MATERIAL BALANCE. A method of using the law of conservation of matter. All the material entering a process must equal all the material leaving it. It provides a basis for evaluating unknown amounts of material. (D.E.M.)

MATERIALS HANDLING. **Conveyor, Elevator, Hoist, Dredge, Crane, Cableway.**

MATHEMATICAL STATISTICS. Mathematical statistics may be considered as that part of **statistics** which is concerned with the mathematical proofs and theorems employed in statistics. Topics in mathematical statistics are **sampling,** the theory of statistical inference, **correlation theory, statistical probability,** the **Neyman-Pearson theory of testing hypotheses,** theory of **distribution functions,** theory of characteristic functions, the **analysis of variance,** and the design of experiments. (L.A.A.)

MATING. The process of securing a consort of the opposite sex for the purpose of reproduction.

Among some animals sexual union seems to follow the meeting of the sexes without preliminaries while among others a period of more or less elaborate courtship precedes the actual choice of mates and sexual union. Under the simpler conditions the sexes must be together at the time when their reproductive cells are ripe, but this results usually from the normal course of development, aided in some cases by special behavior such as the swarming of marine **annelids.** When sexually mature these worms respond to the same conditions by vigorous activity which brings them, in some cases, to the surface waters in great numbers at twilight. Here their mating takes place.

Birds and mammals offer many examples of special courtship. As a rule the male is active in the process and the female receives his attentions, which may involve no more than close personal interest and may include a great variety of display. Birds often sing at their best during this period and often go through strange evolutions to display the beauties of their plumage. Displays such as that of the **prairie chicken** combine vocal efforts, such as they are, with display of plumage and mimic combat with other males, and in many species both of birds and of mammals combat between males is a prominent feature of the mating period.

The acceptance of a mate by the female is followed by their physical union, or **copulation,** and in many cases by mutual preparation for the care of the young. Some species, however, including the **wrens,** include nest building in mating activities. The male provides one or more nests as a practical accompaniment for his abundant song while he seeks a wife. (A.W.L.)

MATRICES. A matrix is an ordered set of mn elements a_{ij} arranged in a rectangular array, having m rows and n columns. The notation commonly used is

$$A \equiv \begin{Vmatrix} a_{11} & a_{12} \cdots a_{1n} \\ a_{21} & a_{22} \cdots a_{2n} \\ \cdot \quad \cdot & \cdot \quad \cdot \quad \cdot \\ a_{m1} & a_{m2} \cdots a_{mn} \end{Vmatrix} \quad \text{or} \quad \begin{pmatrix} a_{11} & a_{12} \cdots a_{1n} \\ a_{21} & a_{22} \cdots a_{2n} \\ \cdot \quad \cdot & \cdot \quad \cdot \quad \cdot \\ a_{m1} & a_{m2} \cdots a_{mn} \end{pmatrix}$$

If $m = n$, the matrix is called a square matrix of order n.

Any two matrices A and B of the same number of rows and of columns are said to be equal if and only if $a_{ij} = b_{ij}$ for every i and j.

If the matrix is square, from the elements of this matrix a **determinant** can be formed, which is called the determinant of the matrix. From the elements of a rectangular matrix, by striking out rows or columns or both, determinants can be formed.

A matrix A is said to be of rank r if there exists at least one determinant of A of order r which is not zero, while all determinants of A of order higher than r are zero.

The idea of the rank of a matrix is of importance in stating the conditions under which a **system of linear equations** has a solution. (L.L.S.)

MATRIX. Printing film used in color photography for the transfer of an image to another support. Dyed relief films or differentially hardened films are generally called matrices when used in an **imbibition** process. (H.C.C.)

MATRIX MECHANICS. **Quantum Mechanics.**

MATTERHORN. **Cirque.**

MAVIS. Aves, Passeriformes. The European song **thrush,** *Turdus philomelus,* a bird that resembles the wood thrush of North America. (A.W.L.)

MAW WORM. Nemathelminthes, Nematoda. A large roundworm parasitic in the intestine of the horse. When present in large numbers its attack is serious. A member of the genus *Ascaris* which contains the **eelworm** and other species of similar habits. (A.W.L.)

MAXILLA. 1. A bone of complex shape that forms the greater part of the upper jaw in the **vertebrates.** 2. One of a pair of jointed appendages developed as mouth parts in the **arthropods.** They lie behind the **mandibles.** The typical maxilla consists of a basal segment, the cardo, bearing a second segment, the stipes, from which two parts arise. On the outside the **palpifer** serves as the attachment for a sensory palpus consisting of several joints. Mesially the stipes bears the subgalea from which arises the galea, of one or two segments, and a cutting or chewing part called the lacinia. The entire structure may be greatly modified. In the **butterflies,** for example, the maxillae are developed into long flexible structures which fit together to form a tubular proboscis. (A.W.L.)

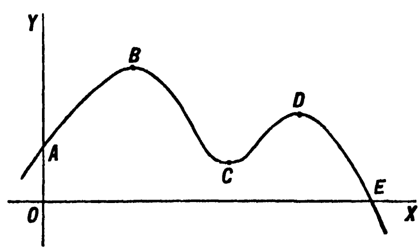
MAXILLARY GLAND. An excretory organ of **crustaceans.** Its duct opens at the base of the **maxilla.** (A.W.L.)

MAXILLIPED. A jointed appendage of the body region of **arthropods,** modified to serve as an accessory mouth part. The term is applied to one to three pairs of the thoracic appendages of some **crustaceans** and to the poison claws of the **centipedes.** (A.W.L.)

MAXIMA AND MINIMA. Maxima and minima of **functions** of one variable:

If, as x increases and passes through a value x_1, a function $f(x)$ ceases to increase and begins to decrease, then $f(x)$ is said to have a maximum at $x = x_1$ and $f(x_1)$ is called a maximum value of the function; if $f(x)$ ceases to decrease and begins to increase, then $f(x)$ is said to have a minimum at $x = x_1$ and $f(x_1)$ is called a minimum value of the function.

A maximum value of a function as just defined is not necessarily the greatest value of the function, nor is a minimum the least value. Maxima and minima should properly be called relative maxima and minima. Together they are often called extremes of the function.



For the graph of the function, the points corresponding to the maximum and minimum values are called turning points of the curve. Thus, in the accompanying figure, the points B and D are maximum points and C is a minimum point of the graph.

In the case of both maxima and minima, the value of the first derivative at $x = x_1, f'(x_1)$, is either o or ∞.

If, as x passes through x_1, increasing, $f'(x)$ changes sign from $+$ to $-$, then $f(x_1)$ is a maximum; if from $-$ to $+$, $f(x_1)$ is a minimum. If $f'(x)$ does not change sign in passing through x_1, then $f(x_1)$ is neither a maximum nor a minimum.

If at $x = x_1$ we have $f'(x_1) = 0$ and if also $f''(x_1)$ is negative, then $f(x_1)$ is a maximum, but if $f''(x_1)$ is positive, then $f(x_1)$ is a minimum.

Hence, to determine maxima and minima of a function $f(x)$:

First find all the real values x_1 of x for which $f'(x)$ is o or ∞; these are called critical values. To test the critical values, to find which give maxima and which minima, we may use either of the following two methods:

(1) If $f'(x)$ changes sign from $+$ to $-$ as x passes through a critical value x_1, increasing, then $f(x_1)$ is a maximum, but if $f'(x)$ changes from $-$ to $+$, $f(x_1)$ is a minimum.

(2) If $f''(x_1)$ is negative, then $f(x_1)$ is a maximum, but if $f''(x_1)$ is positive, then $f(x_1)$ is a minimum.

At a maximum or minimum, $x = x_1$, we must have $f'(x_1) = 0$ (or ∞), but it may happen that $f''(x_1)$ is also o. In this case the preceding tests fail.

If $f'(x_1) = 0$ and $f''(x_1) = 0$, and if also $f'''(x_1) = 0$ and $f^{(4)}(x_1) < 0$, then $f(x_1)$ is a maximum, but if $f'''(x_1) = 0$ and $f^{(4)}(x_1) > 0$, then $f(x_1)$ is a minimum.

For the general case:

Suppose that $f'(x_1) = 0$, $f''(x_1) = 0$, $f'''(x_1) = 0$, $\cdots$, $f^{(k-1)}(x_1) = 0$, but $f^{(k)}(x_1) \neq 0$, then if k is odd, $f(x_1)$ is neither a maximum nor a minimum, but if k is even, then $f(x_1)$ is a maximum if $f^{(k)}(x_1) < 0$, and a minimum if $f^{(k)}(x_1) > 0$.

Maxima and minima of functions of several variables:

A function $f(x, y)$ is said to have a maximum value at a point (a, b) if $f(a, b)$ is its greatest value in some region about (a, b), i.e., if $f(a + h, b + k) - f(a, b) < 0$ for all values of h, k (except o, o) which are numerically less than some positive number d. In like manner, $f(x, y)$ is said to have a minimum value at (a, b) if $f(a + h, b + k) - f(a, b) > 0$ for all values of h, k (except o, o) such that $|h| < d, |k| < d$.

A function $f(x, y)$ can have a maximum or minimum only at points where $\frac{\partial f}{\partial x} = 0$ and $\frac{\partial f}{\partial y} = 0$.

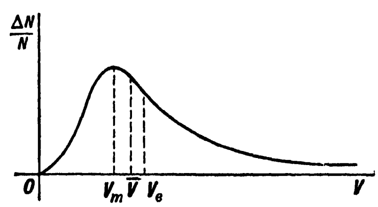
If at a point (a, b), we have $\frac{\partial f}{\partial x} = 0$ and $\frac{\partial f}{\partial y} = 0$, and if also $\left(\frac{\partial^2 f}{\partial x \partial y}\right)^2 - \frac{\partial^2 f}{\partial x^2} \cdot \frac{\partial^2 f}{\partial y^2} < 0$, then $f(a, b)$ will be a maximum if $\frac{\partial^2 f}{\partial x^2} < 0$ and $\frac{\partial^2 f}{\partial y^2} < 0$, and will be a minimum if $\frac{\partial^2 f}{\partial x^2} > 0$ and $\frac{\partial^2 f}{\partial y^2} > 0$.

For maxima and minima of functions of three variables, there are similar conditions. (L.L.S.)

MAXWELL-BOLTZMANN LAW. Equipartition of Energy.

MAXWELL COLOR TRIANGLE. Color.

MAXWELL DISTRIBUTION LAW. A law expressing the relative numbers of **molecules** in a gas which have various given speeds, or various given kinetic energies, of thermal agitation at any instant. In its usual forms, it is limited by certain simplifying conditions, viz., uniformity of temperature, absence of turbulence or convection currents, negligible effect of gravity, and purity of the gas (molecules all of equal mass). The



Graph of the Maxwell distribution law.

law may be expressed in various terms. For example, if N is the total number of molecules, the proportion of them having speeds confined to the interval Δv between $v - \frac{1}{2}\Delta v$ and $v + \frac{1}{2}\Delta v$ (and hence having v cm. per sec. as their representative speed), is

$$\frac{\Delta N}{N} = \frac{4h^3(\Delta v)}{\sqrt{\pi}} v^2 e^{-h^2 v^2}. \tag{1}$$

h is a constant which may be shown to be equal to

$$h = 6.034 \times 10^7 \sqrt{\frac{m}{T}}, \tag{2}$$

in which T is the absolute temperature and m is the mass of one molecule in grams. From (1) it is easily deduced that the modal (most frequent) speed of the molecules is

$$v_m = \frac{1}{h}; \tag{3}$$

the mean speed is

$$\bar{v} = \frac{2}{\sqrt{\pi}h}; \tag{4}$$

and the effective speed (corresponding to average kinetic energy) is

$$v_e = \sqrt{\frac{3}{2}} \cdot \frac{1}{h}. \tag{5}$$

This last quantity, and hence h, can be calculated from the density and the pressure of the gas. (See **Kinetic Theory.**) (L.D.W.)

MAXWELL'S EQUATIONS. A set of four classic formulae of the electromagnetic theory. They deal with certain **vector** quantities pertaining to any point of a region under varying electric and magnetic influence. If the point is in empty space, the equations are somewhat simplified; in general, provision must be made for the presence of dielectrics, conductors, or magnetizable bodies. In these equations, H is magnetic intensity, B is magnetic induction, E is electric intensity, D is electric displacement, ρ is electric space density, u is conduction current density, t is time, c is the **electromagnetic constant.** The "curl" and the "divergence" of a function are well-known operators of **vector analysis.** The equations, in this notation, are

$$\text{curl } H = \frac{1}{c}\frac{\partial D}{\partial t} + \frac{4\pi u}{c}, \tag{1}$$

$$\text{div } B = 0, \tag{2}$$

$$\text{curl } E = -\frac{1}{c}\frac{\partial B}{\partial t}, \tag{3}$$

$$\text{div } D = 4\pi\rho. \tag{4}$$

(L.D.W.)

MAXWELL'S LAW OF RECIPROCAL DEFLECTIONS. Deflection.

MAY FLY. Ephemerida.

MAYFISH. Pisces, Teleostei. A species of **killifish,** *Fundulus majalis,* found in shallow bays from Massachusetts to Florida. (A.W.L.)

MAYFLOWER. Heath Family.

McLEOD GAUGE. Pressure Gauges.

McQUAID-EHN TEST. A method of determining **grain size** of steels, particularly carburizing grade steels. The sample is **carburized** at 1700° F. by the pack method and cooled slowly. The **microstructure** of the case then contains **pearlite** grains outlined by **cementite** in the grain boundaries, thus the McQuaid-Ehn grain size can readily be determined by comparison with standard charts.

When the pearlite and cementite tend to agglomerate, leaving patches of ferrite, the structure is said to be "abnormal." So-called "abnormal" steels tend to be fine-grained and to have lower **hardenability** and less tendency to distort in the hardening treatment than "normal" steels. The abnormal steels are also tougher after heat treatment. Determination of this characteristic of the microstructure is a part of the McQuaid-Ehn test. (R.H.H.)

MEADOW-BROWN. Insecta, Lepidoptera. **Butterflies** of dull gray-brown color marked with eye-like spots, in some species set in a yellow patch on the fore wings. Family Satyridae. (A.W.L.)

MEADOWLARK. Aves, Passeriformes. A common North American bird (**Aves**) more closely related to the blackbirds and orioles than to the true larks. The eastern meadowlark, *Sturnella magna,* is less attractive than the western, *S. neglecta,* which has a brief but glorious song. Both have the characteristic yellow breast with a black chevron at the throat. (A.W.L.)

MEAGRE. Pisces, Teleostei. Fishes (**Pisces**) of numerous species, widely distrbuted in the oceans and to a limited extent in fresh water. Most are of moderate size but one species of the Old World reaches a length of six feet. Excellent food fishes. (A.W.L.)

MEALY BUG. Insecta, Homoptera. Small active scale **insects.** The body is covered with a granular white secretion.

Mealy bugs are important greenhouse pests. Spraying with whale-oil soap (1 lb. per gal. of warm water) is recommended for resistant plants and with fir-tree oil (1 part to 20 parts water) for ferns and orchids. (A.W.L.)

MEAN. Arithmetic Mean.

MEAN EFFECTIVE PRESSURE. Effective pressure acting against a **piston** face and transmitted into a thrust in the piston rod is at any instant the difference between the pressures on the two sides of the piston. In the **steam engine, gasoline engine, air compressor,** and other piston and cylinder mechanisms, this effective pressure varies throughout the stroke. The average of the effective pressure is known as the mean effective pressure. It may be predicted by means of equations and empirical constants, and also found experimentally by the use of the **indicator.** The mean effective pressure is represented by the average height of the diagram drawn by an indicator. (F.T.M.)

MEAN FREE PATH. Kinetic Theory.

MEAN SEA LEVEL PRESSURE. The value assigned to surface pressure of the Standard Atmosphere: 29.92″ of mercury, or 1013.2 millibars. (P.E.K.)

MEAN SUN. The mean, or average, sun is a purely fictitious object used as a reference point for measuring mean or civil **time** by the rotation of the earth. The term mean sun comes from the fact that the day as determined by use of it, i.e., the mean solar day, is very nearly equivalent in length to the average of the lengths of the different apparent solar days throughout the year.

The apparent motion of the true sun through the stars is produced by the actual motion of the earth in an elliptical **orbit** about the sun, the plane of which is inclined to the plane of the **equator.** To remove the irregularity in the apparent motion of the sun due to the **elliptical motion** of the earth a fictitious object is assumed to move in the plane of the **ecliptic** with constant angular velocity which passes through **perihelion** coincident with the true sun. The mean sun is a fictitious object assumed to be moving in the plane of the equator with constant angular velocity passing through the **vernal equinox** coincident with the fictitious object just defined. (W.K.G.)

MEAN TEMPERATURE DIFFERENCE. Heat transfer surfaces, for which one or both of the media on opposite sides of the surface exhibit variable temperatures, obviously are subject to a variable temperature

difference. Since the temperature difference is of primary importance to heat transfer through a conducting surface, its mean, or average, value should be carefully investigated. Consider a case of heat transfer surface, illustrated by a tube surrounded by a medium at t', and through which flows another medium which rises from t_i at inlet to t_o at outlet of the tube. The arithmetical mean temperature difference is the simple average of the terminal temperature differences; arithmetical m.t.d. $= t' - \frac{t_i + t_o}{2}$.

The arithmetical m.t.d. is only an approximation of the true thermal m.t.d. When the heat received by the flow w of the medium in the tube past a unit of the surface dS ($= wcdt$ in which c is specific heat) is equated to heat passed through that area under the temperature difference $t' - t$ existing across $dS (= KdS(t' - t)$ in which K is the conductivity assignable to the existing conditions of heat transfer), the integration for true over-all m.t.d. may be simplified to:

$$\text{Thermal m.t.d.} = \frac{t_o - t_i}{\log_e \dfrac{t' - t_i}{t' - t_o}}.$$

If the first medium changed in temperature from t'_i to t'_o instead of remaining constant, then the

$$\text{Thermal m t d.} = \frac{(t'_i - t_o) - (t'_o - t_i)}{\log_e \dfrac{t'_i - t_o}{t'_o - t_i}}.$$

(F.T.M.)

MEAN VALUES OF FUNCTIONS. The mean value of a function $f(x)$ over an interval (a, b) is defined by

$$\frac{\int_a f(x)dx}{b - a}.$$

The mean value of a function $f(x, y)$ over an area S is defined by

$$\frac{\iint_S f(x, y)dS}{S}.$$

The mean value of a function $f(x, y, z)$ over a region V of space is defined by

$$\frac{\iiint_V f(x, y, z)dV}{V}.$$

(L.L.S.)

MEAN VALUE THEOREM FOR DERIVATIVES. Let $f(x)$ be a **function** which has a finite **derivative** at all points of the interval (a, b). Then there exists a value ξ of x between a and b such that

$$f(b) - f(a) = f'(\xi)(b - a).$$

(L.L.S.)

MEAN VALUE THEOREMS FOR INTEGRALS. The first law of the mean for **integrals** is:

$$\int_a^b f(x)dx = (b - a)f(\xi),$$

where $a \leqq \xi \leqq b$.

The second law of the mean for integrals may be written:

$$\int_a^b f(x)\phi(x)dx = \phi(a)\int_a^\xi f(x)dx,$$

where $a \leqq \xi \leqq b$, provided $f(x)$ is **continuous**, and $\phi(x)$ is continuous and is also a positive monotonic decreasing function in the interval (a, b), and

$$\int_a^b f(x)\phi(x)dx = \phi(a)\int_a^\xi f(x)dx + \phi(b)\int_\xi^b f(x)dx,$$

where $a \leqq \xi \leqq b$, provided $f(x)$ and $\phi(x)$ are continuous functions, and $\phi(x)$ is a monotonic decreasing function in the interval (a, b) without being always positive.

There are similar formulae for the case when $\phi(x)$ is an increasing function. (L.L.S.)

MEANDER LINE. Traverse.

MEASLES. A common and highly contagious disease of childhood which tends to recur in epidemics every 2 to 4 years. It is world wide in distribution. The etiologic agent is a filterable **virus.**

The incubation period of measles is 8 to 11 days. The disease is ushered in as an upper respiratory infection. During the period of invasion the signs and symptoms are slight fever, malaise, congestion of the **mucous membranes** of the nose and throat, and **conjunctivitis.** After 36 hours pathognomonic lesions appear in the mouth. These are Koplick spots, small bluish-white specks which are seen inside the lower lip or opposite the molar teeth. The rash begins 3 to 4 days after the onset of fever, and lasts 4 to 5 days. Characteristically it starts at the hair line and spreads down over face, neck, trunk and eventually over the entire body. The lesions start as tiny flat red spots; they enlarge and spread to become confluent in many areas. At the height of the disease the temperature may be as high as 105°, and the patient suffers from itching and burning of the skin. Marked sensitivity of the eyes to light, and cough, are present at this stage; the patient looks and feels miserable. After the eruption reaches its peak it begins to fade, in the order of its appearance, and at the same time the patient improves dramatically. The fever and constitutional symptoms resolve rapidly.

The complications of measles are serious. **Encephalitis,** probably due to the virus itself, is fortunately rare. It has a high mortality and, in those patients who survive, permanent sequellae such as muscular weakness, spasticity and mental deterioration are usual. Secondary infections—**otitis media,** cervical **adenitis,** and bronchopneumonia—are common complications. Bronchopneumonia is the most frequent cause of death in measles.

The treatment of measles is symptomatic once the disease is full blown. If a susceptible child is seen soon after exposure, the disease can be prevented, or at least modified, by the injection of convalescent **serum,** gamma globulin, or placental extract. (D.M.H.)

MEASURE OF CENTRAL TENDENCY. A measure of central tendency is an **average.** It is a typical value of the set of **variates.** The common measures of central tendency are the **mean, median, mode, harmonic mean** and the **geometric mean.** (L.A.A.)

MEASURE OF POSITION. A measure of position is a **statistic** or a **population parameter** determined by the position of the **variate** in the **frequency distribution** or in the **probability function.** Typical measures of position are the **median,** the **quartiles, quintiles,** and **percentiles.** (L.A.A.)

MEASUREMENT. A fundamental process in all production systems, generally involving comparison with some accepted standard or a mating part. The significance of a measurement is determined by the degree of accuracy to which elements may be measured. Two types of accuracy are important: accuracy of form and accuracy of size. The former involves not only the duplication of irregular profiles, but also the accuracy of form embodied in straight-edges, squares, true cylinders and cones, etc. Accuracy of size implies comparison with some accepted standard; in linear measurements, the fundamental unit is the yard, which is the

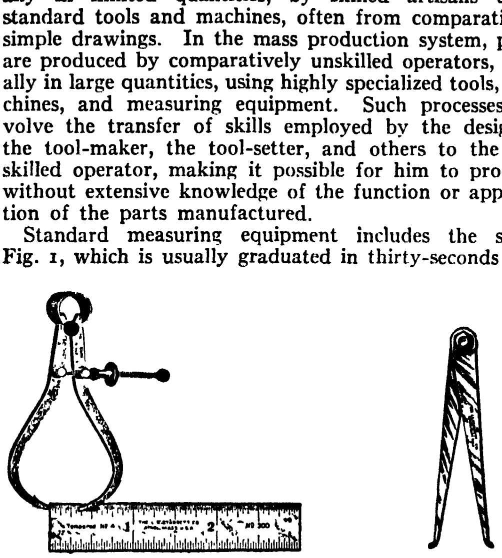
distance at a temperature of 62° F. between two fine lines on gold plugs in a bronze bar at Westminster, England, and the meter. In 1866, the United States Congress established the following relation between the yard and the meter:

$$\frac{1 \text{ yard}}{1 \text{ meter}} = \frac{3600}{3937}.$$

The simple ratio of one inch equal 25.4 mm. has been approved by the American Standards Association for United States industrial practice, since it involves only a negligible error as far as ordinary industrial practice is concerned.

Methods of measurement are largely controlled by methods of manufacture, which may be roughly classified as unit production and mass production systems of manufacture. In the former, articles are produced, usually in limited quantities, by skilled artisans using standard tools and machines, often from comparatively simple drawings. In the mass production system, parts are produced by comparatively unskilled operators, usually in large quantities, using highly specialized tools, machines, and measuring equipment. Such processes involve the transfer of skills employed by the designer, the tool-maker, the tool-setter, and others to the unskilled operator, making it possible for him to produce without extensive knowledge of the function or application of the parts manufactured.

Standard measuring equipment includes the scale, Fig. 1, which is usually graduated in thirty-seconds and



L. S. Starrett Co. *L. S Starrett Co.*

Fig. 1.

sixty-fourths of an inch. A capable mechanic can estimate within a third of a division, or to an accuracy of .006". Some scales are provided with a hook attached to one end, to facilitate taking measurements over rounded corners, or from an edge. Calipers, Fig. 1, are used for transferring scale measurements. Scribing or hermaphrodite calipers have one caliper and one pointed leg, and are used for scribing parallel lines and arcs on bosses or the ends of bars to locate centers. Dividers are calipers with two pointed legs for layout work, scribing circles, or spacing lines.

For more precise work, vernier calipers are used. The vernier caliper, Fig. 2, consists of a scale with a fixed head; a movable head may be adjusted along the scale, and the reading between the jaws of the instrument read on the scale by means of a reference point and a vernier. The vernier caliper can be used for measurements accurate to within .001". The micrometer or micrometer caliper employs the principle of a screw moving in a fixed nut; the screw has forty threads per in., and the thimble of the micrometer is divided into twenty-five equal parts, permitting direct reading to .001". By means of an appended vernier, measurements to .0001" may be taken. Inside micrometers and screw thread micrometers are also available.

In many machine shops, precision gauge blocks are used for measurement and reference purposes, and consist of small hardened steel blocks of a definite thickness, held to a tolerance of a few millionths of an inch. Precision gauge blocks may be used singly or in combination to give an almost unlimited variety of sizes within their range. Two or more blocks may be assembled by "wringing" their surfaces together, since these are so

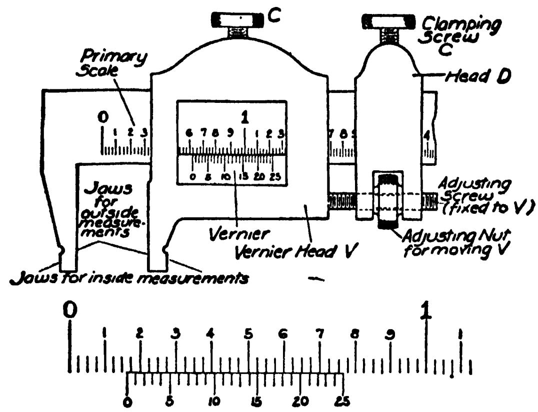


Fig. 2.

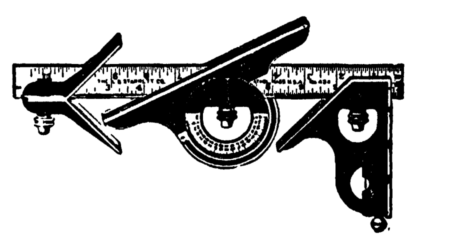
nearly perfect planes that they will resist separation in a direction perpendicular to their contact faces with a force considerably greater than the atmospheric pressure. Gauge blocks may be used for setting gauges, for measuring between pins and plugs, and for height measurements, in which instance they are often used in conjunction with surface gauges. A surface gauge consists of a base fitted with an adjustable arm which carries either a scriber point of some form of dial test indicator.

For hole measurements, a plug may be fitted to the hole, and the diameter of the plug measured with calipers or a micrometer. In some instances, a telescoping gauge, which is a tee-shaped device having a sliding part in the head of the tee, is used. The sliding leg may be locked after insertion in the hole, and a measurement taken by a micrometer over the head. The combination set, Fig. 3, may be used as a center head, for locating



L. S. Starrett Co.

Fig. 3

the centers of cylinders, as a bevel protractor, or as a square, in conjunction with the scale on which these devices are carried.

In the mass production system, single-size or special gauges are usually employed. A fixed gauge is a measuring tool that conforms to an established dimension and will show whether a certain part is correct or not, but will not indicate the degree of error. Fixed gauges are not necessarily non-adjustable, since many have measuring surfaces that can be adjusted for wear or for a limited size range. Limit gauges are those which indicate the permissible variation in the size of a part; a progressive limit plug gauge, for gauging the size of a hole which has a basic size of .188", with a tolerance of +.001", is shown in Fig. 4. Progressive gauges enable

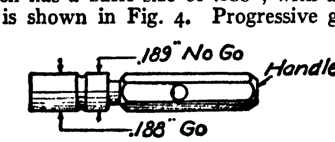


Fig 4

the gauging operation to be performed in one operation, but are not applicable to blind holes, for which double-end gauges, with the high and low limits on either end of the gauge, should be used. Plug gauges may be made in one piece, or may have a handle and renewable gauging plugs, as in Fig. 4, to reduce expense.

Cylindrical surfaces are usually gauged by snap gauges, as shown in Fig. 5. Most snap gauges, however, are equipped with adjustable measuring anvils or buttons, so that adjustment for wear may be effected. Cylindrical surfaces may also be measured by hollow cylinders or ring gauges, of which either the single-size variety, or limit ring gauges, are available. Plug and ring thread gauges for checking threaded holes and screws are extensively used; the gauging surfaces usually refer to the pitch diameter of the thread. Many other varieties of gauges, including those used for alignment of holes, tapers, straightness of parts, and keyway sizes, are commercially available. (H.C.H.)

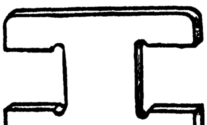

Fig. 5.

MEASURING WORM. Insecta, Lepidoptera. A **caterpillar** which loops the body by drawing the hind legs up close to the front legs as it crawls. The movement is associated with the lack of most of the legs near the middle of the body. Caterpillars of the family Geometridae and a few species of Noctuidae are of this type. (A.W.L.)

MECHANICAL ADVANTAGE. Machines.

MECHANICAL EFFICIENCY. An **efficiency**, including only the effect of losses arising from mechanical sources, mainly **friction**, would be mechanical efficiency. A **machine** such as a **hoist** has an efficiency expressible only as the mechanical efficiency. A **steam engine** has not only a mechanical efficiency which measures the friction in windage losses, but a thermal efficiency which is an entirely different quantity. The mechanical efficiency of a hoist is the output divided by the input. The former is the weight lifted multiplied by the height through which it is lifted. The input is the pull exerted on the hoist, multiplied by the distance through which that pull acts. The mechanical efficiency of a steam engine is the ratio of net hp. available at the pulley to hp. developed by the steam in the cylinder. The mechanical efficiency of a pump is the ratio of power expended on the water to that which the motivating source supplies to the pump. These are a few examples of mechanical efficiency, and might be multiplied endlessly since any moving machine incurs friction losses, and consequently has a mechanical efficiency of less than 100%. (F.T.M.)

MECHANICAL EQUIVALENT OF HEAT. It was in 1840 that Dr. James P. Joule began his classic researches on the quantitative relationship between **heat** and **work**. Rumford and Davy had established the fact that heat is a form of energy; it remained to determine how many **foot-pounds** are equivalent to one **British thermal unit**. In the arrangement adopted by Joule, a heavy weight, in descending, was caused to drive a mechanism for "churning" water in a calorimeter. The energy furnished by the weight in its descent, with correction for friction losses, was then equated to the heat indicated by the rise in temperature of the agitated water, with the usual calorimeter corrections; the result indicated that 1 British thermal unit equals about 774 foot-pounds of energy. Translated into c.g.s. units, this meant that there are 41,600,000 ergs to the calorie; and when we consider that the most elaborately precise modern electrical methods give, as the present accepted value of "J," 41,855,000 ergs per calorie or about 778 foot-pounds per British thermal unit, it is clear that Joule's experimental skill must have been of a high order.

It has been customary, in writing thermodynamic equations involving both thermal and mechanical energy terms, to include the factor J in the former in order to reduce them to the same denomination; but the tendency at present is to express quantities of heat directly in ergs or joules, thereby avoiding the necessity of this factor. (See **Thermodynamics.**) (L.D.W.)

MECHANICAL EQUIVALENT OF LIGHT. Since any radiation is a flux of energy, it should be possible to express the emission of **light** in equivalent power units. Great precision in such measurements is hardly possible, because of the difficulty of separating the visible sharply from the invisible components of radiant energy. One procedure is to enclose a lamp, whose total power input (and hence its total output) is known, in a jacket of transparent material which strongly absorbs throughout both the infra-red and the ultra-violet, so that only the visible radiation comes through. The absorbed energy is deduced calorimetrically from the rise in temperature of the jacket, while the luminous intensity is obtained photometrically in the usual way. The dynamical power corresponding to the light is the difference between the total power output of the lamp and the power absorbed by the jacket. Measurements of this type carried out by Ives in 1926 with lamps giving white light gave an equivalent to 0.0016 watt per lumen. (Since the visibility of light varies greatly with the color, being a maximum near the middle of the visible spectrum, the lumen would represent more power for blue light than for average light or for white.) The "light-source efficiency" of a good lamp is of the order of 10 lumens per watt input power, which is thus equivalent to 0.016 watt per watt or only 1.6%. It is therefore evident that there is still room for much progress in lighting economy. (L.D.W.)

MECHANICAL POWER TRANSMISSION. Belting, Chain, Gearing, Gear Train, Bearings, Lubrication, Speed Reducers, Friction Gearing, Spur, Bevel, Worm Gearing.

MECHANICAL PROPERTIES OF METALS. Metal, Physical Properties of.

MECHANICAL RATING. Speed Reducers.

MECHANICS. Mechanics is that science which deals with the effects of forces upon bodies at rest or in motion. The laws and phenomena of gases and liquids and solid bodies have a part in this subject, and it is one of the basic studies of engineering, physics and astronomy. It is customary to subdivide mechanics into the study of liquids (**hydraulics, hydrodynamics** and **hydrostatics**), the study of the action of gases (**pneumatics**), and the study of rigid or elastic particles or bodies of solid materials. It is to the latter field that the term mechanics is frequently restricted. For convenience it is further subdivided into **statics, kinematics,** and **kinetics**, each of which is treated in this book. Statics deals with bodies at rest, in equilibrium under the action of forces or of torques; kinematics deals with abstract motion and kinetics treats of the effect of forces or of torques upon the motions of material bodies. Modern usage favors the term **dynamics**, reserving mechanics for the more practical phases of the field (machinery, building, etc.).

Fluid mechanics is that branch of mechanics which deals with those fundamental laws which apply to all fluids (liquids or gases) at rest or in motion. (F.T.M., C.W.C.)

MECOPTERA. Insects with four narrow wings with numerous veins. The head is prolonged downward in a beak bearing biting mouth parts at the tip. The rela-

tively few species inhabit moist woods and are not commonly known.

This order includes two chief forms, the **scorpion flies** and a group of slender long-legged insects usually known by their generic name, *Bittacus*. In the former the tip of the abdomen is modified so that it resembles that of a scorpion slightly. *Bittacus* has the general appearance of the crane flies but for its four wings, and is chiefly remarkable for the grasping joints at the tips of the legs. (A.W.L.)

MEDIAL MORAINE. If one or more tributary **glaciers** coalesce with the main glacier the **lateral moraines** unite to form trains of debris on the surface of the glacier at or near its center, these are called medial moraines. (R.M.F.)

MEDIAN. The median, a **measure of central tendency,** is the value of that **variate** which divides a distribution into 2 equal parts. In a **serial distribution,** after the variates have been arranged in order of magnitude, the median is the value of variates $\frac{N+1}{2}$ if N is odd; if N is even, the median is the **arithmetic mean** of variates $\frac{N}{2}$ and $\frac{N}{2}+1$ where N is the number of variates. The median then is clearly a **measure of position.** The median in a **frequency distribution** is found by determining the value of variate $\frac{\Sigma f_x}{2}$ by linear interpolation in the **cumulative frequency distribution.** The chief virtue of the median is its simplicity and ease of calculation. It always exists and in some instances it is superior to the mean as a measure of central tendency. It is commonly used if the distribution of variates is considerably skewed. The sum of the **absolute value** of the deviations about the median is a minimum. (L.A.A.)

MEDIAN LINE (of an airfoil profile). Airfoil.

MEDIASTINUM. The space in the **chest** between the **lungs,** around and above the heart, bounded in front by the anterior wall chest and in back by the posterior chest and spine. The space contains many blood vessels, nerves, and lymph glands. Infections and tumors of the various structures are the chief pathological disturbances. The mediastinum is difficult of access because the greater part of the space is filled with large blood vessels and the heart. (D.M.H.)

MEDINA WORM. Guinea Worm.

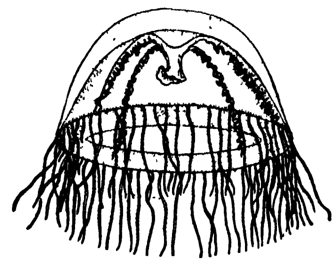
MEDIOSILICIC. A term proposed by Clarke, in 1911, to describe **igneous rocks** whose silica content is between 52 and 66%. (R.M.F.)

MEDULLA. 1. An axial structure found in some hairs. 2. The central portion of the **adrenal glands.** 3. The medulla oblongata, the posterior region of the vertebrate **brain.** (A.W.L.)

MEDUSA, HYDROMEDUSA. A form of **coelenterate** in which the body is shortened on its principal axis and broadened, sometimes greatly, in contrast with the **hydroid** or **polyp.** It varies from bell-shaped to a thin disk, scarcely convex above and only slightly concave below. The upper or aboral surface is called the exumbrella and the lower surface, on which the mouth opens, the subumbrella. The latter may be partly closed by a membrane extending inward from the margin. This structure is called the velum. The digestive cavity consists of a central chamber, the stomach, and radiating canals which extend toward the margin. These canals may be simple or branching and few or many. The margin of the disk bears tentacles and sensory organs.

In the class Hydrozoa medusae are the sexual individuals of many species, alternating in the life cycle with asexual **polyps,** but in the Scyphozoa or **jellyfishes** proper the medusa alone is well developed. (A.W.L.)

MEDUSOID. The **medusa** of certain **coelenterates** of the class **Hydrozoa.** A hydromedusa. Medusoids



Medusoid.

differ from the free-swimming jellyfishes to which the term medusa is applied in the usual presence of the velum and in the simpler digestive cavity. The term is also applied in some cases to the young medusae budded from the larval **polyp** stage of the **jellyfishes.** (A.W.L.)

MEERKAT. Mammalia, Carnivora. A South African animal of the **civet** family, related to the **mongooses.** The name is sometimes applied to the penciled mongoose. (A.W.L.)

MEERSCHAUM. Sepiolite.

MEGAGAMETE. Gamete.

MEGALONYX. Pleistocene.

MEGANUCLEUS. Macronucleus.

MEGAPODE. Aves, Galliformes. Dull-colored birds (**Aves**) of the Pacific islands, from the Philippines to Australia. They have strong legs and feet and resemble turkeys slightly. The eggs are deposited in mounds of decaying vegetation which generates the heat necessary for incubation. The family includes the **brush turkeys** of the Australian region and the **maleo** in addition to the true megapodes. (A.W.L.)

MEGASCLERES. The large spicules in **sponges.** They form the chief support of the body wall. (A.W.L.)

MEGASCOPIC. Macroscopic.

MEGATHERIA. Pleistocene.

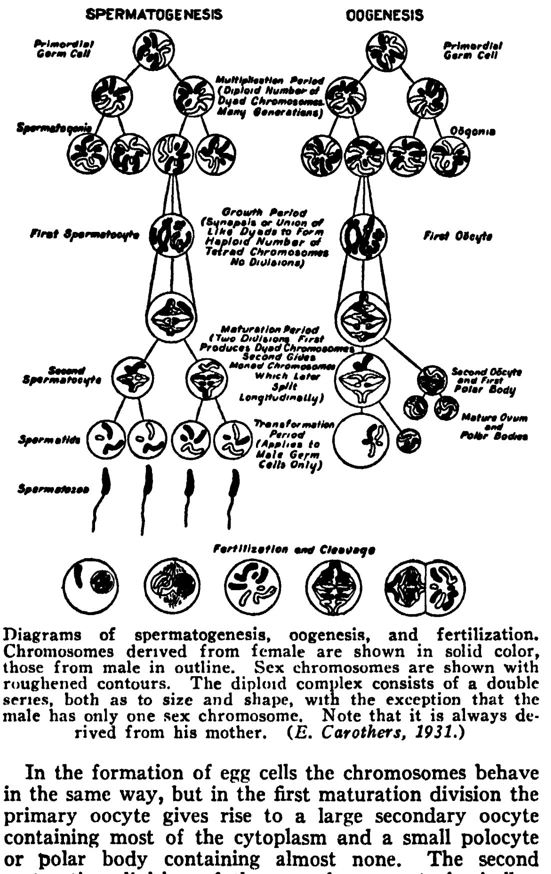
MEIGEN'S REACTION. The use of a solution of **cobalt** nitrate as a stain and reagent for determining the difference between **aragonite** and **calcite.** Aragonite, when boiled in the solution, is tinted lilac, which remains visible in thin section. Calcite and **dolomite** may be colored blue, but the color does not show in thin section. (R.M.F.)

MEIONITE. Wernerite.

MEIOSIS. A process of **cell division** accompanied by the reduction of the chromosomes from the diploid condition, in which two of a kind occur in the same cell, to the **haploid,** with only one of a kind. In a great majority of animals the cells of the body are diploid

and the reduction occurs in the process of maturation, which culminates in the formation of the sexual reproductive cells (**Gametes**).

The **germ** cells in the **gonads** of the male (spermatogonia) subdivide repeatedly by **mitosis** and the resulting cells may undergo meiotic division. The foundation of the process is the same as that of mitosis but the behavior of the chromosomes differs. The similar chromosomes pair in a process of synapsis as the primary spermatocyte develops from the spermatogonium, and each chromosome of the pair splits so that a group of four parts, called a tetrad, results. Without further change two maturation divisions ensue, the primary spermatocyte splitting to form two secondary spermatocytes and each of these dividing into two spermatids which develop into spermatozoa. Each of the four cells contains one of the four members of each tetrad of the original cell, and thus bears representative halves of only one-half of the original chromosomes.



Diagrams of spermatogenesis, oogenesis, and fertilization. Chromosomes derived from female are shown in solid color, those from male in outline. Sex chromosomes are shown with roughened contours. The diploid complex consists of a double series, both as to size and shape, with the exception that the male has only one sex chromosome. Note that it is always derived from his mother. (*E. Carothers, 1931.*)

In the formation of egg cells the chromosomes behave in the same way, but in the first maturation division the primary oocyte gives rise to a large secondary oocyte containing most of the cytoplasm and a small polocyte or polar body containing almost none. The second maturation division of the secondary oocyte is similar, and in some cases the first polar body also divides equally to form two. The net result is then one ovum and three polar bodies from each oogonium. The polar bodies disintegrate.

The union of the two kinds of gametes in the process of **fertilization** restores the diploid number of chromosomes.

In plants, meiosis never accompanies the formation of gametes. In Spirogyra and related algae meiosis reduces the diploid chromosome number of the zygospore to the haploid number characteristic of these algae. In the **Basidiomycetes** it accompanies basidiospore formation. In the **Bryophytes, Pteridophytes,** and **Spermatophytes,** it reduces the diploid chromosome number of the spore-producing (sporophyte) generation to the haploid number of the gamete-producing (gametophyte) generation. Haploid spores grow into haploid plants which produce gametes by equational mitosis. These gametes fuse in pairs (egg with sperm) to produce diploid plants which produce haploid spores by meiosis.

Meiosis is best defined as a series of two rapidly succeeding mitoses in which each chromosome divides but once. This reduces the chromosome number by half because in any other two succeeding mitoses each chromosome would divide twice and all of the original chromosomes would be represented in each of the four resulting cells.

It should be understood that the term diploid (2n) refers to the existence in an individual of two distinct sets of chromosomes one from the mother, one from the father. These two sets are identical in size, shape, and form. They may differ in the genes which they contain. Each chromosome has a mate, a homologous chromosome. Furthermore the chromosome is not *formed* during mitosis; it maintains its individuality throughout the life of the cell. In the nucleus it is in the form of a long thread, a string of genes. In the early stage of the first meiotic division each long thread-like chromosome pairs with its homologue. Then each chromosome contracts and divides lengthwise into two parts, the chromatids, each gene reproducing itself in the process. Each pair of chromosomes now consists of four chromatids forming the tetrad. During the process of contraction the chromatids twine about each other and may break between genes and exchange whole portions. If one chromatid carries the dominant genes ABCDE and the homologous chromatid the recessive genes abcde, such an exchange might produce the two new combinations ABcde and abCDE. This would be known to students of **heredity** as crossingover. Unequal crossingover may produce the combinations ABCcde and abDE, the C-locus being duplicated in the first chromatid and lost in the second. During the early stages of meiosis other types of chromosomal interchange or gene rearrangement may occur. Meiosis therefore provides, not only for the accurate separation of the duplicate sets of chromosomes in a diploid individual so that each gamete or spore contains one complete set, but also for profound changes in the hereditary constitution of a species. The abnormal effects are enhanced by the use of x-rays applied to organs in which meiosis is taking place. **Colchicine,** applied to cells during meiosis, prevents the chromatids from separating and produces, eventually, the tetraploid (4n) condition. Tetraploid plants are larger, often more valuable, than diploid ones. (A.W.L., P.A W)

MELANCHOLIA. A form of mental illness characterized by great depression, anxiety and fears. *Involutional melancholia* is the common form which comes on at the **menopause,** or in males in their late 50's. At this period there is a conscious recognition that the peak of life has passed, early dreams and desires cannot be fulfilled, ambition and life's forces are waning. Often a disturbing experience, such as breaking up of the home, loss of position, or the death of one upon whom the individual felt dependent precipitates the disease. Frustration, disappointment and fears of a lonely future activate old conflicts and culminate in profound depression. Remorse, feelings of guilt, delusions, and **hallucinations** may occur.

About 40% of patients with involutional melancholia recover, although the convalescence may last several years. Shock treatment with metrazol, a powerful central-nervous-system stimulant, **insulin,** or electric shock which produces convulsions, have been most successful in treating this type of psychosis. (D.M.H.)

MELANISM. A condition of unusually dark pigmentation. Melanism is conspicuously shown in occasional aberrant individuals of certain **butterflies** whose wings

are usually colored yellow or red-brown over most of their area. Melanic (melanistic, melanotic) individuals have the normal black markings extended into the lighter areas or in extreme cases have these areas entirely obscured. The black leopard is a melanic phase of the spotted leopard and the black fox is related in the same way to the red fox. (A.W.L.)

MELANOCRATIC. The term proposed by W. C. Brögger for eruptive igneous rocks containing more than 50% of **femic** minerals. Derived from the Greek, meaning black. (R.M.F.)

MELAPHYRE. An old general term proposed by Brongiart, in 1813, for altered **amygdaloidal andesites** and **basalts.** (R.M.F.)

MELON. *Cucumis Melo.* **Gourd Family.**

MELTING POINT. With the exception of certain glassy or resinous substances devoid of crystal structure and some that are chemically unstable, every pure substance has a more or less well-defined melting point (or freezing point) under any given pressure. By this is meant a temperature at which the solid and the liquid phases of the substance may exist together in equilibrium, without either phase changing into the other. Thus, at atmospheric pressure, a mixture of ice and water kept at 0° C. will not change in relative proportions unless heat is applied or withdrawn; and the temperature of the mixture will remain constant so long as both phases are present. Applying heat will merely melt some of the ice, withdrawing it will freeze some of the water. The melting point is in general affected by pressure; for some substances it is lowered by increased pressure, for some it is raised, according to whether the liquid or the solid phase has the greater density. The melting points of substances in an impure state (mixture or solution) are often profoundly modified by the presence of the impurity; thus solder, a mixture of lead and tin, has a much lower melting point than either pure metal. The **freezing-point law** and the properties of **solutions** give further information on this aspect of the subject.

MELTING POINTS OF SOME ELEMENTS

Aluminum	660° C.	Platinum	1774° C.
Copper. .	1083° C.	Silver	960° C.
Gold. .	1063° C.	Sulfur	113° C.
Iron .	.1535° C.	Tin.	232° C.
Lead. .	327° C.	Zinc	419° C.
Mercury	−39° C.		

(L.D.W.)

MEMBRANELLE. A thin projection adjacent to the mouth of most ciliate **protozoans,** formed of fused **cilia.** (A.W.L.)

MENDELISM. **Heredity.**

MENEGHINITE. A mineral lead-antimony sulfide, $Pb_{18}Sb_7S_{23}$. Crystallizes in the orthorhombic system. Hardness, 2.2; specific gravity, 6.36; color, gray with metallic luster; opaque. Named after Meneghini (1811–1889) of Pisa. (R.M.F.)

MENHADEN. Pisces, Teleostei. An abundant marine fish (**Pisces**), *Brevoortia tyrannus,* related to the herrings. Massachusetts to Florida. Edible and also used for oil and fertilizer. (See **Esters.**) (Also called mossbunker, bug fish and fat back. (A.W.L.)

MENINGITIS. **Inflammation** of the meninges, the membranes covering the brain and spinal cord. Meningitis is most often caused by infection with meningococci, but may be due to streptococci, staphylococci, pneumococci, influenza bacilli or tubercle bacilli. (See **Bacteria.**) Ocasionally sterile meningitis due to an irritant such as blood in the **cerebrospinal fluid** occurs.

Meningococcus meningitis (cerebrospinal fever, spotted fever) is an epidemic disease, although sporadic cases occur. Outbreaks are common among soldiers in wartime. The causative organism may be carried for weeks or months in the nose and throat without producing symptoms. When the meningococci invade the blood stream, chills, fever, and a characteristic petechial or hemorrhagic rash appear; and when they localize in the meninges, the characteristic signs of meningitis develop: severe headache, irritability, stiff neck, vomiting and sometimes delirium and coma. The organism can usually be found in the spinal fluid, or cultured from it in the acute stage of the disease.

Until the advent of modern chemotherapy, the mortality rate for meningococcus meningitis was high—about 35%. Anti-meningococcus **serum** reduced this figure slightly, but the **sulfonamides** have replaced serum completely. Sulfadiazine is the drug of choice, and if it is given early in an uncomplicated case, the prognosis is excellent. Complications include ear infections (**otitis media**), eighth (auditory) nerve involvement with deafness, purulent **conjunctivitis, arthritis,** which is relatively common, and **endocarditis,** which is rare. A rare and extremely virulent form of the disease is accompanied by hemorrhages into the vital organs, particularly the **adrenal** glands, and death invariably ensues within a few hours after onset.

Meningitis caused by organisms other than the meningococcus has a similar clinical picture but a higher mortality, in general. **Sulfonamides** and **penicillin** are used in the treatment of the coccal infections, and antiserum when the agent is the **influenza** bacillus. There is no effective treatment for tuberculous meningitis; this disease is almost uniformly fatal, although **Streptomycin** appears to have some therapeutic value. (D.M.H.)

MENISCUS. In anatomy, this term denotes a crescent-shaped piece of cartilage in a joint. The medial and lateral meniscus are two flat pieces of cartilage on either side of the knee joint between the femur and the tibia. They serve as cushions between the long surfaces. At times they become injured or torn loose from their attachments. This causes considerable pain and interference with function, with accumulation of fluid in the knee joint. In such a case, operation is performed and the injured meniscus is removed. No interference with function follows such a procedure. (D.M.H.)

MENOPAUSE. That period of life at which permanent cessation of the menses occurs. The average age for the onset of the menopause is 47 years. The menstrual periods may cease abruptly, or they may be irregular over a period of several years, gradually diminishing, and finally stopping. The cause of the menopause is a sudden decrease in ovarian hormone production. Although the period may be completely asymptomatic, various nervous and **circulatory system** manifestations are common. When they are severe, the menopause may be stormy both from the psychological and the physiological point of view. The symptoms include hot flashes, increased sweating, irritability, depression, fatigue, and emotional instability. Transient **hypertension** occurs not infrequently, and **obesity** often appears at the time of the menopause. The symptoms may be controlled by the administration of stilbesterol, a synthetic hormone preparation. (D.M.H.)

MENORRHAGIA. **Menstruation.**

MENSES. **Menstruation.**

MENSTRUATION. The monthly discharge of blood from the **uterus** which begins with puberty and continues until the menopause. It is absent during pregnancy, after removal of the uterus or both ovaries, and after exposure of the ovaries to sufficient radiation from x-ray or radium. It may cease during severe illnesses.

The primitive explanation of menstruation (and this explanation is still believed by many uninformed people) was that of periodic purging of the woman's body of poison. The Greek word for menstruation was the same as that for catharsis.

The menstrual cycle is dependent upon the activity of the anterior pituitary and ovarian hormones. In brief, two hormones from the ovary, estrogen and luteinizing hormone, acting in sequence, are directly responsible for the changes that take place in the uterus during the 28-day cycle. The production of these ovarian hormones is controlled by hormones secreted by the pituitary gland, the follicle-stimulating and luteinizing hormones.

Immediately following menstruation, follicles mature in the ovary under the stimulation of the pituitary follicle-stimulating hormone. Follicles consist of egg cells with their protective and nutrient covering. (See illustration page 629.) During their growth, a hormone is secreted by them into the blood stream. This follicular hormone is called by various names—estrogenic hormone, female sex hormone, theelin, folliculin, estrin, etc. Estrogenic hormone is responsible for growth and regeneration of the lining of the uterus, helping to prepare it for reception of the ovum if pregnancy is to take place.

Ovulation or escape of the ripe ovum from the ovary by rupture of the follicle occurs between the 10th and 17th day of the menstrual cycle (the cycle beginning on the first day of menstrual flow, extending to the beginning of the next period—an average duration of 28 days). Following ovulation a new development begins in the collapsed follicle which then becomes the corpus luteum. During development of the corpus luteum the follicular hormone is still produced, but, in addition, a second hormone is secreted under stimulation of the luteinizing hormone of the pituitary. This is called progesterone (progestin, corpus luteal hormone) and it causes the lining of the uterus to change from a vascular to a secreting type of mucosa, further preparing the uterus for implantation of the fertilized ovum. If the ovum is not fertilized (if pregnancy does not take place) the corpus luteum degenerates and the production of the follicular and luteal hormone ceases. The withdrawal of these hormones is believed to cause the onset of menstrual bleeding and the sloughing away of the lining of the uterus.

The periodicity of the menstrual cycle is characteristic; 80% of normal women have a cycle of 28 days between periods. The cycle may be longer or shorter. Under normal conditions great variation may be seen.

The average duration of flow is from 3 to 5 days and the amount of blood lost varies from 2 to 8 ounces. The menstrual discharge consists of blood, mucus, cellular debris and bacteria. Menstrual blood does not clot. It is normal for lassitude, a feeling of heaviness in the pelvis, mild headache, irritability, depression, frequency of urination, painful swelling of the breasts to accompany the menstrual period.

The average age of onset of menstruation is 13.9 years; it is influenced by physical health, temperament, and environment and to a less extent by race and climate. Menstruation ceases with the menopause or change of life which occurs in the majority of women at 47 years.

Abnormalities of the menstrual cycle include (1) amenorrhea, (2) dysmenorrhea, (3) menorrhagia, and (4) metrorrhagia.

Amenorrhea is the absence of the normal period. It may be a physiological suppression of the menses as before **puberty**, during **pregnancy** and **lactation**, or after the **menopause**. It occurs pathologically in structural abnormalities such as failure of development of the genital tract, endocrine disorders of the ovary, **pituitary** or **thyroid** glands; at times in severe infections; **tuberculosis**; prolonged wasting diseases; **diabetes**; and **psychoses**.

Dysmenorrhea is painful menstruation. It is most often functional, caused by congestion of the pelvic organs. Psychogenic factors may play a significant role. Organic causes are endocrine disturbances, obstruction and infections in the genital tract, particularly gonorrheal infection of the **fallopian** tubes (**salpingitis**).

Menorrhagia is excessive flow of blood during the menstrual period. The common causes are **fibroid tumors, cancer, polyps** and other tumors of the uterus; endocrine disturbances in the pituitary and ovary resulting in overgrowth and abnormal vascularity of the lining mucosa of the uterus during each cycle; infections of the uterus and tubes, particularly gonorrheal salpingitis.

Metrorrhagia is irregular bleeding from the uterus, independent of menstruation. It is due to tumors of the uterus (cancer or a fibroid), pelvic infections, and **abortion**, or ruptured ectopic **pregnancy** (see **Pregnancy**). (D.M.H.)

MENTAL DEFICIENCY. Arrested or incomplete development of the mind due to arrested or incomplete development of the brain. Mental defectives are classed as (1) idiots, those whose mental development never gets beyond that of a normal child of 3 years; (2) imbeciles, who reach the mental age of 7 years; (3) feebleminded individuals, who reach the mental age of 10 years, and (4) morons, whose mental age is 12 years. The morons are often intelligent enough to provide for themselves and lead a simple normal social life.

The causes of mental deficiency are numerous. In *primary* mental deficiency heredity is a prominent factor. Mental deficiency is a complex of hereditable characteristics and does not behave as a simple Mendelian recessive. Yet it has been established that if two mental defectives marry, all their children will be mental defectives; if a mental defective marries a normal, there is a strong likelihood that mental deficiency will appear in an early subsequent generation. *Secondary* mental defect results most commonly from **encephalitis**, either of the epidemic variety, or as a complication of such diseases as measles. Deficiency of the hormone produced by the **thyroid gland** is responsible for cretinism and mental defect. Degenerative processes and mental deterioration early in life are occasionally associated with **epilepsy** and juvenile **paresis**. In children who are blind and deaf and are thus deprived of stimuli which are necessary to normal mental development, a degree of mental deficiency commonly exists.

The diagnosis of mental deficiency rests on the presence of abnormalities of development and behavior, plus the score in certain standard intelligence tests. Failure of normal development may be indicated by the late appearance of bladder and rectum control, and of walking and talking. In the older child, stunted growth, impaired muscle power, extreme backwardness at school, senseless or asocial behavior, inability to fix the attention, all may point to mental defect. However, since these characteristics may be based on environmental factors and personality difficulties as well as on mental deficiency, caution must be exercised in making the diagnosis. In some types of mental deficiency, bodily characteristics are diagnostic. This is true of cretinism (see **thyroid gland**) and Mongolian idiocy. In the latter the child at birth has certain stigmata: a small

round head, oblique eyes with narrow lid slits, squat nose, short stubby fingers and hypermobility of the joints. Mongolism occurs as an unaccountable aberration in families of normal mental heredity.

Intelligence tests have been devised and standardized to test the mental capacities of an individual. They do assume a certain amount of education, however, and a completely illiterate person would fail in such a test though he be of normal intelligence. The tests are merely aids and are useful in the hands of experienced psychologists only. They supplement the real criterion of mental deficiency which is social failure; they must be interpreted in relation to reports from the home, or school, or employer, and by observation of the patient himself. The common standard tests are known as the Merrill-Palmer for children under the mental age of six, and the Stanford-Binet for all over six. These consist of simple exercises in logic, reasoning ability, and powers of observation. The Porteus performance tests indicate manipulative skill. (D.M.H.)

MENTHOL. **Alcohols and Ethers.**

MENTHONE. **Aldehydes, Ketones, and Related Compounds.**

MENTUM. 1. **Labium.** 2. The chin. (A.W.L.)

MERCAPTANS. **Thioalcohols and Related Compounds.**

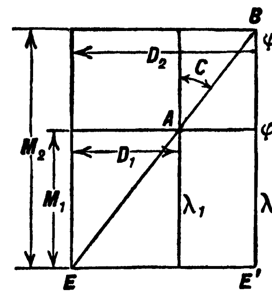
MERCATOR PROJECTION. The Mercator method of projecting the surface of the earth on a plane was invented by Gerard Mercator, who lived in Flanders during the latter part of the 17th century. At the present time, 90% of the chart work of the deep-sea navigator is done on the Mercator Chart. To realize the general outline of the method, say that we have a terrestrial globe and wish to peel off the surface. One method of procedure would be to make cuts through the surface along **meridians** of **longitude** and remove the sectors of the surface thus obtained. If the material of which the surface was constructed was of sufficient elasticity, these segments could be placed on a plane with a small amount of stretching. The segments would be tangent along the equator, but would separate as the poles were approached, thus forming a discontinuous map. To make the map continuous requires stretching the segments along parallels of **latitude,** the stretching increasing as higher latitudes are reached. This east-west stretching will introduce distortion in the shape of objects, e.g., a circular object would be distorted into an ellipse. To maintain the shape of objects the same amount of stretching must be introduced in the north-south direction in any latitude, as is necessary in the east-west direction in that latitude to make the segments tangent. The final result is that objects retain their true shape, but there is considerable alteration in the relative sizes of surface features in different latitudes.

On the completed Mercator Chart meridans of longitude and parallels of latitude appear as perpendicular straight lines. The meridians are equally spaced, but the distance between successive parallels becomes greater and greater as we proceed away from the equator. This distance becomes so great that Mercator projection is not used beyond 70° latitude. The actual computation of the distances of the successive parallels from the equator, taking into account the ellipticity of the earth, is a complicated mathematical task. The results of the computation have been tabulated in a number of places (e.g., Bowditch—"American Practical Navigator," and similar publications) being generally known as the meridional parts.

The great advantages of the Mercator Chart over all others are that meridians and parallels are perpendicular straight lines, and also **rhumb lines** are straight lines. Problems in **dead reckoning** may be solved graphically on the Mercator Chart using straight lines to indicate the courses of the vessel. To facilitate such problems and avoid the marking-up of actual charts Mercator plotting sheets are published by the different governments, which show meridians and parallels drawn on the proper relative Mercator scale. (See **Small Area Plotting Sheet.**) (W.K.G.)

MERCATOR SAILING. In case the distance run by a ship does not exceed 300 **nautical miles** the various problems of **dead reckoning** and the **sailings** may be solved without sensible error by methods which assume that the surface of the earth is a plane. The distances run by modern steamships and aircraft during a single day frequently exceed this limit and the true shape of the earth's surface must be taken into consideration. The method of solving the various problems connected with **course** and distance in such cases is usually one which depends for its theory upon the **Mercator projection** and is known as Mercator sailing.

In the accompanying figure we have the representation of the general problem, drawn on a section of a



Mercator sailing.

Mercator Chart. The vessel is proceeding from A in **latitude** φ_1 and **longitude** λ_1, to B, in latitude φ_2 and longitude λ_2. The course is extended to cross the **equator,** EE' in the point E. The angle C is approximately the **rhumb-line** course between the two points. M_1 and M_2 represent the stretched distances of the parallels φ_1 and φ_2 from the equator, the values being taken from tables of meridional parts. D_1 and D_2 represent the difference of longitude of the points A and B from the point of equator crossing of the extended course.

Now call $M_2 - M_1 = m$ and $D_2 - D_1 = \delta\lambda$ (the longitude difference between A and B) and we have at once from the figure $\delta\lambda = m \tan C$. The value of C thus computed, taking into account the Mercator stretching, is frequently referred to as the Mercator course between A and B. The distance along AB is a stretched distance and, if calculated from the above figure, or obtained graphically, would be greater than the distance actually traveled between A and B. To avoid this discrepancy the distance is computed by the methods of **plane sailing,** solving the plane triangle using the Mercator course as computed above for the vertex angle and the difference of latitude as one leg. The so-called Mercator distance is obtained as $d = (\varphi_1 - \varphi_2)$ secant C, the value of $(\varphi_2 - \varphi_1)$, the difference of latitude, being expressed in minutes of arc which is practically identical with nautical miles. (W.K.G.)

MERCURY. Mercury is the name of a **planet,** and of a chemical **element.** They will be discussed in that order in this article.

The planet Mercury (see planetary tables, page 1109) is the closest planet to the sun of those thus far discovered. It has been known from remote antiquity and there are recorded observations of it as far back as the 3rd century B.C. Mercury is so close to the sun that at its maximum **elongation** it is less than 30° away,

as seen from the earth, with the result that it will never rise more than two hours before the sun, nor be above the horizon in the evening more than two hours after sunset in the latitudes of the United States. The early astronomers failed to recognize the planet as the same object when seen east and west of the sun; it being known as Apollo when seen west of the sun in the early morning, and as Mercury when seen east of the sun in the evening.

As well as being the closest planet to the sun the **orbit** of Mercury is the most eccentric of all planetary orbits. This high eccentricity, coupled with the proximity of the sun, give to the planet a velocity of more than 36 miles per sec. when at perihelion, a value more than twice as great as that for the earth. After orbits had been computed on the basis of the Newtonian and Keplerian laws and all **perturbations** applied for the gravitational effects of all known planets, there still remained a progressive motion of the longitude of **perihelion.** For many years this unexplained perturbation was attributed to the attractions of an unknown planet between Mercury and the sun. The search for this intra-mercurial planet, provisionally called Vulcan, formed a part of many **eclipse** programs during the past century. The application of the theory of **relativity** to the orbit calculations for Mercury removed this hitherto unexplained perturbation and was one of the early triumphs of the theory.

Because of the fact that Mercury is always very low in the sky during darkness it must be observed with a telescope in the daytime to obtain reliable results regarding surface characteristics. Only very few observers have ever been able to distinguish any surface markings on the planet and the different reports are quite conflicting. The general consensus seems to be that these markings do not change their apparent positions, a result which can only be explained on the hypothesis that the planet is rotating about the sun in the same period as it revolves, as is the case with the **moon** relative to the earth.

The physical conditions of the surface of Mercury are quite comparable with those on the moon. The surface gravity and reflecting power of both the moon and Mercury are very comparable and these results have led to the conclusion that Mercury is without atmosphere and hence barren of life as we know it on the earth. Observations of the temperature of the sunlit surface of Mercury give a value of over 600° K. (621° F.), a temperature comparable with that of molten lead.

When inferior **conjunction** occurs with the sun close to one of the nodes of the apparent path of the planet, the planet will pass between the earth and the sun. This phenomenon, known as a transit of Mercury, occurs about 13 times in each century. Transits of Mercury formerly were used as a method for determination of **solar parallax,** but this method for determining the value of this important constant has been superseded by other methods. At the time of a transit of Mercury the planet appears as a very small dot visible only with a telescope, and moving slowly across the disk of the sun.

The chemical element mercury: Symbol: Hg (hydrargyrum). Atomic number: 80. Atomic weight: 200.61. Density: 13.546 at 20° C. Melting point: −38.87° C. Boiling point: 356.90° C. Isotopes (page 290).

Mercury or quicksilver is a silver-white liquid metal—the only metal that is liquid at ordinary temperatures (the melting point of gallium is 29.75° C.); forms alloys, called amalgams, with most metals, but not with **iron** or **platinum;** does not wet glass but forms a convex surface when in a glass container; is slightly volatile at ordinary temperatures and a health hazard due to its poisonous effect; slowly tarnishes in moist air; upon heating in **air** or **oxygen,** somewhat below its boiling temperature of 357° C., forms mercuric oxide slowly, as in the classical experiment by Lavoisier on the composition of air; may be purified by distillation and condensation (health hazard); unattacked by dilute **hydrochloric** or **sulfuric acid,** but dissolved by dilute or concentrated **nitric acid** with the formation of mercurous and mercuric nitrates, respectively, and by hot concentrated sulfuric acid with the formation of both mercurous and mercuric sulfates; unattacked by **alkalis.** Discovery ancient.

Mercury is used (1) in scientific apparatus on account of its remarkable range of properties, (2) in the preparation of dental and other amalgams, (3) recently, in some industrial **boilers** instead of steam, (4) in the manufacture of fulminate of mercury **explosive,** vermilion (mercuric sulfide) pigment, and other mercury compounds, (5) in the amalgamation process for the recovery of **gold** and **silver,** (6) in medicine. In the treatment of syphilis, it has been employed for centuries. Mercury bichloride is used as an antiseptic. Mercurial **diuretics** are effective in treating **edema** due to heart disease. Mercury occurs infrequently as free metal, but chiefly as the red colored sulfide (cinnabar, HgS) in Spain (the Amaden mine has been continuously worked for over 2500 years and furnishes all of Spain's production), Italy, California, Oregon. The ore is roasted with air and the exit gases passed through a condensing system where the mercury is collected.

Bromides: Mercurous bromide (HgBr), pale yellow precipitate, formed by reaction of mercurous salt solution and **potassium** bromide solution; sublimes at 345° C.; mercuric bromide ($HgBr_2$), white, sparingly soluble precipitate, formed by reaction of mercuric salt solution and potassium bromide solution. Melting point of mercuric bromide 237° C.

Chlorides: Mercurous chloride, "calomel" (HgCl), white precipitate, formed by reaction of mercurous salt solution and **sodium, potassium** or **ammonium** chloride solutions or **hydrochloric acid.** Melting point of mercurous chloride 302° C. Turned black by ammonium hydroxide; mercuric chloride, "corrosive sublimate" ($HgCl_2$), formed by heating mercuric sulfate and **sodium** chloride whereupon mercuric chloride, melting point 277° C., sublimes. Used in medicine; mercurammonium chloride, "infusible white precipitate" (NH_2HgCl), by adding ammonium hydroxide to mercuric chloride solution; mercurodiammonium chloride, "fusible white precipitate" ($HgCl_2 \cdot 2NH_3$), formed by adding mercuric chloride slowly to a hot mixture of **ammonium** hydroxide and ammonium chloride.

Chromates: Mercurous chromate (Hg_2CrO_4), red precipitate, formed by reaction of mercurous salt solution and **potassium** chromate solution; mercuric chromate ($HgCrO_4$), red precipitate, formed by reaction of mercuric salt solution and potassium chromate solution.

Cyanide: Mercuric cyanide ($Hg(CN)_2$), white solid, soluble—the only soluble cyanide of the heavy metals—slightly ionized and giving no precipitate with sodium hydroxide. Used in the manufacture of cyanogen gas.

Fulminate: Mercuric fulminate ($Hg(CNO)_2$), dark brown powder, formed by the reaction of mercury, **alcohol** and concentrated **nitric acid.** Used to detonate explosives of various types in military, industrial, and sporting practice.

Iodides: Mercurous iodide (HgI), greenish-yellow precipitate, formed by reaction of mercurous salt solution and **potassium** iodide solution, melting point of mercurous iodide 290° C. with decomposition; mercuric iodide (HgI_2), pale yellow turning to red precipitate, formed by reaction of mercuric salt solution and potassium iodide solution, melting point of mercuric iodide 259° C.; potassium mercuriiodide (K_2HgI_4), yellow crystals, formed by addition of excess of potassium iodide to mercuric iodide and crystallization of the mixture. Used in the presence of **sodium** hydroxide as an important reagent (Nessler's) for **ammonia,** with which it

forms the "iodide of Millon's base" ($HgO(NH_2)HgI$), yellow to brown precipitate.

Nitrates: Mercurous nitrate ($HgNO_3 \cdot H_2O$), white crystals, formed by reaction of mercury metal in excess and dilute **nitric acid,** and crystallization; mercuric nitrate ($(Hg(NO_3)_2 \cdot \frac{1}{2}H_2O)$), white crystals, formed by reaction of mercury metal with excess of concentrated nitric acid, and crystallization.

Oxides: Mercurous oxide (Hg_2O), black precipitate, formed by reaction of mercurous salt solution and sodium hydroxide solution; mercuric oxide (HgO), (1) yellow precipitate, formed by reaction of mercuric salt solution and **sodium** hydroxide solution, (2) red solid, by ignition of mercuric nitrate, or by heating mercury somewhat below its boiling point in an enclosed volume of air or oxygen.

Sulfates: Mercurous sulfate (Hg_2SO_4), white precipitate, formed by reaction of mercurous salt solution and **sodium** sulfate solution; mercuric sulfate ($HgSO_4$), white solid, soluble, formed by reaction of mercury metal and excess hot concentrated sulfuric acid; basic mercuric sulfate "turpeth mineral" ($HgSO_4 \cdot 2HgO$), lemon-yellow solid, formed by reaction of mercuric sulfate with water, but soluble in **sulfuric acid.**

Sulfides: Mercuric sulfide (HgS), (1) black precipitate, as final result of reaction of mercurous or mercuric salt solution with **hydrogen sulfide.** With mercurous, free **sulfur** is also formed and with mercuric, the color change is first yellow, then red, brown, black successively. Insoluble in dilute nitric acid, but soluble in **aqua regia,** slightly soluble in **ammonium** sulfide, but soluble in **sodium** sulfide and hydroxide mixture. Sublimes at 446° C., (2) red solid ("vermilion," "artificial cinnabar"), by sublimation of black mercuric sulfide, or by grinding mercury metal and sulfur under slight pressure. Sublimes at 580° C. Used as a pigment in paints, rubber, and plastics.

Thiocyanates: Mercurous thiocyanate ($HgCNS$), grayish-white precipitate, by reaction of mercuric salt solution and **potassium** thiocyanate solution; mercuric thiocyanate ($Hg(CNS)_2$), white precipitate, by reaction of mercuric nitrate or sulfate solution and potassium thiocyanate solution. An explosive, which upon burning, produces "Pharaoh's serpents" ash.

Numerous organic compounds of mercury have been prepared. "Mercurochrome" is the disodium salt of 2,7-dibromo-4-hydroxymercurifluorescein, used in medicine.

All mercury-containing substances, when dry and mixed with dry sodium carbonate and heated in a glass tube, yield a metallic mercury mirror in the colder part of the tube.

All solutions of mercury salts deposit mercury metal on a strip of **copper** placed in the solution. (W.K.G., R.K.S., D.S.H.)

MERCURY ARC. The electric discharge through mercury vapor, between electrodes either of mercury or of some solid metal, is among the richest sources of **ultraviolet** radiation and has long been used as such. In the more common forms now in use at least one electrode is of mercury, deposited in a suitable reservoir at the end of a quartz tube. As these tubes are operated on moderate voltage, it is necessary to start or "strike" the arc by temporarily running a small stream of mercury through the tube from one electrode to the other. This makes a mercury conductor which quickly grows hot and fills the tube with mercury vapor, after which the mercury stream is broken and the arc is self-sustaining. The temperature is not nearly so high as in solid-electrode arcs, and these lamps are quite efficient. If the mercury vapor becomes too dense, the conductivity falls off; therefore in some forms, as the Cooper-Hewitt lamp, arrangements are provided for condensing the vapor to a fixed density. The bulb must be made of quartz for ultra-violet because glass is highly opaque to that radiation. In some forms, a fluorite window is inserted, instead, in a glass bulb. Mercury arcs with glass tubes have proved useful to some extent for illumination and especially in photography, the light being a highly actinic blue-green.

The mercury-arc tube is used primarily as a power **rectifier** but occasionally has **grids** inserted and is used for power control purposes. Since the voltage drop across the tube is small and is constant the tube losses may be made relatively small by using fairly high circuit voltages. At a few hundred volts it is the most efficient converter for a-c to d-c transformation. In the larger power applications the tubes are operated on polyphase circuits, going even as high as 24 or more phases, with a common cathode and multiple anodes. This gives a d-c output which has very little ripple and hence needs little if any filtering. (L.D.W., L.R.Q.)

MERCURY-ARC TUBE. Mercury Arc.

MERCURY VAPOR CYCLE. Although water vapor has been the standard working medium of the commercial power plant employing an external **combustion** cycle, it was recognized long ago that water vapor had physical properties not altogether desirable at either the high temperature or low temperature end of the cycle, but at no time has any vapor been discovered which would be more satisfactory at both extremes of the expansion range than steam. The use of two vapors in series makes it possible to keep an extensive temperature range and eliminate several of the disadvantages attending the use of a single vapor. The mercury-steam is the only binary vapor cycle operated on a commercial scale at present. This cycle was pioneered by Emmet. After experimenting with small-size units, the problems peculiar to **mercury** vapor were solved, and a few large mercury vapor installations have recently been built.

The advantages of mercury as a binary cycle vapor can be briefly stated.

1. At high temperatures its vapor pressure is moderate.
2. The liquid is of sufficient density to be returned to the boiler by gravity, thus eliminating a boiler feed pump.
3. Its high vapor density results in moderate spouting velocities and simple turbines can be used. Exhaust passages can be small, and the size of the heat-exchanging mercury condenser is not excessive.
4. No tube scaling or other difficulties attending poor feed water are possible. Feed treatment is eliminated as mercury is a stable liquid. (F.T.M.)

MERGANSER. Duck.

MERIDIAN. On the **celestial sphere** a meridian is a great circle passing through the poles of rotation and, hence, perpendicular to the celestial **equator.** The local meridian is the great circle passing through both the poles of rotation and also through the **zenith.** It is both a **vertical circle** and also an **hour circle.** However, the local meridian differs from the ordinary circles on the sphere in that it apparently remains fixed as the celestial sphere apparently rotates once each day. An object on the local meridian is said to be in culmination and if it is on that section of the meridian between the horizon and above the pole it is said to be in upper culmination, if below the horizon, or below the pole and still above the horizon, it is said to be in lower culmination. The **spherical coordinates** both of **hour angle** and **astronomical azimuth** are measured from the local meridian in the direction of apparent rotation of the celestial sphere.

A terrestrial meridian is a curve cut on the surface of the earth by a plane containing the earth's axis of rotation. The local meridian of a point on the surface of

the earth is the meridian passing through that point. The plane of the local terrestrial meridian coincides with the plane of the local celestial meridian. Terrestrial **longitude** is measured from the local meridian of Greenwich, England.

See **Bearing** for the meaning of meridian as used in **plane surveying.** (W.K.G.)

MERIDIAN CIRCLE. A meridian circle is a telescope adjusted so that the **collimation plane** of the instrument is in the plane of the local meridian, and the telescope may be rotated about a horizontal axis. The instrument is usually fitted with a circle, accurately graduated in degrees, minutes, and seconds, which is perpendicular to the axis of rotation and hence is in the plane of the meridian. In case the instrument does not carry the circle in the meridian, the instrument is known as a transit circle.

At the principal **focus** of the telescope is placed a **reticle** with an odd number of vertical wires, the middle one of which is in the collimation plane. One horizontal wire through the optic axis of the telescope is usually present.

The instrument is used to determine the **equatorial coordinates** of the stars, when the local sidereal **time** and terrestrial **latitude** are known; or, conversely, to determine accurate local sidereal time by observation of stars of known right ascension. The local sidereal time of the instant of passage of a star across the middle wire of the reticle must be the **right ascension** of the star. The declination is obtained from the readings of the graduated circles when the star passes through the field of view along the horizontal wire. The instrument is also used for the accurate determination of terrestrial **longitude** by determining the local sidereal time and knowing the corresponding Greenwich time. (W.K.G.)

MERISTEMATIC. Parenchyma.

MERLE. Aves, Passeriformes. The common **blackbird,** *Turdus merula,* of southern Europe. A French name. (A.W.L.)

MERLIN. Falcon.

MEROGONY. Development of an egg deprived of its nucleus, or of a cytoplasmic fragment of an egg, after **fertilization** by a normal sperm. The process is biologically interesting as proof that the nucleus of the male germ cell is capable of bringing about embryonic development although the cell itself is unable to develop because its cytoplasm is chiefly in the form of specialized structures. (A.W.L.)

MEROPODITE. Biramous Appendage.

MEROSOMA. The broad anterior part of the **abdomen** of **scorpions.** Preabdomen. (A.W.L.)

MESA. A flat-topped, steep-sided, table-like mountain capped with a formation or stratum which is relatively horizontal and resistant to **erosion.** When such a topographic feature is less than 1 sq. mi. in area it is usually called a butte. (R.M.F.)

MESCAL. Cactus.

MESENCHYME. A diffuse tissue formed chiefly from the middle **germ layer** (mesoderm). It appears in the embryo as a mass of scattered angular or stellate cells with long processes.

The mesenchyme of vertebrates forms the **connective tissues, bone, cartilage,** and other special tissues. (A.W.L.)

MESENTERY. A thin **tissue** which attaches the intestine to the wall of the body and in some cases holds it suspended in the body cavity. It is formed in animals with a **coelom** by the splitting of the mesoderm (**germ layer**) around the alimentary tract to form this cavity. Separate splits occur on the two sides of the body. In some parts they meet in the median line and become confluent, and elsewhere a thin mesodermal partition persists between them, continuous with the lining of the cavity and with a mesodermal covering of any organ around which the advance of the cavity has taken place. This median partition in connection with the intestine is the mesentery.

The mesentery of vertebrates persists only above the alimentary tract as a dorsal mesentery save in very limited regions. The liver grows into the ventral mesentery, which persists as the gastro-hepatic ligament between liver and stomach and as the falciform ligament between liver and body wall. The regions of the dorsal mesentery are named for the regions of the tract with which they are connected. That of the stomach is the mesogastrium, that of the duodenum the mesoduodenum, and that of the large intestine the mesocolon. In mammals the dorsal mesogastrium forms a saccular extension called the great omentum.

In the sea anemones and related **coelenterates** the tubular stomodaeum is held in place by radiating septa from the body wall formed of a central **mesogloea** covered with endodermal tissue. These structures are also called mesenteries. Similar thin septa extending inward from the body wall but not reaching the stomodaeum bear the same name. Those which connect with the stomodaeum are primary mesenteries, the next longest are secondary mesenteries or metacnemes, and still shorter septa are tertiary mesenteries. (A.W.L.)

MESH CONNECTION. This is a polyphase circuit connection in which the phase elements are connected end to end as opposed to the star connection where all phase elements have one end in common. The **delta connection** is the three-phase mesh connection and is by far the most common. (L.R.Q.)

MESOCARP. Fruit.

MESODERM. Germ Layers.

MESOGLOEA. A layer of material between the ectoderm and endoderm in **diploblastic** animals, including **sponges, coelenterates,** and possibly **ctenophores.** The layer does not form like the other **germ layers** as a compact mass of cells but is of unorganized material containing specialized cells derived from the formed layers. In the sponges these cells form the spicules and the reproductive cells and in the coelenterates they include many nerve cells.

The **jellyfishes** have a thick jelly-like mesogloea which is responsible for their common name, and in the ctenophores this layer is similar but contains all of the muscular tissue of the body. Some observers regard it as a true mesoderm in the latter group. It is, in any case, at the border between the diploblastic and triploblastic forms. (A.W.L.)

MESOHIPPUS. Fossil Mammals; Oligocene.

MESON. Nuclear Particles.

MESOPHYLL. Leaf.

MESOPHYTES. Plants which are adapted for growth in soil with a plentiful supply of both air and water, as distinguished from **Hydrophytes** adapted to an excess and **Xerophytes** adapted to a deficiency of water. All common garden plants and the large majority of wild

plants are mesophytes. Certain mesophytic trees such as the oak may adapt themselves during growth to root submersion by overgrowth of the base of the trunk. (P.A.W.)

MESOTHORIUM. Symbol: $MsTh_1$, and $MsTh_2$. Two radioactive elements of the thorium series. (See **Radioactive Changes.**)

MESOTRON. A **nuclear particle** which appears to originate as a **secondary emission** from the incidence of **cosmic rays** on matter. It carries a single elementary charge, either positive or negative, and has a mass estimated at from 100 to 200 times that of the **electron.** The term "mesotron" indicates that this mass is intermediate between that of the electron and any other known mass, such as the **proton.** Some writers prefer the shorter term "meson," and several other synonyms have been used.

The mesotron was first recognized by Dr. Carl D. Anderson in 1936, by means of **cloud chamber** tracks whose properties could not be attributed to any particle then known. The extraordinarily high ionization and penetrating power, together with the small curvature of the tracks in a magnetic field, indicated a mass much greater than that of the electron or the **positron.** Mesotrons are of such rare occurrence that insufficient data are yet available to yield a precise determination of the mass, but its magnitude is unquestionably of the order indicated above.

The numerical equality of the mesotronic charge to that of the electron makes it doubtful that the mesotron is an independent entity. Indeed there is indirect evidence that mesotrons are radioactive, which means that they have a complex structure. This evidence is based largely on the fact that mesotrons have a habit of disappearing whenever they traverse any considerable distance, and the number so disappearing seems to be proportional to the distance, and not to the density of the matter as in ordinary absorption. The inference is that a certain percentage suffer radioactive disintegration, with products not so far recognized as such. The very short half-life (decay coefficient) deduced from the observations would preclude any possibility of mesotrons having come from interstellar space; hence they must be regarded as secondaries to the original cosmic radiation. (L.D.W.)

MESOZOIC. A major subdivision of the geologic time-scale. The **era** of "Middle" life, or the age of reptiles. Subdivided from the base up, into the following periods: **Triassic, Jurassic, Comanchean, Cretaceous.** The Era was characterized by: the rise of **dinosaurs** (Triassic); rise of birds and flying reptiles (Jurassic); rise of flowering plants (Comanchean); great development of **ammonites** which became extinct at the end of the Cretaceous; culmination and extinction of most reptiles, and rise of the **archaic mammals** between the Cretaceous and the **Tertiary.** The Mesozoic era began 200 million years ago and lasted 140 million years. (R.M.F.)

METABASIPODITE. A subdivision of the **basipodite** of the **biramous appendages** of some crustaceans, also called the preischiopodite. (A.W.L.)

METABENTONITE. Injurated or lithified **bentonite** in which the "clay" mineral is beidellite. Important horizon markers, of volcanic ash, in the **Ordovician** stratigraphy of the Appalachian Mountains and the upper Mississippi Valley. (R.M.F.)

METABOLISM. The interchange of materials between living organisms and the environment, by which the body is built up and energy for its vital processes is secured.

Within the body of the individual both constructive and destructive processes take place. The incorporation of materials is known as anabolism and the breaking down of these materials for the release of the energy contained in them is katabolism.

Among different kinds of living things three principal types of metabolism are recognized, that carried on by green plants, that of plants which have no chlorophyll, including bacteria, yeasts, molds, etc., and that of animals.

The metabolism of green plants, based on the process of photosynthesis, is also carried on by some 1-celled creatures classed with the **protozoans.** They are not strictly plants or animals but are intermediate forms with some characteristics of each. Briefly this process consists of the utilization of water, carbon dioxide, and mineral salts as raw materials for the formation of complex organic compounds rich in energy. The green substance, chlorophyll, is the active agent in the process and the sun is the source of energy. **Carbohydrates** are formed by the union of carbon dioxide and water, with the release of oxygen. By the reorganization of these compounds and the addition of nitrogen, sulfur, and other elements from inorganic salts the **fats** and **proteins** are made.

Such plants as the bacteria and yeasts secure energy by chemical transformations of many kinds. Some act on carbohydrates and produce carbon dioxide and alcohol. Others oxidize ammonia and produce nitrites, and still others form nitrates from atmospheric nitrogen. The net result of their activities is that all compounds discarded by either green plants or animals, or left in their bodies at death, are transformed into substances which can be used again by one or another form of organism. Thus the three types of metabolism are related in a cycle. Any one alone would gradually transform the available foods into unavailable wastes, and would automatically come to an end. Together they carry on an endless circulation of materials.

Animals are utterly dependent on the complex compounds as foods and so must rely directly or indirectly on the green plants. They break the compounds down partially in digestion and resynthesize similar compounds from the resulting products. Both plants and animals utilize compounds of the three groups as sources of energy, releasing the energy by oxidation in the process of respiration. The resulting simplified wastes are then disposed of by excretion.

From the chemical changes included in metabolism, life is maintained, and heat, mechanical energy and electric currents are produced within the body. Metabolism may be measured as heat produced. To produce the changes of metabolism, oxidation of food must take place. Oxidation in the body is a slow process, but the same amount of heat is produced in this way as occurs when the food products are burned outside of the body.

The unit of measure used for metabolic heat production is the kilogram calorie. This unit represents the heat necessary to raise 1 kilogram of pure water 1° C.; 1 gram of carbohydrate yields 4.1 kilogram calories; 1 gram of fat yields 9.3 kilogram calories; 1 gram of protein yields 4.1 kilogram calories; 1 gram alcohol yields 7 kilogram calories.

Heat production, and therefore metabolism, may be measured directly by the **calorimeter** (by means of a compartment so constructed that all heat given off by the body may be measured); and indirectly by the respiration calorimeter (by measuring the oxygen absorbed by the lungs and the carbon dioxide given off). In medicine the respiration calorimeter is used exclusively for measuring the basal metabolism. The heat produced by a fasting individual at rest 12–15 hours after the last meal is called basal metabolism. Thus basal metabolism forms a standard for comparison of metabolism under

varying conditions of health and disease. Particularly does it indicate the activity of the thyroid gland. (A.W.L., R.S.M.)

METACENTER. **Buoyancy; Hydrostatics.**

METACENTER HEIGHT. **Buoyancy.**

METACHROSIS. The change of colors in animals. Changes occur relatively slowly in fishes, fairly rapidly in some reptiles, and as a rapid play of different shades in the octopus and related mollusks. (A.W.L.)

METACNEME. A secondary **mesentery** of sea anemones and related **coelenterates.** (A.W.L.)

METACRYST or **METACRYSTAL.** A term proposed by A. C. Lane, in 1902, for large pseudo-porphyritic crystals (**porphyroblasts**) which occur in the **metamorphic rocks.** (R.M.F.)

METAGENESIS. **Alternation of Generations.**

METAL SPRAYING. A method of coating metal or other surfaces by spraying with molten metal from a portable spray gun. The coating metal or alloy is generally fed into the gun as wire or in powdered form. It is melted in an oxyacetylene or oxyhydrogen flame and blown out in finely divided form by an air blast. The spray consists of semi-molten particles which impinge on the base material and generally form an adherent coating of somewhat lower density than normally cast metal. Metals having low melting temperatures such as zinc, aluminum, and tin are the easiest to spray. However, copper, brass, nickel, iron, stainless steel, and many other metals can be applied. Zinc-sprayed coatings are used to protect steel from corrosion. Aluminum coatings on steel provide heat resistance for mufflers and exhaust pipes, combustion chambers, etc. In addition to the application of protective coatings, metal spraying is widely used in building up worn bearing surfaces of shafts, cylinders, rolls, and other machine parts. (R.H.H.)

METALLIC TONING PROCESS. Many subtractive processes of color photography form their colorant images by the conversion of the black silver images into metallic compounds having suitable hues. Reds are obtained by conversion with uranium or copper, magenta with nickel salts, blues and cyans with iron salts and yellows with cadmium or lead salts.

These metallic-toning procedures have been widely practiced in the production of 2-color motion pictures and to a lesser extent in making 3-color prints on paper. Such processes are relatively simple and yield reproductions of good photographic quality although the colors obtained are not so brilliant as those obtained with some other methods of color printing. (H.C.C.)

METALLOGENY. The genetic study of ore deposits (R.M.F.)

METALLOGRAPHY. Study of the structure and properties of **metals and alloys**, principally by microscopic and x-ray diffraction methods. The term is also used in a broader sense to include the processing of metals by mechanical and heat treatments and the fabrication and testing of finished products. In this usage it is synonymous with **physical metallurgy.**

Metallographic samples are prepared for microscopic examination by grinding and polishing a flat surface to a mirror finish, finishing with a very fine abrasive such as rouge or levigated alumina. Intermediate abrasives may be a series of successively finer emery papers but the final abrasive is used on a wet polishing cloth mounted on a horizontal rotating disk. The small sample may be held by hand or in an automatic polishing device. It is possible to polish most metals so that no scratches are visible when observed at a magnification of 1000 times. **Electropolishing** can also be used to obtain a smooth scratch-free surface.

Unless there are non-metallic impurities present, such as **inclusions,** or other particles whose appearance and mechanical properties are markedly different from those of the base metal, such as **graphite** flakes in cast iron, the polished metallographic specimen does not yield any useful information. Etching of the polished surface, usually in dilute acids, develops the grain structure of the metal by preferential attack of the grain boundaries or of one or more of the constituents present in alloys having duplex structures. The metallurgical microscope is equipped with a camera so that the microstructure may be photographed. (See **Dendrite, Cast Iron,** and **Steel** for typical examples of photomicrographs.)

The practical limit of magnification for any microscope using visible light is about 2000 times. Ultra-violet microscopes have been used up to about 10,000 times. The new **electron microscope** is capable of much higher magnification. In examining opaque objects such as metals with the electron microscope it is necessary to make a replica of the surface with a transparent material. The thin film of variable thickness which is stripped from the prepared metal surface is examined by transmission methods in the electron microscope. The resolving power of this instrument far surpasses that of light microscopes and many important metallographic applications are being found. (R.H.H.)

METALLOID. An element which behaves chemically as both a metal and a non-metal, such as arsenic, antimony, or tellurium. In steel metallurgy, however, the term metalloid is applied to the elements carbon, manganese, silicon, phosphorus, and sulfur when present in small amounts in iron and steel. (R.H.H.)

METALLURGICAL CHEMISTRY. See each metal.

METAL-MARK. Insecta, Lepidoptera. **Butterflies** of small or moderate size, in many species marked with metallic spots and dashes. They constitute the family Rhiodinidae (Erycinidae). Relatively few species occur in temperate climates but in the tropics they are numerous and varied. (A.W.L.)

METALS AND ALLOYS. The pure metals are described under their own titles, and various alloy groups such as **Brass and Bronze, Aluminum Alloys, Magnesium Alloys, Nickel Alloys, Lead Alloys, Steel, Cast Iron,** and **Stainless Steel** are also discussed.

Process metallurgy is the science of extraction of metals from their ores. The study of metals and alloys from the standpoint of their production or alloying from metallic base materials, their mechanical and heat treatment, fabrication, and testing are known as physical metallurgy. **Metallography** is generally restricted to the study of the structure of metals and alloys by means of the microscope and x-ray. There is some conflict, however, in the use of these terms, especially physical metallurgy and metallography.

Most metals are soluble in one another in the liquid state and alloying procedures usually involve melting; however, alloying by treatment in the solid state without melting is accomplished by the methods of **powder metallurgy.** When molten alloys solidify they may remain soluble in one another or may separate into intimate mechanical mixtures of the pure constituent metals. More often there is partial solubility in the solid state and the structure consists of a mixture of the saturated **solid solutions.** Another important type of solid phase is the **intermetallic compound** which is characterized by hardness and brittleness and usually has only limited solid solubility with the other phases present. Many

possibilities exist and these can be portrayed by diagrams showing the relationships between the solid and liquid phases at various temperatures under equilibrium conditions.

It is a well-known fact that many important alloy combinations have properties which could not be predicted on the basis of the properties of the constituent metals. For example, copper and nickel, both having good electrical conductivity, form solid-solution type alloys having very low conductivity, or high resistivity, making them useful as electrical resistance wires. In some cases very small amounts of an alloying element produce remarkable changes in properties, as in **steel** containing less than 1% carbon with the balance principally iron. Steels and the **age-hardening** alloys depend on **heat treatment** to develop special properties such as great strength and **hardness.** Other properties which can be developed to a much higher degree in alloys than in pure metals include **corrosion**-resistance, oxidation-resistance at elevated temperatures, abrasion- or wear-resistance, good **bearing** characteristics, **creep** strength at elevated temperatures, and **impact toughness.** (R.H.H.)

METALS, PHYSICAL PROPERTIES OF. Most substances that are chemically classified as metals have certain characteristic and almost unique physical properties. Among these are: high electrical and thermal conductivity, attributed to free electrons; great opacity and high reflectivity for light, due to the same cause, and responsible for the "luster" commonly associated with metals; malleability—a sort of plasticity by virtue of which a metal may be cold-worked and rolled into thin sheets; ductility—a combination of malleability and toughness which permits a metal to be drawn into wire. Metals in their normal, pure state are crystalline. They exhibit a characteristic effect upon **polarized light** reflected from their surfaces. A highly useful property is their ability to mix with each other to form an almost endless variety of alloys, having properties often subject to wide control. For example, an alloy of 60% copper with 40% nickel, called constantan, developed for use in resistance coils, has almost invariable electrical resistivity under varying temperatures. Some substances such as selenium, not chemically metals, exhibit one or more of these metallic physical properties. Mercury is the only metal with a melting point below room temperature.

In engineering and metallurgical usage a distinction is made between physical and mechanical properties. **Hardness, tensile strength, impact toughness,** and many other properties vary with the mechanical and heat treatments which a metal has undergone. These are known as mechanical properties. On the other hand, the **modulus of elasticity,** coefficient of thermal **expansion, specific heat,** etc. are essentially constant for a given composition and are designated as **physical properties.** (L.D.W., R.H.H.)

METAMERE. A division of the animal body occurring as one of a series along the principal axis. Segments of this type are well developed in the earthworms. As a general rule each segment of such a body contains similar internal organs but a certain amount of specialization of the segments is evident both internally and externally in different parts of the body. **Arthropods** and **vertebrates** are also metameric but in these animals the specialization of segments is more advanced and has given rise to body regions. The arthropods have a head, thorax, and abdomen, with metameres clearly evident only in the abdomen in many species. **Vertebrates** have a head, trunk, and tail, and as a rule show metameric segmentation only internally. (A.W.L.)

METAMORPHIC ROCKS. Metamorphism of rock material, whatever its original nature and origin, may produce such profound changes that the resulting mass has distinctive characters which warrant a new classification. The chief agents of metamorphism are pressure and heat, and circulating liquids and gases, and usually a long time interval is required for their operation. Metamorphic changes affect mineral composition, texture, and structure of rocks. Minerals that compose most rocks are definite chemical combinations, which commonly are stable only under definite conditions. If these minerals are subjected to radically new conditions, they will tend to change slowly into new chemical combinations, stable under the new conditions. For example, **bituminous coal** that has been subjected to long-continued pressure and increased temperature in a belt of deformation becomes changed into **anthracite** coal through loss of volatile constituents and concentration of fixed carbon.

Metamorphic rocks have acquired distinctive physical as well as chemical characteristics. Commonly they have taken on a definite banding or foliation, partly by mechanical elongation and flattening of mineral particles already present, partly through growth of new mineral grains with an orientation imposed by stresses. A metamorphic rock that has coarse and rather crude banding is called a **gneiss** (pronounced nīce); one that has close foliation, and splits readily because of parallel arrangement of flat or elongate mineral grains, is known as a **schist. Slate** may be regarded as an incipient schist in which the individual mineral particles are too small to be distinguishable. Two common types of metamorphic rock commonly have no distinctive banding, although they retain in some degree their original primary sedimentary stratification. One of these, **quartzite,** results from recrystallization and thorough cementation of the grains in quartzose sandstone; the other, **marble,** is formed by recrystallization in limestone or dolomite. (See also **Rocks.**) (C.R.L.)

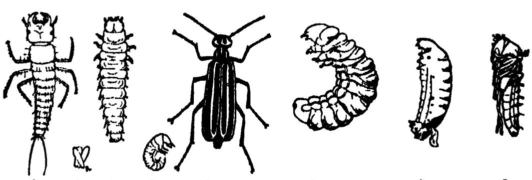
METAMORPHISM. Derived from the Greek, meaning change of form. Used by geologists to designate rocks derived from pre-existing rocks by mineralogical textural and structural changes within the original mass. All metamorphic rocks are either **crystalline** or **cryptocrystalline,** the crystallization or recrystallization usually producing alignment and segregation of the minerals into bands. This type of banding is called **foliation.** In the case of the fine-grained metamorphic rocks, such as **slate,** the foliation results in a high degree of fissility or cleavage. **Schists** usually display both banding and cleavage. The processes of metamorphism may be roughly classified as follows: 1. Contact metamorphism. The result of igneous intrusions into sedimentary, **igneous** or **metamorphic rocks,** producing at the contact bands or **aureoles** of metamorphism. This type of metamorphism causes alteration of the intruded rock by the heat and solutions of the **magma.** Sometimes also the margins of the intrusive body are chemically affected by impregnations of solutions from the rock which is intruded. A number of varieties of valuable **ore** deposits occur in zones of contact metamorphism.

Regional metamorphism is from a quantitative point of view, a type of greater importance, and originates well below the surface of the earth (zone of metamorphism) very slowly, often the result of differential pressures; but high temperature, hydrostatic pressure, and the effects of solutions may produce certain types of regionally metamorphosed rocks. Sedimentary rocks may be metamorphosed with or without apparent crystallization.

Hydrothermal metamorphism is the result of hot, aqueous solutions circulating through fractures, and usually causing the alteration of the adjacent rocks (R.M.F.)

METAMORPHOSIS. Development of the individual after birth or hatching, involving marked change in form as well as growth and differentiation.

Metamorphosis usually accompanies change of habitat or of habits. In some forms, however, it is merely development through a succession of forms which probably represent ancestral stages in the evolution of the species. The first type is illustrated by many **insects** and by **amphibians.** Immature **dragon flies** are aquatic although the adults are flying insects, and **frogs** undergo a transition from the aquatic tadpole to the air-breathing, if not entirely terrestrial, adult. Change of habits is illustrated by the transformation of free-swimming young of many aquatic invertebrates into **sessile** adults, and by the development of adult **butterflies** and **moths** with sucking mouths from caterpillars which eat solid food. The **crustaceans** afford many examples of transformation through several immature forms without conspicuous change of habits or of habitat.



Hypermetamorphosis of a blister beetle. Number shows stage in development. (*After Riley and Chittenden.*)

The immature stages are wholly or partly designated by the term **larva.** In the complex metamorphosis of **insects,** however, only the first stage is called the larva and even it sometimes bears a different name. The distinction depends on the nature of the metamorphosis.

Some insects hatch from the egg with the general form of the adult and the attainment of the adult stage is marked chiefly by the completion of the wings. This type of metamorphosis is said to be gradual and in its early stages the insect is called a nymph. The orders that develop in this way are grouped as the **Paurometabola.** A few orders are aquatic in early life and are then called naiads. They transform directly into the terrestrial adult and are known as the **Hemimetabola,** or insects with incomplete metamorphosis. The **Holometabola,** with complete metamorphosis, pass through a larval stage, then enter an inactive stage known as the **pupa,** and finally become the conspicuously different adult. A few beetles undergo hypermetamorphosis with a sequence of different larval forms preceding pupation. (A.W.L.)

METANILIC ACID ($NH_2C_6H_4SO_3H$). This is a **dye** intermediate and the meta isomer of **sulfanilic acid.** (R.K.S.)

METAPHOSPHATE. Phosphoric Acid.

METAPLASM. Inactive or lifeless matter included in living **protoplasm.** (A.W.L.)

METAPODIUM. The posterior part of the foot of **mollusks.** (A.W.L.)

METASOMA. The slender posterior part of the abdomen of **scorpions.** Postabdomen. It bears the sting at its tip. (A.W.L.)

METASOMATISM. This term was proposed by Naumann to designate that type of mineral alteration whereby one mineral is dissolved and removed by the solution which introduces and deposits a new mineral in its place. Metasomatism is therefore a process of replacement with or without the formation of **pseudomorphs,** and is frequently a very important process in the formation and enrichment of ore deposits. (R.M.F.)

METASTABLE STATE. A peculiar state of pseudo-equilibrium, in which the system has acquired energy beyond that for its most stable state, yet has not been rendered unstable.

By using great care, water at 760 mm. pressure may be heated several degrees above its normal boiling point, say to 105° C., yet not boil. In this condition it has received heat energy beyond that normally required for liquid-vapor equilibrium, energy which it might be expected to release by spontaneously exploding into steam; and only a slight disturbance will precipitate that change, but the disturbance must come from some external source. This situation may properly be called a metastable, that is, beyond the stable, state.

The term is most commonly applied in physics to that state of an atom which is described as "excited" (as by the application of an electric field), but which for some reason does not release its excitation energy as radiation unless disturbed by some additional influence. The energy of **resonance radiation** is spontaneously released by an atom returning from some "resonance state" to a more stable, lower-energy level; but an atom in a metastable state must be prodded into action, so to speak, by some such disturbance as a **collision.** The electron voltage required to transform an atom in its most stable condition to a metastable state has been called the "transformation potential" corresponding to that state. (L.D.W.)

METASTASIS. A secondary implantation of **tumor** cells at a distant site from the primary tumor. In **cancer,** metastasis may occur by the transportation of detached cells through blood or lymph channels. The term is used also to describe **abscesses** which arise as a result of widespread distribution of **bacteria,** usually through the blood, from a primary focus of infection. (D.M.H.)

METASTOMA. A structure behind the **mandibles** in some **crustaceans.** Formed of the fused **paragnatha.** (A.W.L.)

METASTOMIUM. The posterior part of the head of segmented **worms.** (A.W.L.)

METATHERIA. Mammalia. Synonymous with Didelphia.

METATYPE. A topotype which has been approved by the author of the species. (R.M.F.)

METAZOA. All animals except the 1-celled species and the sponges. Characterized by multicellular structure and by the organization of the body in compact tissues and organs coordinated by a nervous system. In most metazoans the food is digested in a special cavity, although some may be taken into cells as in the sponges and protozoans. (A.W.L.)

METEOR SHOWER. This term is applied to indicate a number of **meteors** coming from the same general part of the sky known as a **radiant point.** (W.K.G.)

METEORIC WATER. Ground Water.

METEOROLOGICAL INSTRUMENTS. Some atmospheric properties can be measured but others must be judged or estimated. Properties, like cloud types, total sky cover, visibility, generally are estimated by a competent observer. Those atmospheric properties that are measured include: water-vapor content, temperature, pressure, wind direction and velocity at the surface and aloft, cloud-base height and movement, rain and snow fall, evaporation, upper level pressure, temperature, and humidity, duration of sunshine and amount of heat received.

1. Water-vapor measuring devices.

a. A psychrometer is a combination of wet- and dry-bulb thermometers. A conventional sling psychrometer consists of two thermometers mounted parallel, with the wet bulb slightly lower than the dry. This instrument is whirled at approximately 3 meters per sec. for 3 or more minutes until the wet-bulb reading reaches a steady reading. The difference between dry- and wet-bulb reading is known as the wet-bulb depression and is correlated to other humidity criteria in tabular or graph form for instant use. Ventilation is required for most psychrometers.

b. Hair hygrometers are instruments in which strands of human hair mounted under tension expand with increasing relative humidity and contract with decreasing relative humidity. One end of a set of strands is fixed and the other end operates a set of levers whose initial movement is magnified mechanically to cause a pointer or other indicating device to ride over a calibrated scale. Hair hygrometers, after they are calibrated, indicate relative humidity which, in conjunction with tables of specific humidity and temperature, can be converted to other humidity criteria. Hygrographs are hygrometers in which a pen records relative humidity continuously on a rotating drum. The drum is operated by a clock mechanism.

c. Dew-point hygrometers are instruments which measure the temperature at the time of formation and evaporation of dew. A mean of the temperature at time of formation and evaporation is approximately the actual dew-point temperature. Some instruments require visual observation of dew drops on the instrument and the disappearance of the same drops, but others use photoelectric cells to determine the time of dew formation and evaporation. Dew-point hygrometers must contain both heating and cooling mechanisms, a polished surface upon which the dew forms, and a means of measuring the temperature of the surface or the temperature of the air in contact with the surface.

d. Absorption hygrometers, diffusion hygrometers, and optical hygrometers are other instruments in limited use. Some absorption instruments are constructed to alter the passage of electrical current in a thin film of the absorbing material in relation to the relative humidity of the air surrounding the film. Other absorption instruments require the passing of a limited weight of air through a drying agent which is weighed before and after the passage of air.

2. Thermometers.

a. Ordinary mercury or alcohol thermometers are used for surface temperature measurements, including wet-bulb temperature measurements.

b. Maximum thermometers are so constructed that the column of mercury will break as soon as the temperature begins to fall. A small segment of the mercury column, therefore, remains in place until the instrument is read, at which time it can be shaken down.

c. Minimum thermometers have within the bore a small index which moves downward toward the bulb as the column of fluid contracts but remains in its nearest-to-the-bulb position as the fluid again expands. Thus the index can be read and then readjusted to the top of the fluid column. Alcohol is the usual fluid used.

d. Bimetal thermometers are so constructed that they have a bending coefficient in relation to the temperature. They are made of two metal strips with different coefficients of thermal expansion welded together, usually Invar and brass or Invar and steel. One end of the strips is fixed and the other end operates a series of magnifying levers which in turn operates an indicating device. Thermographs are usually bimetal instruments in which a pen records temperature continuously on a rotating drum.

e. The Bourdon thermometer is a flat hollow tube filled with an organic liquid. As the temperature of the liquid increases, its expansion causes the tube to straighten. It is not used to any great extent in meteorology.

f. Electrical thermometers depend on the thermal coefficients, or on thermoelectrical properties, of dissimilar metals. Any metal that has a more or less linear thermal coefficient of resistance over the necessary temperature range can be used to measure temperature by its resistance to the passage of electricity. A **Wheatstone bridge** circuit is usually employed, one branch of which is the thermometer coil. Thermocouples are the other type of electrical thermometers, potentiometers being used to measure the output of the thermocouple. Electrical thermometers have the advantage of the practicability of remote installations with the recording dials placed where easily accessible.

3. Pressure indicators.

a. Mercury barometers are the standard instruments for measuring atmospheric pressure. Generally speaking, they are simply a tube erected vertically with the bottom end submerged in a pool of mercury. The top of the tube is sealed and evacuated of all air and other gases except mercury vapor. Mercury rises in the sealed tube above the level in the pool in direct relation to the air pressure on the mercury pool. Many refinements must be built into a mercury barometer before it is sufficiently accurate for precise pressure measurements.

b. An aneroid barometer consists of one or more disk-like cells inside which a partial vacuum is maintained. When one side of the cell is fixed, the other side will move and operate a system of levers which in turn cause an indicator to move over a scale. If atmospheric pressure falls, the disk expands; if atmospheric pressure increases, the disk contracts. Aneroid barometers must be calibrated against a mercury barometer and checked frequently. A barograph is an aneroid barometer which operates a pen over a rotating drum and thus records pressure continuously.

4. Wind-measuring devices.

a Surface wind direction is measured by use of a wind vane which is nothing more than an arrow with considerable tail surface. Air flowing past the tail surface keeps the arrow pointed in the direction from which the wind is coming. The vane is usually mounted some 20–30′ above the ground or water level.

b. Wind velocity is measured generally by use of a cup anemometer, although there are other available instruments. A cup anemometer consists of a set of three or four semispherical or conical cups mounted on a wheel whose axle is vertical. When the wind blows it forces the cups and the wheel to rotate; the wind velocity is related to the total number of rotations over a short period of time. Various types of counters are used to determine the rotations per min. or per sec.

Plate anemometers are the oldest in terms of use, having been used since about 1660. They consist of a simple plate mounted in such a manner that the wind blows against it, deflecting it in the direction toward which the wind is blowing. A pointer or scale mounted along the plate measures the deflection of the plate which can be correlated to the wind velocity.

Pressure-tube anemometers employ the difference in static and dynamic pressure in a wind blowing across a tube mounted vertically, and into a tube mounted with its opening directly into the wind. This type of anemometer is not in great use in meteorology but is used almost exclusively in aircraft as an air speed indicator.

c. Winds above the surface of the earth are measured by use of pilot balloons which have a sensibly con-

stant ascension rate and drift with the wind as they rise. A theodolite is used to follow the balloon as it drifts. Azimuth and altitude angles observed each minute permit the path of the balloon to be plotted. Wind direction and velocity at any altitude are determined from the plotted track of the balloon. At night the balloon may be fitted with a light.

5. Cloud observations.

a. Cloud types and amount of sky cover are estimated by an observer.

b. Cloud heights are often measured by use of ceiling balloons and ceiling lights. A small balloon with a relatively constant ascension rate is released, and the time from release until it penetrates the cloud base is a measure of the heights of the cloud base. At night a spotlight mounted vertically forms a spot on the cloud base, and a clinometer is used to measure the altitude angle of the spot.

c. Direction and relative speed of cloud movement are measured with a **nephoscope** which is a grid or a mirror with reference points enabling an observer to note details of cloud motion. Neither type is in extensive use.

6. Rain- and snow-fall measuring devices.

a. Rain gauges measure, by collection in a cylindrical tube, the total fall of rain during one or more rain storms, or over a period of time.

b. Snow fall is conveniently measured with a ruler and the total fall correlated to rain by a 10 to 1 reduction. More accurate measurement is achieved by lowering a cylinder vertically into the snow and melting the depth of snow collected into its rain equivalent.

7. Evaporation is generally measured by exposure of a water surface to the atmosphere. Loss of water from a pan or vat is a measure of evaporation. Other specialized devices are in use for particular problems such as transpiration from plants.

8. Sunshine measurement.

a. Duration of sunshine is measured by making use of the sun's rays to burn a record on suitable sensitized or photographic paper.

b. Pyrheliometers measure the intensity of solar radiation. They absorb radiation with a consequent rise in temperature in the absorbing medium of the instrument which in turn is converted into calories.

9. Upper-air temperature, humidity, and pressure measurement.

a. A meteorograph is a clock-operated instrument in which pens trace on a rotating drum a record of temperature, relative humidity, and pressure. The instrument can be carried aloft by the use of a balloon, airplane, or kite. A bimetal element operates the temperature pen; human hair strands operate the humidity pen; and an aneroid cell operates the pressure pen. Frequent calibration is necessary.

b. Radio-meteorographs utilize small radio transmitters to send modulated signals which have equivalents in temperature, humidity, and pressure. A balloon carries the measuring devices and the transmitter aloft to great altitudes. Four different methods of sending the signals are used, (1) time-spaced signals, (2) audio-frequency change, (3) radio-frequency change, and (4) codes. Measurements of temperature, relative humidity, and pressure are introduced into the transmitter which transmits the measurements in terms of a radio signal. An electrical thermometer is generally used. The humidity element is usually a special human-hair instrument or an absorption instrument which utilizes the electrical resistance of lithium chloride in a thin film on a tube. Pressure elements are generally aneroid cells. (P.E.K.)

METEOROLOGY. Science of the atmosphere including all its aspects. In a more restricted sense in wider use it is the science of weather, being particularly concerned with the physics of the elements which make the weather. (P.E.K.)

METEORS (OR METEORITES). Meteors, or "shooting stars," are visitors from space which come into the atmosphere of the earth with high velocities. They are made visible by being raised to incandescence by resistance offered by the atmosphere of the earth.

The term meteor comes from the fact that since the late 18th century they have been associated with the atmosphere of the earth. The terms **fireballs, bolides,** and **meteorites** or aerolites are also applied to meteors. The difference between the various objects depends merely upon their observed characteristics and there is considerable evidence in support of the hypothesis that they are all made up of the same fundamental materials. The term meteor is sometimes restricted to that class which does not attain a brightness greater than zero stellar **magnitude** (i.e., is not brighter than the **planet Jupiter**). Objects which attain a brightness greater than this, and which leave behind them trails which may persist for several minutes, are known as fireballs. Frequently, the direction of flight of a fireball is observed to change suddenly, and not infrequently a distinct sound is heard either during or shortly after the passage of a fireball. A fireball which is observed to explode into several fragments is known as a bolide, and frequently a loud detonation is heard following the explosion. Meteors, fireballs, and bolides, in the true sense of the terms, are so completely disintegrated during their passage through the earth's atmosphere that they fall to the surface of the earth as dust. Any one of these classes of objects which is large enough to penetrate the atmosphere and arrive at the surface of the earth as a solid body is known as a meteorite, or aerolite.

Meteors are observed most frequently by pure chance, but at present there are a number of systematic photographic surveys in progress. The most effective method for determining accurate data regarding the heights, velocities, and other characteristics of a meteor is to have two cameras situated about 20 miles apart, with the distance between them accurately known. If the same meteor is photographed by both cameras, it will be found to be projected against different backgrounds of stars on the two plates. From the difference in position relative to the stellar background, the angle subtended by the meteor at the length of the distance between the cameras may be determined, the triangle solved, and the height of the meteor obtained. If one of the cameras is equipped with a rotating shutter, which will produce breaks in the meteor trail at accurately timed intervals, the lengths of the segments of the trail may be measured and the velocity at which the object is moving be determined after the height has been found.

The results of the recent and accurate surveys are just beginning to appear, but from these results thus far obtained it appears that more than half the meteors enter the earth's atmosphere with velocities less than 42 kilometers per sec. (26 miles per sec.), while the remainder have velocities greater than that. Furthermore, those with velocities less than 42 kilometers per sec. are found to be members of meteoric showers emanating from **radiant points,** and hence are actually members of the **solar system.** It may be shown theoretically that any true member of the solar system when situated at a distance from the sun equal to that of the earth, cannot have a velocity greater than 42 kilometers per sec. This seems to indicate that half of the observed meteors are actually visitors to the solar system from interstellar space. How many such objects there may be in interstellar space we have no means for determining at present. A survey which has been in progress by

Whipple at Harvard fails to show any meteor with velocity greater than 42 kilometers per sec.

Another result of the recent surveys indicates that the average height of the middle of a meteor trail is about 89 kilometers (55 miles). The fact that this is the same as the height of one of the layers of the earth's atmosphere which reflects radio waves has led to interesting speculation as to the constitution of this region of the atmosphere.

The determination of the actual number of meteors which enter the atmosphere of the earth in a given period of time is a difficult task. The most recent surveys indicate that there may be as many as a billion each day. The size of the average meteor may be determined from studies of the brightness of the object and is found to average about the order of magnitude as the size of a drop of water. A hundred million objects of this size, and of the density of the average meteorite, would have a total mass of about 100 tons. Such an increase in the mass of the earth would slightly increase the rotation period and would increase the radius by about ¼" in the 3000 million years that the earth has had its present form.

The composition of meteors may be determined only from meteorites or from fragments of meteoric dust which have been collected. A more complete discussion of the actual composition of meteorites will be found elsewhere. There has never been anything found in meteorites which has not previously been found on the earth, and the average percentages of the different chemical elements found in meteorites is comparable with the distribution found elsewhere in the solar system. The wholly metallic meteorites are chiefly an iron-nickel alloy and are called siderites. **Sideriolites** are meteorites composed of both metallic and silicate materials. Meteorites made up almost entirely of silicates are called **aerolites.**

Nothing is known regarding the origin of those meteors which enter the earth's atmosphere with velocities greater than 42 kilometers per sec, and hence come from outside of the solar system. Of the slower objects we know that some of the radiant points are following orbits similar or identical with orbits of comets. The cases are too frequent and the agreement too close to be assigned to mere chance and hence we know that many meteors are definitely connected with comets. As soon as the question as to how many of the slow-moving meteors are members of meteoric showers is answered, we shall be able to make more definite statements regarding the origin of these terrestrial visitors. Such objects, however, must be actual members of the solar system.

Since by far the greater percentage of meteors fall to the surface of the earth as fine dust, there is no danger to the earth or its inhabitants from these objects. The meteorites, however, are a potential source of danger. The air wave and earthquake which would follow the impact on the surface of the earth of a mass of, perhaps, several hundred tons, moving with a velocity of many miles per sec., are almost beyond imagination. The results of such impacts are found in the huge meteor crater in Arizona and in the more recent fall in northern Siberia. Fortunately, large meteors are very rare and they seem to have the happy faculty of selecting uninhabited portions of the earth for their descent. The fall of such an object on a city would completely destroy it. (W.K.G.)

METEPIPODITE. A broad thin lobe on the outer side of the appendage and at its upper end in crustaceans which have the flattened form of **biramous appendage** called a **phyllopodium.** An epipodite. Also called the branchia. (A.W.L.)

METER. **Standard Meter.**

METERS. Meter and instrument have frequently been used interchangeably, but now there is a tendency to restrict the use of *meter* to instruments which record and/or integrate as well as indicate. These devices in various forms are used extensively in research and instruction, also in commercial installations such as factories and power plants.

Instruments are used in industry for a number of reasons. For efficient operation, the personnel must know, not guess at, the conditions of pressure, temperature, flow, etc., of the process. Indicating instruments are satisfactory for operating guidance but recording or integrating meters serve better the calculation of performance, the allocation of cost, and supervision.

Unless a record is needed for operating supervision or for plant calculations, the initial expense and maintenance of recording instruments plus the fact that index instruments are more easily read precludes the use of recording instruments as operating guides alone. However, many applications will be found for which recording instruments will be selected. There are two types of recording instruments: those using circular charts and those using strip charts. The circular charts must be replaced each day; the strip charts last several days. Circular charts are: (1) less expensive than strip charts, (2) more easily planimetered, (3) rugged and easily filed, (4) of a form to expose a full day's record at all times, (5) accurately held in position by the centering point. Considering points in favor of the strip chart: (1) they are more suitable than circular charts when many records are to be centralized or when multiple records of draft, temperature, etc., are to be put on one chart; (2) being electrically operated, strip chart meters are, as a rule, more accurate than circular chart meters; (3) the chart speed may be changed. (F.T.M.)

METES AND BOUNDS. A method of describing, in **surveying** terms, tracts of land for the purpose of establishing legal titles is known as metes and bounds. In early days the boundaries of a piece of land were described in a haphazard manner, but as property became more valuable it was necessary to define these boundaries in terms of definite quantities. Legal titles called deeds now commonly contain the length and **bearing** (direction) of the individual sides, a description of the **corners,** the names of the adjoining property owners, and the calculated area. Thus, if one of the original corners is known, the boundaries of a tract of land may be relocated from this description by metes and bounds. (C.W.C.)

METHANE. Methane, "marsh gas," "fire damp" (CH_4), is a colorless, odorless gas, boiling point $-161°$ C., density 0.72 gram per liter at 0° C., 760 mm. (specific gravity 0.55, air equal to 1.00), practically insoluble in water, moderately soluble in alcohol, burns when ignited in air with a pale, faintly luminous flame, forms an explosive mixture with air, when between 5% and 13% methane, with excess air the products are **carbon dioxide** plus water; with deficiency of air, **carbon monoxide** plus water, when mixed with air and passed over **magnesium** oxide at 350° C. and 500° C. **formaldehyde** is found among the products. Methane is among the chemically less reactive organic substances. It reacts, however, with **chlorine** (and similarly with **bromine**) to form mixtures of methyl chloride (CH_3Cl), methylene chloride (CH_2Cl_2), **chloroform** ($CHCl_3$), **carbon tetrachloride** (CCl_4), depending upon the conditions (one-half of the chlorine used forms **hydrogen chloride**), or may form free carbon with explosive violence, as is the case when one volume of methane plus one volume of chlorine is exposed to direct sunlight. Methane occurs in natural gas, of which it is the main constituent; forms in coal mines and swamps, where vegetable matter is decaying under water (anaerobic fermentation); and is a constituent of coal gas. The

fuel value of methane (995 B.T.U. per cu. ft.) is high (hydrogen and carbon monoxide about 320 units each). Carbon monoxide and hydrogen react to form methane in the presence of nickel catalyst. Methane is also formed by reaction of magnesium methyl iodide in anhydrous ether (**Grignard's reagent**) with substances containing hydroxyl (—OH) group. Methyl iodide (bromide, chloride) is preferably made by reaction of methyl alcohol and **phosphorus** iodide (bromide, chloride).

Important methane derivatives, by replacement of each hydrogen atom, step by step, by hydroxyl are (1) **methyl alcohol** (CH_3OH or $H \cdot CH_2OH$), (2) **formaldehyde** ($CH_2(OH)_2$ by loss of water to CH_2O or $H \cdot CHO$), (3) **formic acid** ($CH(OH)_3$ by loss of water to $CHO(OH)$ or $H \cdot COOH$), (4) **carbonic acid** ($C(OH)_4$ by loss of water to $CO(OH)_2$ or $HO \cdot COOH$ or H_2CO_3). Methyl alcohol is, therefore, the simplest **alcohol,** formaldehyde the simplest **aldehyde,** and formic acid the simplest **carboxylic acid.** (R.K.S.)

METHYL ALCOHOL. Methyl **alcohol,** methanol, "wood alcohol" (CH_3OH or $H \cdot CH_2OH$), is a colorless liquid of pleasant odor, boiling point 64.5° C., miscible in all proportions with water, alcohol, or ether, when ignited burns in air with a pale blue transparent flame, producing water plus **carbon dioxide,** the vapor forms an explosive mixture with air. Methyl alcohol reacts (1) with **sodium** metal, forming sodium methylate, sodium methoxide (CH_3ONa) plus **hydrogen** gas, (2) with **phosphorus** chloride, bromide, iodide, forming methyl chloride, bromide, iodide, respectively, (3) with **sulfuric acid** concentrated, forming dimethyl **ether** ($(CH_3)_2O$), (4) with organic acids, warmed in the presence of **sulfuric acid,** forming **esters,** e.g , methyl acetate (CH_3COOCH_3), methyl salicylate ($HO(2)C_6H_4COOCH_3$), possessing characteristic odors (see the various individual acids), (5) with magnesium methyl iodide in anhydrous ether (**Grignard's solution**), forming **methane** as in the case of primary alcohols, (6) with **calcium** chloride, forming a solid addition compound ($4CH_3OH \cdot CaCl_2$), which is decomposed by water, (7) with **oxygen,** in the presence of heated smooth copper or silver forming **formaldehyde.** The density of pure methyl alcohol is 0.792 at 20° C. compared with water at 4° C. (the corresponding figure for ethyl alcohol is 0.789), and the percentage of methyl alcohol present in a methyl alcohol-water solution may be determined from the density of the sample. Anhydrous methyl alcohol may be obtained by fractional **distillation** (anhydrous ethyl alcohol must be obtained by special treatment). Methyl alcohol is obtained (1) by the destructive distillation of hardwoods at about 350° C. along with **acetic acid** and small percentages of **acetone** in the water condensate. After neutralization of the acetic acid, methyl alcohol is recovered by distillation, usually accompanied by acetone and **acetaldehyde,** and then purified by further distillation, (2) by reaction of **carbon monoxide** plus **hydrogen** in the presence of a **catalyzer,** such as **zinc** oxide or basic zinc chromite, at 400° C. and 150 to 250 atmospheres pressure, (3) by regulated reduction of formaldehyde or formic acid.

A common test for methyl alcohol is by its **oxidation** in air with a hot copper wire to form **formaldehyde.**

Methyl alcohol is used (1) as the source of the methyl group (CH_3—) in organic chemistry, using methyl alcohol or methyl chloride, bromide, or iodide, and of the methoxy group (CH_3O—), using methyl alcohol or sodium methoxide, (2) in the manufacture of formaldehyde, (3) as a solvent for many organic substances, especially in the preparation of lacquers, varnishes, (4) as a denaturant in the form of crude wood spirit for ethyl alcohol. (R.K.S.)

METOL. Developing Agents.

METRIC SYSTEM. The metric system had its origin in the need, imposed by the development of scientific thought, for immutable, and at the same time conveniently related, units of physical measure. Prior to the end of the 18th century, uniformity and consistency in this matter were notably absent. The French Revolution revolutionized many things besides government. Even the system of number notation was brought into question, but fortunately was not disturbed. One outgrowth of the upheaval was the metric system. In 1791 a committee of the French Academy, including the well known Lagrange and Laplace, made a report to the National Assembly which, after much delay, was finally put into effect. Their report fixed the standard of length as the **meter,** defined as one ten-millionth of the earth's meridian quadrant at sea level, and determined from elaborate geodetic surveys between Barcelona, Spain, and Dunkirk, France. The unit of mass then became a secondary standard, viz., the **gram,** based on the centimeter and the density of water; but this was soon displaced by the present standard **kilogram,** which departs rather seriously from the original ideal. All subdivisions and multiples in the system are decimal, with terminology in accord with the following scheme:

deci-	= one-tenth (decimeter, decigram)
centi-	= one-hundredth (centimeter, centigram)
milli-	= one-thousandth (millimeter, milligram)
deka-	= ten times (dekameter, dekagram)
hecto-	= one-hundred times (hectometer, hectogram)
kilo-	= one-thousand times (kilometer, kilogram)

While the metric system has come into general use throughout continental Europe and most of the civilized world, it has yet to gain general recognition in Great Britain and the United States, for other than scientific purposes. (See **C.G.S. System; M.K.S. System.**) (L.D.W.)

MEXICAN ONYX. Travertine.

MIASKITE. An old term proposed by Rose, in 1839, for an **oligoclase-nephelite-syenite** in which the chief **mafic** mineral is **biotite.** The type locality for this **igneous** rock is at Miask, in the Ural Mountains. (R.M.F.)

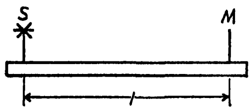
MICA. The mica group of minerals includes several closely related species, having a highly perfect basal **cleavage;** all are **monoclinic** with a tendency toward pseudo-**hexagonal** crystals, and are closely similar in chemical composition. The highly perfect cleavage, the most prominent characteristic of the group, is explained on a basis of **x-ray** studies of these minerals, which seems to show a sheet-like arrangement of the atomic structure and a hexagonal grouping of **atoms** which apparently explains the pseudo-hexagonal crystals above mentioned. The word mica is believed to have been derived from the Latin *micare,* meaning to shine, in reference to the brilliant appearance of this mineral, especially when in small scales.

The following members of the mica group are treated under their respective headings: **Biotite, Muscovite, Lepidolite,** and **Phlogopite.** (E.S.C.S.)

MICA-SCHIST. Schist.

MICHELSON-MORLEY EXPERIMENT. In 1881 two American physicists, Michelson and Morley, first carried out an experiment which was destined not only to raise doubts regarding the behavior of the supposed **ether,** but ultimately to revolutionize a large part of our thinking about physical phenomena. The details of the experiment are somewhat complicated, involving an adaptation of the **interferometer,** but its essential principle may be set forth as follows:

A source of light S and a mirror M, facing it, are mounted on a rigid base at a distance l apart (see figure). Light travels from S to M and back in a certain time, expressed by $t_1 = 2l/c$, where c is the speed of light. Suppose the whole apparatus is set moving lengthwise with a speed v. If this is actually the relative motion of apparatus and ether, so that the ether is "blowing past" the source and mirror with the speed v, then a very simple calculation shows that the time now required for the journey $SM + MS$ should be greater, namely, $t_2 = 2l/c \left(1 - \frac{v^2}{c^2}\right)$. It is true that the term v^2/c^2 is necessarily small; but by utilizing the earth's orbital speed of about 18.5 miles per sec. as the value of v, the change to be expected was brought well within the reach of observation. This was accomplished by turning the whole apparatus, first across, then parallel to, the earth's orbit.



Source of light S and mirror M at opposite ends of a rigid bar which carries them with it when it moves.

No difference whatever could be detected between observations in the two positions; the result indicated that $t_1 = t_2$. And no one has yet been able to obtain even an approximate approach to the effect predicted.

Naturally this discrepancy aroused much speculation. The only satisfactory explanation in classical terms was that offered by Lorentz, following a suggestion of Fitzgerald, and known as the **Lorentz-Fitzgerald contraction,** which has now been incorporated in the foundation of the **relativity theory.** (L.D.W.)

MICROBE. Bacteria.

MICROCLIMATE. The aggregate of physical conditions in limited habitats, corresponding to the climate of large geographical areas. (A.W.L.)

MICROCLINE. Feldspar.

MICROCRYSTALLINE. The term applied to the ground mass of an **igneous rock** in which the individual crystals can only be made out with the aid of a microscope. Compare with **crypto-crystalline.** (R.M.F.)

MICRO-FELSITE. The term for the ground mass of an **igneous rock** which is not glass but which is still so finely grained that it is extremely difficult, or impossible, to determine the constituent minerals by **polarized light.** Many such textures are probably the result of **devitrification.** (R.M.F.)

MICROGAMETE. Gamete.

MICROLITES. The general term for microscopic tabular or prismatic **crystals.** Microlites differ from **crystallites** in that the former may be distinguished by the **petrographic** microscope under **polarized light.** (R.M.F.)

MICROMETER. The micrometer represents a general principle of **physical measurement,** used on various instruments such as **comparators, spherometers, compensators, interferometers,** etc. It is essentially a screw of accurately known, uniform pitch (commonly 1 mm. or 0.5 mm.), provided with a large head whose periphery is divided into equal parts, forming a scale. Turning the screw through a given number of these parts causes the shaft to travel through a distance which is a proportionate fraction of the pitch. For example, if the pitch is 0.5 mm. and the head is divided into fiftieths, each scale division corresponds to a travel of 0.01 mm. A familiar application is the micrometer caliper, an instrument resembling an ordinary screw clamp. The screw is, however, of the micrometer design, with its scale reading zero when the caliper is closed. When unscrewed and closed again upon a thin plate or wire, the scale reading of the caliper shows the thickness of that object, in hundredths of a millimeter or thousandths of an inch. Measuring **microscopes** and astronomical **telescopes** are frequently equipped with a **filar micrometer.** (See **Measurement.**) (L.D.W.)

MICRON. The 1/1000 of a millimeter. A unit of measure used for microscopic objects. (L.D.W.)

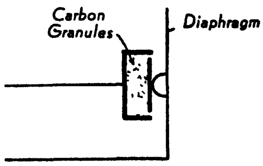
MICRONUCLEUS. A small nucleus found in many one-celled animals associated with a large **macronucleus.** It is active in cell division. Most species have only one micronucleus but in some two or more occur. (A.W.L.)

MICROPALEONTOLOGY. Paleontology.

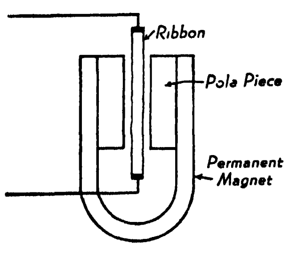
MICROPEGMATITE. A microscopic intergrowth of **quartz** and **feldspar** similar to the coarser-textured **graphic granite.** A form of **pegmatite.** (R.M.F.)

MICROPHONE. A microphone is a device for converting sound waves into corresponding electrical variations. Since the development of the first crude telephone **transmitter** or microphone by Bell in 1875 many types of microphones have been invented but most have been discarded and now only the single-button carbon, double-button carbon, crystal, velocity and dynamic types are used to any extent. In a microphone two things are important, the sensitivity, i.e., the degree of electrical variation for a given intensity of sound wave, and the fidelity or ability to reproduce the audio frequencies in their proper relative magnitudes without generating other frequencies in the process. In **telephony** the first requirement is the more important as only a limited range of frequencies is used and it is not essential that these be reproduced in exactly the correct relative magnitude. Thus the single-button carbon microphone, or transmitter as the telephone engineer calls it, is universally used in this application. Fig. 1*a* shows the basic principle of this microphone. The sound wave striking the diaphragm causes the pressure on carefully selected carbon granules in the cup to be varied, thereby varying the resistance of the carbon between the cup and the diaphragm. This causes the current in the circuit to vary and the speech may then be transmitted electrically. The single-button microphone has the highest sensitivity, but is limited in its frequency response, has appreciable background noise and requires a battery for operation. The double-button microphone operates on the same principle but uses two carbon-containing cups, back to back with the diaphragm between them. This produces a higher fidelity but less sensitive instrument and is used for some public address and special service radio work but not for regular broadcast service. The crystal microphone is of medium sensitivity and gives good fidelity. It utilizes the piezo-electric effect of Rochelle salt, the sound waves striking the **crystal** or a diaphragm connected with it produce mechanical distortions with resultant voltage variations across the crystal. This microphone is a high impedance device which may be connected to the **grid** of an amplifying tube without an impedance-matching **transformer.** It is widely used in public address work and radio other than broadcasting. The velocity microphone, shown in Fig. 1*b*, consists of a thin metallic ribbon suspended between the poles of strong permanent magnets. Sound waves striking this ribbon produce pressure differences on the two sides, causing it to move with the waves and the magnetic field then induces a voltage in the ribbon. This is a very low impedance microphone and is connected to an amplifier tube through a transformer. The dynamic microphone is similar to the dynamic **speaker,** having a coil attached to a diaphragm so the speech

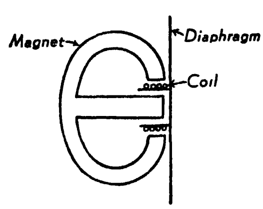
waves will cause it to move in the field of the magnets and thus generate a voltage in the coil. This is connected to an amplifier through a transformer. Both the velocity and dynamic microphones are of low sensitivity, requiring about one more stage of vacuum-tube amplification than the other types, but they have uni-



(a) Single Button



(b) Velocity



(c) Dynamic

Fig. 1. Common microphones.

form frequency response over a very wide range so are almost universally used for high quality sound and radio work. Combination microphones having both velocity and dynamic elements have been developed. Since the polarities of the output voltages are different in the two for different directions of sound travel, the combination can be utilized to give a directional unit which is dead from the back, thus greatly facilitating the use of the microphone in noisy locations or where the reproducing speaker may feed back to the microphone. (L.R.Q.)

MICROPHONIC NOISE. This is the high-pitched note which comes from the **speaker** of an **amplifier** or radio **receiver** when the set is subjected to a mechanical shock. It is caused by mechanical vibration of the vacuum-tube electrodes altering the electrical response of the **tube.** (L.R.Q.)

MICROPHOTOGRAPHY. The processes employed in making photographs of microscopic size; i.e., photographs requiring enlargement to be visible to the unaided eye. Developed about 1860, chiefly in France, microphotography for a long time was utilized chiefly in the making of novelties. These contained a tiny photographic reproduction of a passage of scripture, a famous painting, or a familiar scene, and a small magnifying glass for viewing. Micrometer rulings for optical instruments are another application of microphotography.

The chief application of microphotography today is in the reproduction of books, bank checks, newspapers and other printed matter on a greatly reduced scale for filing purposes. This field is sometimes known as *documentary reproduction.* It has grown rapidly in recent years. There are special cameras and high resolution films for making such copies on 35- or 16-mm. motion picture film, and readers for convenient reading of the small film records. The amount of printed material which can be purchased in the form of copies on film is growing steadily and now includes the daily editions of several of the larger newspapers. These film copies will be available when the originals have disintegrated. Furthermore, new copies can be made at any time quickly and at low cost. Other important applications are the reproduction of rare manuscripts for the use of scholars throughout the world, or to make source material available to the interested public to whom the originals cannot be entrusted; the publication of books or technical papers where the number of copies does not justify the cost of printing; the making of duplicate records of material for storage at different places as a safety measure and the reduction of bulky material for storage. (C.B.N.)

MICROPODIFORMES. The **swifts, hummingbirds,** and related species. An order of birds characterized by strong flight. Although the swifts resemble the swallows superficially more than they do the hummingbirds, these two forms are anatomically related. (A.W.L.)

MICROPOIKILITIC. A term used by mineralogists and petrologists to describe minerals which contain microscopic inclusions of other minerals which have no chemical relationship to each other or to the host mineral. (R.M.F.)

MICROSCLERES. The smaller **spicules** in the tissues of **sponges.** (A.W.L.)

MICROSCOPE. The optical instrument that bears this name consists essentially of two parts. 1. The objective is a lens combination, usually of small aperture and short focal length, which forms a real, inverted, and much enlarged image of the object at a point high up in the microscope tube, very much as a stereopticon objective throws an enlarged picture upon a distant screen. The objective-lens system is composed of several positive lenses, the first of which is hemispherical with its plane surface facing the object. Following this is a larger convexo-concave or "meniscus" lens, and then two still larger plano-convex achromatic lenses. 2. The **eyepiece** or ocular is placed beyond, with its focal plane coinciding with this image, and acts as a collimator, so that one looking into it sees a virtual image, apparently at an infinite distance, and subtending a wide angle. The instrument is focused by varying the distance between objective and object. The **magnifying power** of the microscope depends upon the relative focal length of objective and eyepiece; its resolving power depends upon the dominant wavelength of the light used (see **Diffraction**). In the **ultramicroscope,** the object has a special type of illumination. Sometimes a drop of transparent oil is placed between the anterior surface of the objective and the slide cover in order to cut down the effect of refractive spherical aberration and the loss of light by reflection from these surfaces (oil-immersion objective). In measuring microscopes, a transparent scale or a **filar micrometer** may be introduced into the ocular focal plane; or a pair of cross-hairs may be used and the whole instrument moved laterally by a micrometer screw, thus forming a comparator. See also **Petrographic Microscope.** (L.D.W.)

MICROSEISM. Earthquakes.

MICROSPORANGIUM. Flower.

MICROSPORIDIA. Sporozoa.

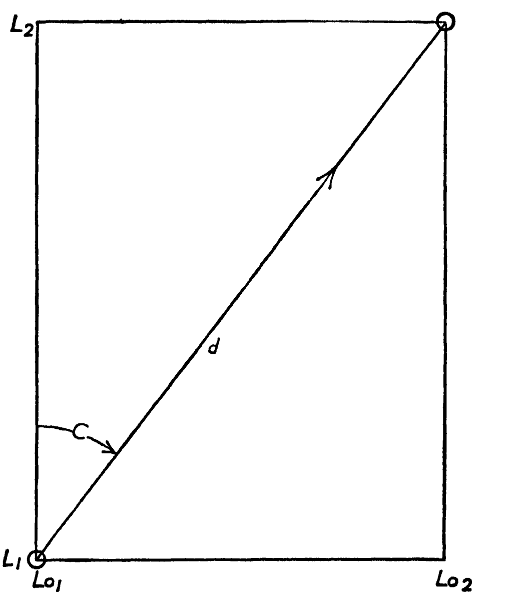
MICROSTRUCTURE. Metallography.

MICROWAVE. These are extremely short radio waves, only a few centimeters or less in wavelength. (L.R.Q.)

MIDBRAIN. Mesencephalon. **Brain.** (A.W.L.)

MIDDLE LAMELLA. The middle lamella consists of the primary walls which surround the cells of plants and the intercellular layer between these walls. This composite layer is usually made up of pectic materials (**colloids** which have a great affinity for water), one of which is calcium pectate. The function of the middle lamella is to hold adjoining cells together. Sometimes, particularly in mature fruits, the middle lamella substance breaks down. As a result the cells of the fruit separate easily, giving to the fruit a meal-like character. (R.M.W.)

MIDDLE-LATITUDE SAILING. The term middle-latitude sailing is applied to that modification of the **plane-sailing** problem in which the earth is assumed to be a sphere. The plane-sailing problem is illustrated in the figure, in which (L_1, Lo_1) are the terrestrial coordinates (**latitude** and **longitude**) of a point



which a ship left, C is the **course** or **track** followed, d is the distance in nautical miles along the track, and (L_2, Lo_2) are the terrestrial coordinates of the point arrived in.
